69 Board #1 May 27 9:30 AM - 11:30 AM Kinetic Asymmetry During Squatting And Landing Are Associated In Anterior Cruciate Ligament Reconstructed Patients

Robin Queen, FACSM¹, Alexander T. Peebles¹, DS Blaise Williams, III, FACSM². ¹Virginia Tech, Blacksburg, VA. ²Nike, Beaverton, OR.
Email: rmqueen@vt.edu
Reported Relationships: **R. Queen:** Industry contracted research; DJO Global.

High kinetic asymmetry during landing is associated with an increased risk for sustaining a second anterior cruciate ligament (ACL) injury in athletes returning to sport following ACL reconstruction (ACL-R). While previous literature has found that ACL-R patients have more kinetic asymmetry than healthy controls during both landing and bilateral squatting, it is currently unknown if landing asymmetry and squatting asymmetry are related in ACL-R patients. **PURPOSE:** Determine the relationship between landing kinetic asymmetry and squatting kinetic asymmetry in ACL-R patients. **METHODS:** 34 ACL-R patients (19 male; 73 ± 16 kg; 174 ± 10 cm; 6.0 ± 1.5 months post-operative) signed informed consent and participated in the study. All participants completed one set of 15 bilateral squats and then ten bilateral stop jump trials, while 3D lower extremity kinematics and kinetics were recorded at 240 Hz and 1920 Hz, respectively. Peak knee extension moment (KEM) and vertical ground reaction force impulse (GRFI) were computed during the descending phase of both tasks. The descending phase was defined between squat initiation and the minimum position of the pelvis during each squat and between initial contact and the minimum position of the pelvis for each stop jump. A limb symmetry index (LSI) was computed for peak KEM and GRFI as the difference between the surgical and non-surgical leg divided by their average during each squat and each stop jump, and then the LSI was averaged across trials. Peak KEM LSI and GRFI LSI were then compared between the stop jump and squat trials using Pearson's correlations. **RESULTS:** There was a significant relationship between both stop jump kinetic asymmetry outcomes and both squat kinetic asymmetry outcomes (Table 1). **CONCLUSION:** Kinetic asymmetry during squatting and bilateral landing are associated in ACL-R patients, which indicates that biofeedback retraining during bilateral squatting could result in improvements in bilateral landing symmetry.

Squat	Stop Jump	
	Peak KEM LSI 45.8% ± 24.6%	GRFI LSI 42.8% ± 26.0%
Peak KEM LSI 34.8% ± 25.4%	r = 0.693 p < 0.001	r = 0.555 p = 0.001
GRFI LSI 14.5% ± 10.5%	r = 0.428 p = 0.012	r = 0.479 p = 0.004

Table 1: Mean ± standard deviation for both outcomes on the squat and stop jump trials, and the relationship between kinetic asymmetry during squatting and stop jump landing

71 Board #2 May 27 9:30 AM - 11:30 AM Individualized Training Improves Inter-limb Joint Kinetic Symmetry During Jump Landing After ACL Reconstruction

Audrey RC Elias, Ryan L. Mizner. *University of Montana, Missoula, MT.*
Email: audrey.elias@umontana.edu
(No relevant relationships reported)

Most athletes with unilateral ACL reconstruction present with reduced knee and hip flexion and asymmetrical vertical ground reaction force (VGRF) and internal knee extension moment during two-legged jump landings. This landing movement pattern is associated with low scores on self-reported outcome surveys and may contribute to the increased risk of re-injury in athletes with ACL reconstruction. The capacity for correction of inter-limb asymmetries during landing remains understudied. **PURPOSE:** To determine whether jump training can correct asymmetrical limb loading and whether corrections are retained over time. **METHODS:** An 8-camera motion analysis system with dual force plates collected kinematic and kinetic data in a 30cm drop vertical jump to screen 48 potential participants with unilateral ACL reconstruction. Twenty-three athletes (14 women, 23 ± 5 years old, 20 ± 15 months post-surgical, Tegner score: 7 ± 2) presented with below-average knee loading symmetry in landing and poor clinical outcomes, and participated in 8 weeks of twice-weekly high-repetition progressive jump landing training. Subjects re-tested at 4 and 8 weeks. Retention testing was performed after 8 weeks post-training. Changes in hip and knee kinematics and kinetics including limb symmetry indices (percent of the uninvolved limb) over time were assessed with paired t-tests. **RESULTS:** Peak hip and knee flexion angles in the involved limb increased significantly in the drop vertical jump after 4 weeks of training (hip: 78±22 to 92±20, p<0.0001; knee: 86±11 to 96±16, p=0.0001). Symmetry in peak VGRF between limbs during landing increased after the full 8-week training period (83%±18% to 91%±16%, p=0.005). Changes in joint flexion and VGRF were retained for at least 8 weeks after the final training session. Symmetry in knee moment between limbs did not reach a statistical improvement until final retention tests (Pre: 80%±17%, Post: 86%±12%, p=0.47; Retention: 94%±21%, p=0.004). **CONCLUSIONS:** Individualized jump training results in normalization of limb loading symmetry during jump landings. Visible kinematic changes occur early in training, but symmetry in loading of the limb and knee specific kinetic measures take more time to achieve as they integrate into an athlete's movement pattern.

72 Board #3 May 27 9:30 AM - 11:30 AM Quadriceps Strength And Rate Of Torque Development Are Associated With Countermovement Jump Knee Kinetics Post-aclr

Daniel G. Cobian, Matthew D. Bjork, Sarah A. Gamillo, Mikel R. Stiffler-Joachim, Jennifer L. Sanfilippo, Bryan C. Heiderscheit. *University of Wisconsin-Madison, Madison, WI.*
Email: cobian@pt.wisc.edu
(No relevant relationships reported)

Quadriceps neuromuscular dysfunction is ubiquitous after anterior cruciate ligament reconstruction (ACLR) and can impair knee function during athletic activities. While peak quadriceps strength is often measured, time-dependent metrics such as rate of torque development may be important to sports performance. **PURPOSE:** To determine the relationships between quadriceps strength, rate of torque development, time since surgery, and knee joint kinetics during jumping in collegiate athletes up to 2 years post-ACLR. **METHODS:** 31 Division I athletes (age 20.3±1.3, BMI 26.1±3.9 kg/m², 17 female) performed countermovement jumps (CMJ) on force plates while whole body kinematics were recorded and completed maximal and rapid voluntary isometric knee extension (KE) contractions. Sagittal plane KE impulses were computed for concentric (CON) and landing (LAND) CMJ phases; KE peak torque (PT) and rate of torque development from 20-80% of peak torque (RTD) were extracted from isometric KE efforts. Limb symmetry indices (LSI) were computed and clinically relevant cutoffs of 90% LSI were investigated. A mixed effects model accounted for repeated measurements and assessed the relationships of PT, RTD, and time from surgery with CON and LAND. All possible pairwise interactions were tested. **RESULTS:** Among 31 athletes, 81 tests were completed 4-24 months post-surgery. PT and RTD were significantly correlated with CON (PT: p=.001, RTD: p=.044) and LAND (PT: p=.009, RTD: p=.008). No significant pairwise interactions between PT, RTD, and time from surgery were detected. Among 24 instances of PT LSI ≥ 90%, mean CON and LAND LSI were 87.3% and 94.2%, respectively. In comparison, among 15 occurrences of RTD LSI ≥ 90%, mean CON and LAND LSI were 93.0% and 102.2%. Among the 22 assessments completed ≥ 1 year post-surgery, mean CON and LAND LSI were 82.4%, and 83.3%, respectively. However, when CON and LAND LSI were ≥ 90%, mean PT was 94.5-94.7% and mean RTD was 85.1-85.3%. **CONCLUSIONS:** Both peak and rapid knee extensor torque development are strongly associated with symmetrical sagittal plane CMJ knee mechanics. CMJ knee

kinetic asymmetries did not resolve over time, independent from quadriceps function. Restoring maximal and rapid quadriceps torque capacity appears to be an important step in recovering symmetrical CMJ mechanics post-ACLR.

73 Board #4 May 27 9:30 AM - 11:30 AM
Biomechanical Determinants Of Return To Sport Following Anterior Cruciate Ligament Reconstruction

Ashley Holzer, Chelsey Roe, Gregory Hawk, Leon Su, Katherine Thompson, Darren Johnson, Cale Jacobs, Brian Noehren, FACSME. *University of Kentucky, Lexington, KY.*
(No relevant relationships reported)

The ability to return to sport (RTS) after an anterior cruciate ligament reconstruction (ACLR) return to sport is due to many factors. To date, few studies have considered the role of poor biomechanics to predict RTS status. Potentially, higher ground reaction forces (GRF) and better frontal plane knee alignment at a 6 month follow up, may indicate an athlete who is able to return to sport at their pre-injury level. However, this has never been formally tested.

Purpose: To determine the biomechanical factors at six months that predict return to sport at pre-injury level following ACLR.

Methods: 21 subjects, (13 F, 20.1 ± 5.9 years, 22.3 ± 2.1 BMI, Pre-injury Tegner 8.1 ± 2.1) six months (190.6 ± 15.3 days) following ACLR, ran on an instrumented treadmill during three-dimensional assessment. Visual 3D was used to analyze peak GRF, impact peak, and frontal plane knee angle. Subjects were contacted at 4.5 ± 2.1 years post-surgery to answer a questionnaire regarding RTS. Logistic regression model selection was performed using the Feasible Solutions Algorithm with AIC as a criterion. p-values presented here are based on the main effect significance tests from the selected model.

Results: Of the 21 subjects, 62% returned to sport at their pre-injury level. Subjects who returned to sport had significantly higher peak GRF (RTS 2.1 ± 0.24 BW, No RTS 1.98 ± 0.18 BW, p=0.03), impact peak (RTS 1.6 ± 0.3 BW, No RTS 1.4 ± 0.16 BW, p=0.04), and maximum frontal plane knee angle (RTS 5.2 ± 3.0°, No RTS 3.3 ± 3.3°, p=0.04).

Conclusion: This data indicates that athletes who run with greater axial loading and whose knee is in a more adducted position are more likely to RTS at pre-injury level. We speculate that athletes who land with greater impact forces are more confident in their knee function and, thus, are more likely to return to sport. In addition, positioning the knee in more adduction may help the athlete feel more secure in their knee and, consequently, return to playing sport. Rehabilitation efforts should focus greater impact loading and improved frontal plane alignment of the knee during running to increase the likelihood of RTS at pre-injury level.

74 Board #5 May 27 9:30 AM - 11:30 AM
Relationship Between Dynamic Limb Symmetry And Subjective Limb Confidence Post ACL Reconstruction In Youth Athletes

Jeffery J. Morgan, Samuel M. Lyons, Salinda K. Chan, Charles M. Chan, Kevin G. Shea, Emily A. Kraus. *Lucile Packard Childrens Hospital, Stanford Childrens Health, Palo Alto, CA.*
 Email: jemorgan@stanfordchildrens.org
(No relevant relationships reported)

Limb symmetry index (LSI) of dynamic movement is used as return to sport criteria for athletes who have undergone an anterior cruciate ligament reconstruction (ACLR). However the relationship between an individual's perception of confidence and dynamic performance is poorly understood. **PURPOSE:** To discern a relationship between dynamic limb symmetry during a drop landing (DL) and single leg hop (SLHOP) task with subjective limb confidence in athletes who have had an ACLR. **METHODS:** 23 subjects (13 female, 10 male; 16±1.4 years) underwent a biomechanical assessment, including a DL and SLHOP task, at around 7±1 months post op ACLR. Subjects were outfitted with a custom marker set and recorded with a 3D camera system while performing tasks on 2 force platforms. To examine dynamic limb symmetry, kinematic variables of peak hip flexion, knee flexion, and ankle dorsiflexion, with kinetic variables of peak hip extension moment, knee extension moment, ankle plantar flexion moment, and vertical ground reaction force (GRFz) were collected and analyzed as an index between the involved and non-involved limb. Subjects completed questionnaires for limb confidence; International Knee Documentation Committee (IKDC)/Pedi-IKDC and Tampa Scale of Kinesiophobia (TSK). The relationship between LSI during DL and SLHOP with the IKDC and TSK scores were tested using a multilinear regression analysis. **RESULTS:** A significant strong relationship was found between LSI of DL mechanics and IKDC (86±12, r= 0.84, p<0.05). Among predictor variables, peak GRFz (LSI 79±21, p<0.05) was significant in its explanation of IKDC scores. Independent regressions showed significant moderate correlations between IKDC and LSI for peak hip extension moments (LSI 107±24, r= 0.56, p<0.01), knee extension moments (LSI 80±23, r=0.51, p<0.05), and GRFz (r= 0.62, p<0.01). No significant relationships were found for SLHOP and IKDC scores, or with TSK for either dynamic test. **CONCLUSIONS:**

Subjective limb confidence demonstrated a strong relationship with limb symmetry of sagittal plane mechanics with a 1% difference in LSI of GRFz corresponding to a 0.4% difference in IKDC scores during a DL and not SLHOP task. Symmetry in mechanics during a bilateral task may be more reflective of patient confidence in utilizing the affected limb prior to return to sport after ACLR.

75 Board #6 May 27 9:30 AM - 11:30 AM
Quantifying The Relationship Between Quadriceps Strength And Aerobic Fitness Following ACL Reconstruction

Lindsay V. Slater¹, Levi J. Hargrove¹, Joseph M. Hart, FACSME.
¹Shirley Ryan AbilityLab, Chicago, IL. ²University of Virginia, Charlottesville, VA. (Sponsor: Joe Hart, FACSME)
(No relevant relationships reported)

PURPOSE: Investigate the relationship between performance measures and quadriceps strength in individuals with ACL reconstruction (ACLR) and healthy controls.

METHODS: Thirty-three individuals with ACLR (22F/11M, 19.9±2.2 years, 68.3±10.9 kg, 170.4±8.4 cm, 22.7±23.3 months post-surgery) and 29 healthy individuals (18F/11M, 20.1±1.5 years, 70.0±9.9 kg, 172.7±8.7 cm) completed isokinetic quadriceps strength testing using a Biodex dynamometer at 180 degrees/sec on both legs then completed vertical jump (VJ) testing with and without countermovement (NCMJ) on a jump mat. All participants completed an incremental treadmill test to determine maximal oxygen consumption testing (VO2max). Initial running velocity was self-selected and increased 0.5mph every 2 minutes until volitional fatigue. Knee extensor torques and VO2max were normalized by mass. Bivariate Pearson's correlations were calculated between strength and performance variables. Significant correlations were retained for a regression analysis.

RESULTS: In ACLR, peak torque was correlated with VJ (r = 0.43, P = .012), NCMJ (r = 0.44, P = .011), and VO2max (r = 0.52, P = .002). The only variable retained in the regression model was VO2max, which explained 26.7% of the variance in strength. In healthy individuals, peak torque was correlated with VJ (r = 0.72, P < .001), NCMJ (r = 0.62, P < .001), and VO2max (r = 0.55, P = .002). Two variables were retained in the regression model, including VJ (R² = 52.2%) and VO2max (R² = 6.8%) which together explained 59.0% of the variance in strength.

CONCLUSIONS: Quadriceps strength was associated with a VJ, a powerful quadriceps movement, in healthy individuals, while strength in individuals with ACLR was associated with aerobic fitness. Although VO₂max was a significant predictor of strength after ACLR, it explained a small amount of variance which suggests other factors contribute to strength after ACLR.

76 Board #7 May 27 9:30 AM - 11:30 AM
Effects Of A 4-week Vibration-induced Hamstrings Fatigue Intervention On Quadriceps Weakness After ACL Reconstruction

Timothy W. Lowe¹, Lisa Griffin¹, Robert W. Dennis², Arturo Arce-Esquivel³, Xuanliang Neil Dong³. ¹The University of Texas at Austin, Austin, TX. ²Azalea Orthopedics & Sports Medicine Clinic, Tyler, TX. ³The University of Texas at Tyler, Tyler, TX.
 (Sponsor: Yong Tai Wang, FACSME)
 Email: t.lowe@utexas.edu
(No relevant relationships reported)

Arthrogenic muscle inhibition (AMI) results from an inability to voluntarily activate all motor units in the quadriceps due to ongoing neuronal inhibition. This may be due to changes in small diameter afferent activity that increase the excitability of the flexor withdrawal pathway, causing over-excitation of the hamstrings and reciprocal inhibition of the quadriceps. Reciprocal inhibition of the quadriceps from Ia afferents of the hamstrings may be reduced with prolonged muscle vibration of the hamstrings via fatigue of the intrafusal muscle fibers.

PURPOSE: To determine the effects of vibration-induced hamstring fatigue on AMI after ACL reconstruction (ACLR).

METHODS: Seven adults (28.7 ± 8.2 yrs) with unilateral ACLr (time since surgery: 19.4 ± 9.7 months) were recruited. Participants received a 4-week long (3x/week) training program. Vibration-induced fatigue of the hamstrings consisted of 20 minutes of prolonged vibration applied directly to the hamstrings. Then, a cuff was placed on the proximal thigh and inflated to 150 mmHg to trap the metabolites in the muscle, and maintain hamstrings fatigue; during which participants performed 4 sets of 15 reps at 30% 1-repetition maximum (RM) unilateral knee extension (KE). Quadriceps strength and quadriceps inhibition were assessed before and after the intervention using KE 1-RM normalized to body weight, and the central activation ratio (CAR) measured by a superimposed burst. The co-activation of the hamstrings was assessed using hamstring EMG during KE. Paired t-tests were used to examine the effect of prolonged vibration on KE strength, quadriceps CAR, and hamstrings co-activation before and after the intervention.

RESULTS: KE strength increased significantly by 38.5% (from 0.45 ± 0.1 to 0.62 ± 0.2 %BW, $P=0.004$); quadriceps CAR also increased significantly by 5.8% (from $93 \pm 0.1\%$ to $98 \pm 0.8\%$, $P=0.02$). Finally, co-activation decreased by 34% (from $12 \pm 1.3\%$ to $8 \pm 0.9\%$, $P=0.03$).

CONCLUSIONS: These results suggest that quadriceps weakness may be due to over excitation of the hamstrings which results in reciprocal inhibition of the quadriceps. Vibration-induced hamstrings fatigue can be used as a rehabilitation strategy to restore normal quadriceps function following ACLr by reducing the hamstrings over-excitability and restoring full quadriceps activation.

A-19 Thematic Poster - Caffeine

Effects Of Caffeine On Physiological Responses To Exercise And Time-trial Performance: Influence Of CYP1A2 Genotype.

Mark Glaister, FACSM, Kiran Chopra, Ana Pereira De Sena, Cassie Sternbach, Yiannis Mavrommatis. *St Mary's University, Twickenham, United Kingdom.*
Email: mark.glaister@stmarys.ac.uk
(No relevant relationships reported)

PURPOSE: The aim of this study was to investigate the influence of CYP1A2 genotype (which influences the rate of caffeine metabolism) on the effects of caffeine on physiological responses to submaximal exercise and cycling time-trial performance. **METHODS:** Eighty six cyclists were screened for their CYP1A2 genotype before being separated into two groups (AA [wildtype] versus AC or CC variant). Seventeen participants from each group (age: 45 ± 9 yrs; height: 1.81 ± 0.07 m; body mass: 76.4 ± 9.9 kg; $\dot{V}O_{2max}$: 4.02 ± 0.46 L \cdot min $^{-1}$) were then matched for self-reported endurance ability before taking part in a randomised, double-blind, placebo controlled study. In Trial 1, participants completed incremental cycling tests to establish the $\dot{V}O_2$ -power output relationship and $\dot{V}O_{2max}$. In trials 2 and 3 participants ingested a capsule containing 5 mg \cdot kg $^{-1}$ of caffeine or placebo one hour before completing a submaximal incremental cycling test (4-min stages) at 40, 55, 70, and 85% of $\dot{V}O_{2max}$, followed by a time trial (~30 mins). 95% confidence limits (CL_{95}) were calculated for all estimates. **RESULTS:** Relative to placebo, caffeine led to a significant reduction in time to complete the time trial (caffeine: 29.21 ± 1.60 mins; placebo: 30.30 ± 1.96 mins); but there was no effect of genotype. During submaximal exercise, caffeine resulted in significant reductions in heart rate (mean difference: 2.4 b \cdot min $^{-1}$; CL_{95} : $1.1 - 3.8$ b \cdot min $^{-1}$), with effects dissipating as exercise intensity increased. Caffeine also led to submaximal exercise reductions in ratings of perceived exertion (mean difference: 0.5 ; CL_{95} : $0.2 - 0.8$) and significant increases in respiratory exchange ratio (mean difference: 0.013 ; CL_{95} : $0.002 - 0.025$), minute ventilation (mean difference: 3.4 L \cdot min $^{-1}$; CL_{95} : $0.4 - 6.4$ L \cdot min $^{-1}$), and blood lactate concentration (mean difference: 0.24 mmol \cdot L $^{-1}$; CL_{95} : $0.11 - 0.37$ mmol \cdot L $^{-1}$). However, the responses were not affected by genotype. **CONCLUSION:** Caffeine influences physiological responses to submaximal exercise and improves time-trial performance. However, those effects are not influenced by CYP1A2 genotype.

79 **Board #2** **May 27 9:30 AM - 11:30 AM**
Caffeine Ingestion Increases The Specific Upper-body Performance Of Combat Sports Athletes

João Paulo Lopes-Silva, André Rocha, Júlio Rocha, Vitor Fabiano dos Santos Silva, Carlos Rafael Correia-Oliveira. *CESMAC University Center, Maceió, Brazil.*
Email: lopesilvajp@hotmail.com
(No relevant relationships reported)

PURPOSE: To investigate the acute effect of caffeine ingestion on upper-body intermittent endurance and maximal isometric strength performance of combat sports athletes. **METHODS:** Ten experienced judo and jiu-jitsu athletes completed two experimental sessions separated by at least 48 hours. Athletes consumed capsules containing either caffeine (5 mg \cdot kg $^{-1}$) or placebo 60 min before performing four bouts of an intermittent judogi's dynamic strength endurance test, interspersed by 3-min recovery, in a double-blind and placebo-controlled crossover design. The performance was determined by the total number of repetitions completed during each of 4 exercise bouts. Furthermore, the sum of all repetition throughout the test was also calculated in

order to analyze the overall performance. Heart rate (HR), rating of perceived exertion (RPE) and maximal isometric handgrip strength (MIHS) were evaluated prior to test and immediately after each exercise bout, while the blood lactate concentration [La] was measured just before and three minutes after the test. **RESULTS:** When compared to placebo condition (41 ± 8 reps and 45.6 ± 2.7 kg), caffeine ingestion increased the total number of repetitions (45 ± 10 reps, +7%, $P < 0.05$) and the MIHS (47.5 ± 2.8 kg, +5%, $P < 0.05$). However, there were no significant differences in RPE (CAF: 11.7 ± 1.1 a.u., PLA: 11.8 ± 0.9 a.u.), HR (CAF: 137 ± 3 bpm, PLA: 133 ± 3 bpm) and [La] (CAF: 6.6 ± 0.4 mmol \cdot L $^{-1}$, PLA: 5.7 ± 0.4 mmol \cdot L $^{-1}$) conditions ($P > 0.05$ for all comparisons). **CONCLUSION:** Caffeine ingestion (5 mg \cdot kg $^{-1}$) improved the upper-body intermittent endurance and maximal isometric strength of combat sports athletes without altering psychophysiological responses.

Perceptions Of Caffeine Use Among Kansas High Intensity Functional Training Participants

Melitza Ramirez, Jesse A. Stein, Katie Heinrich. *Kansas State University, Manhattan, KS.*
Email: melitzar@ksu.edu
(No relevant relationships reported)

Caffeine is a psychoactive drug that decreases perceived effort and improves exercise tolerance. Yet, high-doses of caffeine can result in negative symptoms, which may affect exercise performance. High caffeine users likely perceive positive effects with caffeine-use. While high intensity functional training (HIFT) has expanded rapidly, the perceived effects of caffeine-use during HIFT is unknown.

Purpose: To compare perceived and actual responses to caffeine during HIFT between low and high caffeine users.

Methods: Seventeen HIFT-experienced men were recruited (age = 26.9 ± 6.5 years, weight = 84.7 ± 10.1 kg). Participants were randomized in a double-blind, crossover design to consume 5 mg/kg body mass of caffeine pills or placebo 60-minutes prior to a HIFT workout. Perceptions of caffeine's effect, successful blinding, and actual positive- and negative-symptoms were determined with surveys. Three chi-square tests were conducted to determine differences between caffeine-users (low- vs. high-users) for perceptions of caffeine's effects (positive vs. negative), blinding to the treatment (successful vs. unsuccessful), and symptoms after caffeine supplementation (positive and negative).

Results: Nine participants were low-users (< 200 mg caffeine/day), and 8 high-users (> 200 mg caffeine/day). Chi-square tests were non-significant ($p > 0.05$). Descriptively, 2 low-users and 0 high-users perceived negative-effects, while 6 low-users and 7 high-users perceived positive-effects of caffeine use at baseline. One low-user perceived both positive- and negative-effects. Four participants from each group correctly identified the caffeine condition. After study caffeine consumption, 1 participant from each group reported negative-symptoms, while 2 low-users and 4 high-users reported positive-symptoms.

Conclusion: No significant differences in perceived and actual responses to caffeine supplementation were found between low and high caffeine-users. However, we found that caffeine supplementation may result in negative-symptoms, so individual effects should be considered. Future studies should investigate perceived and actual responses for popular caffeinated pre-workout supplements on; specifically for negative symptoms.

COFFEE VOLUME DOES NOT SUPPRESS APPETITE OR CHANGE PERCEIVED HUNGER IN HABITUAL CAFFEINE CONSUMERS

Vanessa A. Salama, Takudzwa A. Madzima, Eric Hall, FACSM, Svetlana Nepocatych. *Elon University, Elon, NC.* (Sponsor: Eric Hall, FACSM)
Email: ness1534@gmail.com
(No relevant relationships reported)

Caffeine is a heavily consumed substance that has several benefits, including appetite suppression and increased energy metabolism. **PURPOSE:** To determine the effect of caffeine amount and coffee volume on appetite profile, affective response, cognitive function, blood glucose levels and subsequent energy intake in female habitual caffeine consumers. **METHODS:** 19 healthy female (age: 24 ± 8 , BF%: 24.9 ± 5.1) habitual caffeine consumers (255 ± 122 mg/day) ingested coffee of different volumes and caffeine amounts on four different occasions (C1: 237 ml/4 mg/kg; C2: 237 ml/6mg/kg; C3: 473 ml/4mg/kg; C4: 473 ml/6mg/kg) in a single blind, randomized, crossover design. Participants completed a visual analog scale (VAS) of appetite profile at pre, 0, 30 and 60 minutes. Affective response and cognitive function were assessed using the Activation-Deactivation Adjective Checklist (AD-ACL), Trail Making (TM) and Stroop tasks (ST) before and after the test drink. Blood glucose levels were measured at pre, 30 and 60 minutes. In addition, ad libitum breakfast was consumed at 60 minutes and 24-hour self-reported energy intake was recorded. A repeated measures

ANOVA was used for analysis with significance accepted at $p < 0.05$. **RESULTS:** A significant time ($p < 0.001$), but not condition effect was observed in hunger ($p = 0.31$), satiety ($p = 0.16$), fullness ($p = 0.11$), desire to eat ($p = 0.31$) and prospective food consumption ($p = 0.19$). No significant condition effect was observed in blood glucose levels ($p = 0.12$), energy intake at breakfast (C1: 440 ± 213 ; C2: 400 ± 158 ; C3: 440 ± 226 ; C4: 386 ± 138 calories, $p = 0.43$) or over 24-hours (C1: 16773 ± 532 ; C2: 1486 ± 434 ; C3: 1503 ± 321 ; C4: 1662 ± 505 calories, $p = 0.28$). However, a significant interaction effect was observed in tiredness, calmness, energy and tension ($p = 0.02$). In addition, a significant time ($p < 0.001$) but not condition effect ($p > 0.05$) was observed in TM, ST and state anxiety. Participants' time to complete cognitive tasks decreased and state anxiety increased over time. **CONCLUSIONS:** Coffee volume may not have an effect on appetite suppression and perceived hunger, however, may modulate affective responses.

 (No relevant relationships reported)

Ageing is associated with neurodegeneration and loss of muscle function, driving to adverse age-related health events and decreasing quality of life. Of the many contributors to the ageing process, decreased skeletal muscle function plays a large role, but physical, nutritional, and ergogenic interventions can have positive effects on muscle function. For example, evidence suggests that a low dose of caffeine may act on the central nervous system and may improve force-generating capacity. However, the majority of these studies have focused in young individuals, and no study has compared the effects of caffeine on strength between older and younger individuals. **PURPOSE:** To compare the effect of caffeine on force-generating capacity between older and young adults.

METHODS: 21 older (68 ± 6 years) and 22 young men (25 ± 5 years) were tested for peak torque (PT) and contractile impulse (CI; torque integrated to time) of the plantar flexors using a Biodex 4 dynamometer. Participants were familiarized with testing procedures on the first day, and the experimental protocol was applied on two other days (2-7 days apart), which consisted of four maximal isometric contractions before and 60-min after 3 mg/kg of caffeine or placebo (double-blinded). PT, CI 0-50 (CI_{0-50}), and 100-200 ms ($CI_{100-200}$) were analyzed. A three-way mixed ANOVA was used to investigate potential differences between conditions (pre vs post-supplement) and groups (older vs young). Cohen's effect size (ES) was used to show the magnitude of differences and the standardized mean differences for caffeine versus placebo in both groups.

RESULTS: Caffeine increased PT in young (3.2%; $p = 0.007$, $ES = 0.21$) but not in older individuals (2.7%; $p = 0.104$, $ES = 0.13$). No differences were seen in CI_{0-50} and $CI_{100-200}$ in young and older ($p > 0.05$). The standardized mean differences showed a small effect in favor of caffeine on PT in young ($ES = 0.47$), CI_{0-50} in young ($ES = 0.41$) and older ($ES = 0.40$), and $CI_{100-200}$ in older ($ES = 0.24$).

CONCLUSIONS: Caffeine increased isometric peak torque in young but not in older individuals. Caffeine did not increase rapid torque output (i.e. CI_{0-50} and $CI_{100-200}$) in either young or older individuals. However, a small effect was observed in favor of caffeine against placebo in both groups.

Effect Of Caffeine Ingestion On Performance During A Repeated-bout Agility Test In Handball Players

Carlos Rafaell Correia-Oliveira, Julio Cesar Correia Rocha, André Luiz Silva Rocha, Gutemberg Silva Santos Soares. *CESMAC University Center, Maceió, Brazil.*
 Email: crafoliveira@yahoo.com.br
 (No relevant relationships reported)

PURPOSE: To verify whether caffeine would alter the psychophysiological responses and agility performance during repeated bouts of an agility test in handball players.

METHODS: 10 recreationally handball players (20.6 ± 3.3 years, 81.5 ± 10.0 kg, 1.80 ± 0.1 m) performed 6 exercise bouts, interspersed by 1-min recovery intervals, of an agility test (Illinois Agility Run Test) 60 min after ingesting, in a double-blind manner, either caffeine (5 mg·kg⁻¹ of body mass) or placebo (cellulose). The total exercise-bout time (sum of all time during each of the 6 exercise bouts) was compared between conditions using a paired t test, while the rating of perceived effort (RPE), heart rate (HR) and blood lactate concentration ([La]) were compared between conditions using a two-way repeated-measures ANOVA (condition and bout factors). **RESULTS:** There was no significant difference between caffeine (114.3 ± 5.9 s) and placebo (114.4 ± 4.7 s) conditions for total exercise-bout time ($P > 0.05$). The RPE increased progressively throughout the test in all conditions ($P < 0.05$), but without significant differences

between caffeine (bout 1: 8.1 ± 1.6 ; bout 6: 15.6 ± 4.1) and placebo (bout 1: 7.9 ± 1.1 ; bout 6: 15.5 ± 4.0) conditions ($P > 0.05$). Similar responses were found for HR, revealing an exponential increase during the test in both conditions ($P < 0.05$), but with no differences when caffeine condition (rest: 74 ± 17 bpm; bout 6: 179 ± 14 bpm) was compared with placebo condition (bout 1: 83 ± 15 bpm; bout 6: 183 ± 14 bpm; $P > 0.05$). Furthermore, the [La] increased linearly over the test in both conditions ($P < 0.05$), but it was significantly higher in caffeine (16.2 ± 2.7 mmol·L⁻¹) compared with placebo (13.8 ± 2.9 mmol·L⁻¹) 3 min after the repeated-bout agility test ($P < 0.05$). **CONCLUSION:** Caffeine ingestion increases the glycolytic flux but does not alter the performance during a repeated-bout agility test in handball players.

Caffeine May Increase Sugar Intake, Alter Taste Perception And Appetite Profile

Svetlana Nepocatych, Keely Collins, Takudzwa A. Madzima. *Elon University, Elon, NC.* (Sponsor: Eric Hall, FACSM)
 Email: snepocatych@elon.edu
 (No relevant relationships reported)

The effects of caffeine on athletic and cognitive performance have been previously studied, however, less research is available on taste perception and appetite suppression. **PURPOSE:** The purpose of this study was to evaluate the effects of caffeine on taste perception, perceived caffeine amount, affect, energy metabolism and appetite profile. **METHODS:** 18 college-aged females (age 21 ± 1 yrs; BMI 24.3 ± 4.0 kg/m²; BF%: 24.6 ± 8.8) who were habitual caffeine consumers were recruited for the study. Participants reported to the laboratory fasted on two separate occasions and were provided with (355 ml) caffeinated (C) or decaffeinated (D) coffee test drink. Appetite profile, The Stanford Sleepiness (SSS), Feeling (FS) and Felt Arousal (FAS) scales were administered at pre-, 0, 25 and 45 minutes post-coffee drink. In addition, palatability and perceived caffeine amount were assessed using questionnaires at pre- and post- sugar addition. Sugar addition to the coffee drink was recorded. An indirect calorimetry method using ventilated hood technique was used to measure oxygen consumption (VO₂) and respiratory quotient (RQ) at pre- and post-25 minutes. A repeated measures ANOVA and t-test were used for analysis with significance accepted at $p < 0.05$. **RESULTS:** A significant interaction effect was observed for fullness ($p = 0.04$) and amount ($p = 0.03$), but not for hunger ($p = 0.16$), satiety ($p = 0.29$) or desire to eat ($p = 0.11$). A significant interaction effect was observed for RQ (C: 0.83 ± 0.06 and 0.89 ± 0.07 ; D: 0.82 ± 0.05 and 0.84 ± 0.04 , $p = 0.006$) and significant condition effect was observed for VO₂ (C: 3.9 ± 0.5 ml/kg/min; D: 3.7 ± 0.5 ml/kg/min, $p = 0.01$). A significant interaction effect was observed for perceived caffeine amount (C: 3.2 ± 0.5 and 3.7 ± 0.5 ; D: 3.3 ± 0.8 and 3.2 ± 0.8 , $p = 0.007$) and bitterness ($p = 0.02$), but not aftertaste ($p = 0.23$), sweetness ($p = 0.21$) or pleasantness of taste ($p = 0.19$). A significant interaction effect was observed for FAS ($p = 0.04$) and condition effect for SSS ($p = 0.003$) and FS ($p = 0.03$). In addition, significantly ($p = 0.004$) more sugar was added to caffeinated drink (6.3 ± 3.6 g) compared to decaffeinated (3.0 ± 1.9 g). **CONCLUSIONS:** Although, palatability and pleasantness of taste was not significantly different, caffeinated coffee was perceived bitter leading to more sugar added to the drink.

85 Board #8 May 27 9:30 AM - 11:30 AM
Caffeine Intake Influences The Blood Pressure Response To Strenuous Physical Exertion Among Firefighters

Rachel S. Berkowsky¹, Beth A. Taylor, FACSM¹, Amanda L. Zaleski¹, Paul M. Parducci¹, Ming-Hui Chen¹, Kim M. Gans¹, Yin Wu¹, Paul D. Thompson, FACSM², Antonio B. Fernandez², Linda S. Pescatello, FACSM¹. ¹University of Connecticut, Storrs, CT. ²Hartford Hospital, Hartford, CT.
 (No relevant relationships reported)

Caffeine may diminish the immediate blood pressure (BP) reductions that occur after an exercise bout, termed *post-exercise hypotension* (PEH). Neither PEH nor the influence of caffeine on PEH have been studied in firefighters (FF), who have a disproportionate high risk of sudden cardiac death on the job, partially due to its strenuous nature and poor nutrition. **PURPOSE:** To examine the influence of caffeine intake (CAF) on PEH after a maximal graded exercise stress test (GEST) in FF. **METHODS:** FF ($n = 15$) completed a non-exercise control (CONTROL) and GEST in random order on separate non-work days. They left the laboratory attached to an ambulatory BP (ABP) monitor for 19hr. CAF was assessed with the National Health and Nutrition Examination Survey food-frequency questionnaire. Repeated measures ANCOVA in SAS tested if the ABP response after GEST vs CONTROL differed by CAF group divided by the median as high (806.8 ± 190.7 mg) and low (239.3 ± 202.9 mg) with baseline ABP as a covariate. **RESULTS:** FF were overweight (29.0 ± 3.9 kg/m²), middle-aged (40.2 ± 9.5 yr) men with elevated resting BP ($124.1 \pm 10.3/79.6 \pm 11.5$ mmHg). CAF tended to be positively correlated with resting SBP ($r = .50$, $p = .06$) and DBP ($r = .50$, $p = .06$). Among the total sample, the systolic ABP (ASBP) (18.0 ± 4.8 mmHg, $p < .01$) and diastolic ABP (ADBP) (9.1 ± 1.5 mmHg, $p < .01$) changes from baseline were greater after GEST vs CONTROL over 19hr, independent

of CAF ($P_s \geq 0.05$), but with significant interactions among ASBP, ADBP, and CAF over 19hr ($P_s < 0.05$). These interactions revealed ASBP was consistently greater after GEST vs CONTROL over 19hr in high CAF ($p < 0.01$ GEST vs CONTROL); whereas in low CAF the difference in ASBP after GEST vs CONTROL was variable over 19hr ($p = 0.03$ GEST vs CONTROL x Time). By contrast, the ADBP response after GEST vs CONTROL over 19hr tended to be greater in low (15.3 ± 4.5 mmHg, $p = .08$) than high CAF (4.4 ± 2.4 mmHg, $p = .05$). **DISCUSSION:** This small sample of FF exhibited post-exercise hypertension and CAF seemed to modulate this adverse response. Further study is needed in a larger sample of FF to confirm our findings and better establish the relationship of these associations.

Impact Of Neuromuscular Electrical Stimulation On Quality Of Life In Older Adults
Nigel C. Jiwan, Kyndall P. Ramirez, Monica A. Mendoza, Mitchell S. Kane, Lindsay E. Kipp, Joni A. Mettler. *Texas State University, San Marcos, TX.* (Sponsor: Tinker Murray, FACSMM)
(No relevant relationships reported)

Older adults often suffer from sarcopenia, the age-related loss of muscle mass and strength, which negatively impacts physical function and quality of life (QoL). Neuromuscular electrical stimulation (NMES) is frequently used in physical rehabilitation as a muscle strengthening modality; however, little research exists on QoL outcomes in response to NMES. **PURPOSE:** The aim of this study was to determine change in QoL and physical function in older adults after 4 weeks of NMES. **METHODS:** Eight older adults (68.9 ± 2.4 years) completed 12, 40-min NMES training sessions of the quadriceps muscles on each leg over 4 weeks with the stimulation frequency set at 60 Hz. During the treatment, subjects were seated on an isokinetic dynamometer with the leg positioned at a 60° angle. The subjects were given a pre and post survey assessing indicators of QoL: self-efficacy for physical function (0-100 scale), perceived competence in physical domains (e.g., strength, coordination, physical activity, 1-6 scale), physical self-concept (1-6 scale), and intention to be physically active (1-7 scale). Physical function of the lower body was assessed pre and post intervention with a timed up and go test (TUG). Paired sample *t*-tests were used to test for differences over time (pre, post) for TUG and QoL dimensions. Cohen's *d* was calculated for effect size. **RESULTS:** The following QoL dimensions showed a statistically non-significant increase with small to large effect sizes: self-efficacy (97.80 ± 0.84 vs 98.97 ± 0.17 , $p = 0.17$, $d = 0.83$), intention (5.91 ± 0.72 vs 6.59 ± 0.27 , $p = 0.38$, $d = 0.49$), coordination (5.10 ± 0.20 vs 5.30 ± 0.20 , $p = 0.12$, $d = 0.36$), and physical activity (3.84 ± 0.54 vs 4.22 ± 0.39 , $p = 0.20$, $d = 0.29$), pre vs post, respectively. Physical self-concept showed no effect (4.58 ± 0.44 vs 4.67 ± 0.36 , $p = 0.74$, $d = 0.07$), indicating this global dimension may take longer to change. There was a significant decrease in time to complete TUG (8.38 ± 0.60 s vs 7.40 ± 0.45 s, $p = 0.02$, $d = 0.62$). **CONCLUSION:** TUG times showed significant improvement and QoL dimensions trended toward improvement after 4 weeks of NMES. Enhanced physical function from NMES treatment may help improve overall QoL by increasing confidence and willingness to perform physical activities, potentially decreasing risk of sarcopenia.

Age-associated reductions in muscle strength and power are associated with decrements in functional performance. It is unclear which neuromuscular factors that contribute to strength and power (e.g. muscle mass, contractile speed) and limb fatigability (activity-induced reduction in strength and power) are predictive of functional performance among old adults.

PURPOSE: The aim was to determine the contribution of lower limb fatigability and neuromuscular factors to decrements in functional performance tests among older adults.

METHODS: Eighty-one adults (39 females, 42 males: $61 - 93$ years, 73 ± 7.7 years, body mass index = 26.4 ± 4.1 kg/m², body fat = 34.7 ± 7.8 %) participated in sessions to assess; 1) Physical function including a 6-minute walk, chair-rise (x5), timed stair-climbing and balance (Berg balance); 2) Dual-energy X-ray absorptiometry to assess the body composition; and, 3) fatigability of the knee extensor muscles which involved 80 maximal velocity concentric contractions (1/3 s) with a load of 20% of the maximal voluntary isometric contraction. Voluntary activation and contractile properties of the knee extensors were assessed with transcranial magnetic stimulation and peripheral nerve stimulation before, and after the fatiguing task. Correlation analysis and regression analysis were performed to determine which variables were predictive of physical function.

RESULTS: Distance walked over 6 minutes was associated with younger age, greater power, more thigh lean tissue and lower knee extensor fatigability ($R^2 = 0.55$, $P < 0.001$). Faster chair-rise time (x5) was associated with younger age, less body fat, and lower fatigability ($R^2 = 0.44$, $P < 0.001$). Both a faster stair-climb ($R^2 = 0.3$, $P < 0.001$) and a higher Berg balance score ($R^2 = 0.43$, $P < 0.001$) were associated with younger age and less body fat. **CONCLUSIONS:** Our findings demonstrate that younger age, greater peak power and lower fatigability of a dynamic fatigue task were strong predictors of lower limb functional performance tasks that are common to daily activities among older adults. Our results also suggest that interventions to offset age-related declines in lean mass and increases in body fat will aid in maintenance of functional performance with advancing age.

(No relevant relationships reported)

Higher levels of fitness are associated with preserved cognitive function in older adults. Preserved cognition is linked to better mobility and reduced risk of falls. However, it remains to be explored whether cardiovascular fitness (CF) influences the link between cognition and mobility in individuals with cardiovascular disease burden and risk of dementia. **PURPOSE:** We explored whether CF influences the relationship between cognition and mobility in older adults with hypertension and subjective cognitive decline. These individuals are at higher risk of dementia due to cardiovascular disease burden and early signs of cognitive impairment. **METHODS:** Older adults ($n = 118$, age 70.1 (SD = 6.7) years, 62% males) underwent CF assessment (Bruce protocol treadmill stress test) and were grouped based on Bruce protocol stage completion into low (stage 1 [$n = 31$]), average (stage 2 [$n = 57$]), and high (stage ≥ 3 [$n = 30$]) CF groups. Cognition was measured via the Cambridge Brain Sciences cognitive battery; mobility (usual and dual-task gait [naming animals]) was measured using the GAITRite walkway system. We conducted hierarchical regression models adjusting for sex, age and years of education to determine whether CF modulated association between cognition and mobility. **RESULTS:** For usual gait, cognition was positively associated with gait velocity in high CF (Change statistics: $F(1,25) = 14.3$, $p = .001$, $R^2 = .35$), as well as step length in high CF ($F(1,25) = 10.8$, $p = .003$, $R^2 = .27$) and average CF ($F(1,50) = 4.4$, $p = .04$, $R^2 = .08$), and gait variability in average CF ($F(1,48) = 9.8$, $p = .003$, $R^2 = .17$). For dual-task gait, cognition was positively associated with gait velocity in both high CF ($F(1,25) = 9.15$, $p = .006$, $R^2 = .26$) and average CF ($F(1,49) = 5.8$, $p = .02$, $R^2 = .10$), as well as step length in both high CF group ($F(1,25) = 7.2$, $p = .01$, $R^2 = .21$) and average CF group ($F(1,49) = 7.2$, $p = .01$, $R^2 = .13$). **CONCLUSIONS:** Cognition was positively associated with mobility outcomes in individuals with average and high

CF, while no associations were seen in those with low CF. These findings suggest that the protective effects of cognition on mobility (e.g., reduced falls risk and prolonged independence) may be hindered by low CF in older adults with hypertension.

12-week Of Tai Chi Training Improves Cognitive Function In Older Adults With Mild Cognitive Impairment

Angus, Pak Hung Yu, Ray, Yiu Pan Wong, Edwin, Chun Yip Chin, Danny, Ju Cheng Yu, Parco, Ming Fai Siu, FACSM. *The University of Hong Kong, Hong Kong, Hong Kong.* (Sponsor: Dr. Parco, Ming Fai Siu, FACSM)
 Email: aphyu@connect.hku.hk
 (No relevant relationships reported)

Manifestation of mild cognitive impairment (MCI) is an early sign indicative of accelerated decline in cognitive function during ageing that precedes the development of dementia. Its prevalence rate in older adults in China (≥ 60) ranges from 10% to 20%. To date, there is no documented pharmacological intervention for dementia. Preliminary studies, however, have shown that exercise can improve cognitive function.

PURPOSE: This study aims to examine the effectiveness of Tai Chi training in improving cognitive function in older adults with MCI.

METHODS: This randomized controlled trial was conducted between October, 2018 and May, 2019. In this two-arm, single-blinded randomized controlled trial, 20 Chinese adults aged ≥ 50 years with MCI [Score of Montreal Cognitive Assessment Hong Kong Version (MoCA-HK) below 7th percentile of the age and education-corrected normative data of Hong Kong] were randomly assigned to Control (CON, n=10, received no intervention) and Tai Chi (TC, n=10, received 12-week Tai Chi training) groups. Global cognitive function was the primary outcome which was assessed by MoCA-HK 12 weeks after post-randomization. Secondary outcomes including executive function, working memory, long term memory, and attention were assessed by trial making test A and B, digit span, 30-min delay recall test and attention network test respectively. Data were analyzed by generalized linear model with baseline as covariate.

RESULTS: TC provoked a robust improvement in MoCA-HK score compared with CON (TC: +24% vs CON: +9%, $P < 0.001$). TC participants also performed better in 30-min delay recall (TC: +52% vs CON: +8%, $P = 0.005$) and trial making test B/A ratio compared with CON (TC: -21% vs CON: -2%, $P = 0.028$). No statistical difference was observed in forward and back digit span. There was no statistical difference in reaction time, accuracy, alerting network and orienting network between the two groups. However the change in executive network was significantly different between TC and CON (TC: +19% vs CON: -24%, $P < 0.001$).

CONCLUSIONS: A 12-week Tai Chi training can improve global cognitive function in older adults with MCI. Tai Chi improves executive function and long-term memory and alters the attention network.

Effect Of Low Intensity Resistance Exercise Training On Cognitive Function In Middle-aged And Older Individuals

Keigo Tomoo¹, Kento Dora¹, Takeshi Sugimoto¹, Okubo Sahomi¹, Keigo Katayama¹, Akifumi Maeda¹, Hayato Tsukamoto², Takeshi Hashimoto, FACSM¹. ¹*Ritsumeikan University, Kusatsu, Japan.* ²*University of South Wales, Pontypridd, United Kingdom.* (Sponsor: Takeshi Hashimoto, FACSM)
 (No relevant relationships reported)

PURPOSE: Many studies have reported that aerobic exercise training improves cognitive function (CF), even with low-intensity (e.g. walking) (Kramer et al. 1999; Hillman et al. 2008). Alternatively, moderate (MRT) to high intensity RT (60-80% 1RM) improves CF (Chang et al. 2012). However, older individuals and patients with chronic disease often have difficulty with higher exercise loads due to declining cardiovascular and musculoskeletal systems. The purpose of this study was to examine the effect of low intensity resistance exercise training (LRT) on CF in middle-aged and older individuals. Given that an acute bout of even low intensity resistance exercise improves CF albeit less effective than higher intensity (Tsukamoto et al. 2017), we hypothesized that LRT would improve CF although its effect might be lower than higher intensity training. **METHODS:** 50 healthy middle-aged and older individuals (age: 50 to 77 years) were randomly classified into three groups (control (CON), LRT (40%1RM), and MRT (60%1RM)). Resistance exercise programs were leg extension, seated leg curl, leg press, and chest press. For each exercise, all participants performed 14 repetitions for three sets with 2 minutes interval. LRT and MRT participants completed all these exercise for three times per week and CON participants maintained their conventional lifestyle. CF (working memory (WM), short memory (SM), and

inhibitory control (IC)) were determined with reading span test, face-name matching task, and color-word Stroop task, respectively. Each task was performed at before the intervention (PRE), 12 weeks (12W), and 24 weeks (24W) of the intervention period. **RESULTS:** There was significant interaction for the IC score ($p = 0.021$). As compared with the PRE, the IC at the 12W did not change in the MRT ($p = 0.184$), while tended to improve for the LRT ($p = 0.065$), and significantly declined in the CON ($p = 0.020$). At the 24W, the IC score did not change significantly for all conditions as compared with the PRE. The score of WM and SM did not change significantly for all conditions throughout the intervention.

CONCLUSIONS: The finding suggests that even with a lower load, chronic RT may improve IC in middle-aged and older individuals. However, the exercise intensity, training period, and task specificity for the CF should be further elucidated.

92 Board #6 May 27 9:30 AM - 11:30 AM
Systolic Blood Pressure And Heart Rate Recovery Are Related To Cognition In Healthy Older Adults

Brittany Intzandt¹, Tudor Vrinceanu², Kristell Pothier³, Anil Nigam⁴, TT Minh Vu², Karen Li¹, Nicolas Berryman⁵, Claudine Gauthier¹, Louis Bherer². ¹*Concordia University, Montreal, QC, Canada.* ²*Universite de Montreal, Montreal, QC, Canada.* ³*Universit  de Tours, Tours, France.* ⁴*Montreal Heart Institute, Montreal, QC, Canada.* ⁵*Bishop's University, Sherbrooke, QC, Canada.*
 Email: brittany.intzandt@mail.concordia.ca
 (No relevant relationships reported)

SYNOPSIS: Attenuated heart rate recovery (HRR) and systolic blood pressure recovery (SBPR) after a maximal exercise test (VO_{2peak}) are linked to cardiovascular risk factors (CVRF). The relationship between the presence of CVRF and reduced cognition is well established in older adults. Yet the explicit relationship between HRR or SBPR and cognition has yet to be studied in older adults, here we found that reduced HRR and SBPR were directly related to worse cognition. **PURPOSE:** To determine if a relationship exists between cognition and HRR or SBPR measured during a VO_{2peak} test in older adults

METHODS: Prior to enrollment in an intervention, a total of 68 participants (70 \pm 6yrs; 45 women) completed neuropsychological tests and a VO_{2peak} incremental test on a cycle ergometer. After standard verifications at rest, heart rate and blood pressure were continuously monitored during the incremental test and a 3-minute recovery period. HRR was calculated as the first minute recovery heart rate subtracted from the maximal heart rate during the test, where lower numbers were interpreted as reduced recovery and increased likelihood of CVRF. SBPR was defined as the maximal reading during the test divided by the first- and third-minute recovery where a higher ratio indicates higher probability of CVRF. Correlations analyses were completed with sex, age and education as covariates.

RESULTS: VO_{2peak} was inversely related to Stroop inhibition reaction time ($r = -0.275$, $p = 0.048$). HRR approached significance with total digit span score ($r = 0.230$; $p = 0.090$). SBPR was negatively associated with Stroop inhibition reaction time ($r = -0.327$; $p = 0.042$) and Stroop switching reaction time ($r = -0.379$; $p = 0.017$)

CONCLUSIONS: For the first time, we identified that there is a direct relationship between SBPR and cognitive outcomes. HRR and SBPR are early indicators of cardiovascular and endothelial dysfunction, thus, it could be that the relationship between cognition and CVRF are mediated by early vascular dysfunction that could be affecting upstream cerebral vascular health. This hypothesis could be confirmed in future work including larger samples of individuals as well as neuroimaging techniques.

Association Of Cognitive Function With BMI And Physical Function In Older Adults: The CogEx Study

Audrey M. Collins, Renee J. Rogers, FACSM, Fabrisia Ambrosio, Kirk Erickson, Marissa L. Marcin, Andrea C. Kozai, Katherine A. Collins, Nalingna Yuan, John M. Jakicic, FACSM. *University of Pittsburgh, Pittsburgh, PA.* (Sponsor: John M. Jakicic, FACSM)
 Email: amc234@pitt.edu
 (No relevant relationships reported)

Aging negatively impacts cognitive function and physical function in older adults. Physical activity may protect or improve the brain and physical functions that are crucial for multiple health outcomes in older adults, whereas obesity may negatively impact these outcomes.

PURPOSE: To examine the association between cognitive function with BMI and physical function in underactive older adults.

METHODS: Baseline data were examined from sedentary older adults (N=31; age=70.3 \pm 3.7 years; BMI=28.8 \pm 4.6 kg/m²) prior to engaging in a 12-month physical activity intervention. Assessments included height, weight, physical function, and cognitive function. Cognitive function was assessed using the Modified Mini-

Mental State (3MS) examination and the Repeatable Battery for the Assessment of Neuropsychological Status (RBANS). Physical function performance was assessed using the time to complete the 400-Meter Walk Test (minutes).

RESULTS: Average time to complete the 400-meter walk was 6.3 ± 1.0 minutes, which was modestly associated with BMI ($r=0.312$, $p=0.088$). The 3MS Total Score (94.7 ± 3.7) was not significantly correlated with BMI ($r=-.158$; $p=.397$) or 400-Meter Walk Test performance ($r=-.152$; $p=.415$). Similarly, the RBANS Sum of Index Score (209.0 ± 21.1) was not significantly correlated with BMI ($r=-.297$; $p=.105$) or 400-Meter Walk Test performance ($r=-.164$; $p=.378$). When examining this relationship by cognitive domain, a higher BMI was associated with a poorer RBANS Immediate Memory Index Score ($r=-.412$; $p=.021$). We also observed that worse performance on the 400-Meter Walk Test was associated with poorer RBANS Immediate Memory Index Score ($r=-.314$; $p=.08$). Neither BMI nor 400-Meter Walk performance were significantly associated with RBANS Visuospatial/Constructional Index, Language Index, Attention Index, or Delayed Memory Index scores.

CONCLUSION: Findings reveal that RBANS Immediate Memory Index score was inversely associated with both BMI and physical function in sedentary older adults. This may suggest that both obesity and poor physical function negatively impact immediate memory performance in older adults. Future studies to investigate whether and how physical therapeutics may enhance short-term memory function in older adults are warranted.

Introduction: Exercise is an effective strategy on improving cognitive function, but most reports emphasize the benefits of high-intensity exercise. **Purpose:** This study is to investigate whether two acute moderate-intensity exercises can improve cognitive function of the sedentary elderly. **Method:** Twenty-eight women without exercise habits were divided into two groups, each performed yoga ($n=19$; 62.25 ± 1.6 yrs old) or circuit training ($n=9$; 59.53 ± 1.96 yrs old). All participants completed 30 minutes of moderate-intensity exercise with moderate efforts, significant accelerated breathing and heart rate. The cognition function tests were performed before, immediately, 30 and 60 minutes after an intervention consisting of 40 min of either Yoga or circuit training exercise and a seated rest control. The cognitive parameters were compared by a mixed-model analysis for repeated measures. **Results:** The results indicated there were no difference in age between the two groups. Acute exercise improved cognitive function immediately after acute exercise, including got a significant higher total response score ($F(3,75)=7.793$, $p<0.001$), and complete Schulte table (as an indicator of attention, $F(3,75)=4.239$, $p=0.008$) and Stroop's neutral test ($F(3,75)=12.64$, $p<0.001$) faster. There were no significant differences in other items such as responsive rate, memory span, and word, congruent, square, incongruent Stroop test after acute exercise. The benefits of exercise on total response score and Stroop's neutral test can even be maintained up to 60 minutes after exercise. For the benefit of two different exercise, only the performance of Schulte table was significantly better in the circuit training group than the yoga group ($F(1, 25)=4.554$, $p=0.043$, Eta value=0.154). The scores of other cognitive tests did not differ between the two exercises. **Conclusion:** The two different exercises significantly improved cognitive function and can maintain up to 60 minutes after exercise. The circuit training exercise represented a better influence on attention than Yoga.

(No relevant relationships reported)

Interrupting prolonged sitting with short activity bouts may be beneficial for glycemic control in adults with type 2 diabetes (T2D). However, the impact of frequency of interruptions has not yet been assessed in T2D. **PURPOSE:** To investigate acute effects of interrupting prolonged sitting with simple resistance activity (SRA) breaks at different frequencies on postprandial glucose and insulin in adults with medication-controlled T2D. **METHODS:** Inactive adults with medication-controlled T2D ($n=23$, $12 \text{ } \text{♀}$, 62 ± 8 y, 32.6 ± 3.5 kg m^2) completed a three-armed randomised crossover trial (6-14 day washout). The experimental conditions were: sitting uninterrupted for 7 h (SIT); sitting with 3-min SRA breaks every 30 minutes (SRA3); and, sitting with 6-min SRA breaks every 60 minutes (SRA6). Fasting and postprandial glucose and insulin concentrations were measured at -1 h and 0 h, and every 30 min thereafter for 7 h. Breakfast was provided at 0 h and lunch at 3.5 h. Total (7-h) and meal-specific (3.5-h) areas under the curve (tAUC; trapezoid method) were calculated. Mixed model regression analyses examined effects of condition on tAUC, adjusting for baseline concentrations and period effects. **RESULTS:** When compared to SIT, 7-h tAUC were attenuated significantly during SRA6 for glucose (SIT: 84.9 mmol L^{-1} , 95%CI 80.3, 89.8; SRA6 80.8 mmol L^{-1} , 95%CI 76.3, 85.3, $p=0.016$), and insulin (SIT: 1982 pmol L^{-1} , 95% CI 1679, 2340; SRA6: 1783 pmol L^{-1} , 95%CI 1510, 2105 $p<0.01$) but not SRA3 (see Figure). Post-lunch insulin tAUC was significantly lower during both SRA3 (907 pmol L^{-1} , 95%CI 776, 1059, $p<0.01$) and SRA6 (875 pmol L^{-1} , 95%CI 750, 1022, $p<0.001$) when compared to SIT (996 pmol L^{-1} , 95%CI 853, 1163). **CONCLUSION:** In adults with medication-treated T2D, interrupting sitting with bouts of SRA's every 60 minutes over 7 hours significantly attenuated postprandial glucose and insulin concentrations when compared with uninterrupted sitting.

Figure: Effect of the three 7 h trial conditions on postprandial (A) glucose and (B) insulin concentrations in adults with medication controlled T2D ($n=23$). Data are mean \pm SEM. SIT: uninterrupted sitting; SRA3: sitting with 3-minute SRA breaks every 30 minutes; SRA6: sitting with 6-minute SRA breaks every 60 minutes.

Effects Of Interrupting Sitting With Walking Only Or Combined With Resistance Activities On Glycemic Responses
 Xia Sheng Ma, Zheng Zhu, Xiao-Mei Liu, Yan-yu Lin, Zhen-Bo Cao. *Shanghai University of Sport, Shanghai, China.*
 Email: msx-27@163.com
 (No relevant relationships reported)

PURPOSE: To examine whether interrupting prolonged sitting with brief bouts of walking only or combined with simple resistance activity improve glucose levels in healthy, sedentary, young adults. **METHODS:** This study included 16 healthy, sedentary adults (9 women; 23.7±2.3 y; BMI 20.8±4.1 kg/m²; VO₂max 39.1±5.3 ml·kg⁻¹·min⁻¹) who completed three 26-h laboratory conditions, including 22.5 h in a whole-room calorimeter, separated by 5-14 day washout period. The same procedures were performed in each of the three conditions except for the following 9-h activity period: uninterrupted sitting time (SIT); sitting with 8 min intermittent, brisk (60% VO₂max) walking bouts (WALK; 7 bouts for a total of 56 min); or alternating 8-min brisk walks and simple resistance activities (RESIST; 3 bouts of walking and 4 bouts of resistance for a total of 56 min). Continuous glucose monitoring (CGM) was performed for 26 h. Standardized meals were consumed during each condition. The incremental areas under the curve (iAUC) for glucose during the entire observation period and the three segmentation periods (activity, evening, and sleep periods) were compared between conditions after adjustment for standard covariates (e.g., age, sex, et al.) and additional adjustment for energy expenditure (EE). **RESULTS:** Compared with SIT, RESIST reduced 26-h iAUC for CGM by 3.04 mmol·L⁻¹·h [95%CI 0.94-6.33] (p = 0.046). Compared with SIT, WALK and RESIST reduced the CGM iAUC by 3.80 mmol·L⁻¹·h [0.19-7.40] (p = 0.036) and 7.37 mmol·L⁻¹·h [4.08-10.66] (p < 0.001) during the 9 h activity period, respectively. The iAUC was lowered by 3.57 mmol·L⁻¹·h [0.06-7.08] (p = 0.045) in RESIST compared to WALK. Upon adjusting for EE, the only effect that remained was the comparison between RESIST and SIT during the activity period. During the evening period, WALK increased the CGM iAUC by 1.91 mmol·L⁻¹·h [0.29-3.54] (p = 0.019) when compared to SIT, this effect was lost after adjustment for EE. **CONCLUSIONS:** Interrupting 9 h of prolonged sitting time with either WALK or RESIST reduced acute glucose responses in healthy, sedentary adults. This effect was more pronounced in RESIST than WALK and was only maintained during the 26-h period in RESIST.

Simple Resistance Exercise Breaks To Interrupt Sedentary Behavior In College Students
 Robert J. Kowalsky, Tyler M. Farney, Christopher M. Hearon, FACSM. *Texas A&M University Kingsville, Kingsville, TX.*
 Email: robert.kowalskyjr@tamuk.edu
 (No relevant relationships reported)

Emerging research suggests improvement in fatigue, sleepiness, and muscular discomfort from using simple resistance exercises to interrupt prolonged sitting, yet it is unclear if these improvements are observed in college students.

PURPOSE: To examine if interrupting prolonged sitting with simple resistance exercise helps to reduce daily fatigue, sleepiness, muscular discomfort in college students and if it impacts daily physical activity.

METHODS: Twenty four college students (age 23.1 ± 3.4 years, BMI 27.4 ± 5.0 kg/m²) completed two 7-day assessments of subjective measures for discomfort, fatigue, and sleepiness while wearing an ActiVpal Micro (PAL technologies) to track physical activity for steps, sedentary time, standing time, and sedentary time in 10, 30, and 60-minute bouts. The first week was used as control (CON) and consisted of normal daily activities while completing assessments of all outcomes in the morning (M), mid-day (MD), and evening (E). The experimental week (REX) followed a similar protocol, but added hourly resistance exercise breaks consisting of one bodyweight or resistance band exercise for 2 sets of 15 repetitions per exercise. Paired *t*-tests evaluated difference in physical activity variables. Repeated measures ANOVA (0 between, 3 within) evaluated differences in discomfort, fatigue, and sleepiness variables across treatment (CON, REX), day (Mon-Fri), and time (M, MD, and E).

RESULTS: Comparison of physical activity resulted in no statistical significance between CON vs REX for all outcomes (p ≥ 0.05). A main effect for treatment was observed for overall discomfort (CON: 2.97, REX: 1.72; p = 0.042) and for sleepiness (CON: 4.38, REX: 3.89; p = 0.011). Additionally, a main effect for time was observed for mental fatigue (M: 15.16; MD: 16.19, E: 22.15; p < 0.001), physical fatigue (M: 15.41; MD: 15.91, E: 19.53; p = 0.027), and sleepiness (M: 4.78, MD: 3.36, E: 4.27; p < 0.001). *Post hoc* testing observed a difference for mental fatigue from M to E (p = 0.003) and MD to E (p < 0.001). Sleepiness observed a difference from M to MD (p < 0.001), M to E (p = 0.016), and from MD to E (p < 0.001).

CONCLUSIONS: Hourly simple resistance breaks resulted in no compensation in steps or sedentary time when engaging in the REX condition. Furthermore, the REX condition reduced daytime muscular discomfort and sleepiness.

Effects Of 8-week Aerobic Exercise On Markers Of Inflammation And Oxidative Stress In Obese Females
 Kyung-Shin Park¹, Jihyung Yoon², Brett S. Nickerson¹.
¹Texas A&M International University, Laredo, TX. ²New York University, New York, NY.
 Email: kpark@tamiu.edu
 (No relevant relationships reported)

PURPOSE: The current study investigated effects of an 8-week moderate intensity aerobic exercise program on changes of body composition and markers of inflammation and oxidative stress in middle-aged obese females.

METHODS: 35 obese females were randomly assigned to either exercise (EX, N=16) or control (CON, N=19) group. The exercise group performed moderate intensity aerobic exercise on the treadmill for 60 minutes at 55% of VO₂max for 8 weeks (3 days/week). Body composition measurement with dual-energy X-ray absorptiometry and blood collection were conducted before and after the 8-week intervention (PRE and POST). Blood samples were used to measure levels of tumor necrosis factor-alpha, C-reactive protein, adiponectin, total antioxidant status, and 8-hydroxydeoxyguanosine. Two-way repeated measures ANOVA and Tukey post hoc tests were used for data analysis.

RESULTS: 8 weeks of aerobic exercise intervention significantly reduced body weight (89.2±14.1 kg mean±SD → 88.1±14.4, P = .023), BMI (34.2±4.6 → 33.7±4.4, P = .035), %body fat (42.1±5.2% → 41.4±5.2, P = .014) and tumor necrosis factor-alpha (4.57±.28 pg/mL mean±SE → 4.24±.028, P=0.027) and increased total antioxidant status (1.76±.1 mM → 1.98±.1, P = .017); however, visceral adipose tissue mass, C-reactive protein, Adiponectin, and 8-hydroxydeoxyguanosine were unaltered. CON showed no significant changes in any variables at POST.

CONCLUSIONS: It is suggested that levels of inflammation and oxidative stress are associated with changes in %body fat, indicating that fat loss is effective in preventing and managing obesity-associated disorders. This study confirmed results of previous studies suggesting that longer period of exercise training with fat loss may be required to induce significant changes in CRP, adiponectin, and 8-hydroxydeoxyguanosine in the middle-aged obese females.

(No relevant relationships reported)

Purpose: Primary objective of this randomized multicenter trial was to investigate effects of different volumes of high intensity interval training (HIIT) compared to current exercise guideline of moderate-intensity continuous training (MICT) on the composite number of cardiovascular disease risk factors constituting the metabolic syndrome after a 16 week and 1-year, follow-up.

Methods: This randomized international multi-center trial included men and women aged ≥30 years diagnosed with the metabolic syndrome. The study consisted of a supervised and "partly supervised" phase to evaluate the efficacy and feasibility of different exercise doses on the metabolic syndrome in a real world setting. This study included 408 participants to one of the following groups: 3 times/week of 4x4 min HIIT at 85-95% HRpeak; 3 times/week of 1x4 min HIIT at 85-95% HRpeak; or iii) 5-7 times/week of ≥30 min MICT at 60-70% HRpeak. Clinical examinations, physical tests and questionnaires were administered to all participants during all testing time points (baseline, 16 weeks and after 1).

Changes from baseline to 16w and baseline to 1 year were compared between groups using the Kruskal-Wallis test. Change within each group from baseline to 16 weeks and baseline to 1 year were tested using the Wilcoxon signed-rank test. The level of significance was set at 5%.

Results

Between group changes did not show any significant results (16 weeks and 1 year) in any of the risk factors constituting metabolic syndrome. While within group changes induced almost significance in all variables (see table 1)

Conclusion

HIIT exercise with low volume seems to be a time-effective strategy for lowering risk factors constituting metabolic syndrome. Although results from this study show that both HIIT and MICT reduces metabolic syndrome risk factors to a similar degree. Table 1. Metabolic syndrome risk factors, baseline to 1 year

compare the efficacy of a HIIT-low volume protocol vs MICAT on the Homeostatic assessment model, glycated hemoglobin (HbA1c) and skeletal muscle mass, in adults with MS. **METHODS:** controlled, randomized, clinical trial using the minimization method, with two parallel groups for the purpose of showing superiority. Sixty patients with MS, of both genders, 40-60 years old, were included. A clinical evaluation, biochemical tests, an ergospirometry and a dual-energy X ray absorptiometry to determine total and regional skeletal muscle mass were carried out before and after a treadmill exercise program of 12 weeks, 3 sessions/week. Participants were assigned to an intervention with HIIT-low volume (n=29) in 22 min sessions that included six intervals at a load of 90% of maximum oxygen consumption (VO₂max) for 1 min followed by 2 min at 50% of VO₂max. The control group received MICAT (n=31) at an intensity of 60% of VO₂max in sessions of 36 min. **RESULTS:** patients had a mean age of 50.8±6.0 years, body mass index of 30.6±4.0 kg.m⁻², body fat percentage of 38.7±7.0% and VO₂max of 29.0±6.3 mL.O₂.kg⁻¹.min⁻¹; 70% were women. Compared to MICAT, HIIT-low volume was not superior in reducing Ln of IR (marginal mean difference: 0.083 [95% CI -0.092—0.257]; Cohen's d: 0.249; p value=0.346) or increasing Ln of total lean mass (kg) (0.004 [-0.014—0.023]; Cohen's d: 0.120; p=0.637) and Ln of thigh lean mass (g) (0.008 [-0.020—0.038]; Cohen's d: 0.154; p=0.599). After the intervention, the HIIT-low volume group, compared to the MICAT, had a higher HbA1c (5.81% vs 5.69%; 0.119 [0.005—0.233]; Cohen's d: 0.554; p=0.040). When comparing before and after the intervention, both training groups decreased IR. **CONCLUSION:** HIIT-low volume, compared to MICAT, is not superior in reducing IR or increasing skeletal muscle mass in adults with MS. High Intensity Interval Training And Muscular Strength On Academic And Behavioral Outcomes In Children

Jessica Peacock. Merrimack College, North Andover, MA.
 (Sponsor: Kevin Finn, FACSM)
 Email: peacockj@merrimack.edu
 (No relevant relationships reported)

Emerging research demonstrates the link between physical activity and academic outcomes, however, limited evidence exists on whether different modes of physical activity (PA) result in differences in cognitive and academic outcomes in real world settings. **PURPOSE:** The purpose of this study was to evaluate the effects of embedding a high intensity interval training (HIIT) and muscular strength program in physical education (PE) classes on academic and behavioral outcomes. **METHODS:** Seventy children (40 boys & 30 girls; age 8-10 yrs. old) enrolled in Accelerations Academy were assigned into one of three conditions during a one-week period: control (n = 23), High Intensity Interval Training (HIIT) (n = 25), and muscular strength (MS) (n = 22). The HIIT condition consisted of 4 days of HIIT sessions (9 min/session; 30 sec on:30 sec off) followed by X min of standard PE activities; the MS condition consisted of 4 days of strength sessions (3 sets/10-12 reps for 3 exercises/session) followed by ~30 min of standard PE activities; the control condition consisted of ~50 min of standard PE only. PA intensity and duration was measured using actigraph accelerometers (Actigraph, Pensacola, FL). Math Assessment scores and Connor Abbreviated Ratings were conducted at baseline and post-intervention to identify academic and behavioral changes respectively. Intervention effects for outcomes were examined using regression analysis. **RESULTS:** Participation in HIIT predicted higher vigorous (β=2.21, p=0.005) and very vigorous minutes (β=0.80, p < 0.001), but not moderate minutes compared to control. Participation in strength was not statistically different. HIIT participation was also associated with greater improvement on math test scores (β=1.52, p=0.04). No condition was associated with significant changes to behavioral ratings. **CONCLUSION:** Preliminary evidence from this study highlights the potential for embedding an acute HIIT program within PE for improving physical activity levels and academic outcomes in elementary school children. This is consistent with prior studies which show how short bouts of intense exercise can improve cognitive and mental health outcomes in adolescent populations.

 (No relevant relationships reported)

Prediabetes is a highly prevalent precursor to type 2 diabetes, and is also associated with an increased risk of morbidity and mortality. Resistance exercise (RE) is an effective method of reducing cardiometabolic risk factors in persons with a diagnosis of type 2 diabetes, but its efficacy in individuals with prediabetes is unclear. Determining the cardiometabolic impact of RE in prediabetes is necessary for evidence-based exercise prescription for diabetes prevention. **PURPOSE:** To undertake a systematic review and meta-analysis of randomized and non-randomized control trials examining the effect of RE on cardiometabolic risk factors in individuals with prediabetes. **METHODS:** PubMed, Cochrane, Web of Science, and Embase databases were searched for published studies of adults at risk for diabetes and who participated in a RE intervention. All studies included randomized or non-randomized control trials. The database search and data extraction were performed by two separate reviewers. A systematic review and meta-analysis were conducted to determine changes in adiposity, glycemic control, insulin resistance, blood lipids/lipoproteins, and blood pressure (BP) following the interventions using a random effects model to assess standardized mean differences (SMD) between RE and control. **RESULTS:** 10 studies comprising 404 participants were included in the analysis. For RE compared to controls, there were significant improvements in glycosylated hemoglobin (SMD = -0.688; 95% confidence interval [CI] -1.178 to -0.198; p=0.006), fasting plasma glucose (SMD = -0.747; 95% CI -1.003 to -0.460; p<0.001), and total cholesterol (SMD = -0.723; 95% CI -1.177 to -0.27; p=0.002). No changes in waist circumference (SMD = -0.232, 95% CI -.526 to 0.062; p=0.122), insulin resistance (SMD = -0.597, 95% CI -1.65 to 0.457; p=0.267), high-density lipoprotein (SMD = -0.287, 95% CI -0.748 to 0.174; p=0.223) or low-density lipoprotein (SMD = -0.398, 95% CI -1.027 to 0.231; p=0.215) cholesterol, triglycerides (SMD = -0.400, 95% CI -0.850 to 0.050; p=0.081), systolic BP (SMD = -0.16, 95% CI -0.491 to 0.158; p=0.315), or diastolic BP (-0.476, 95% CI -1.05 to 0.105; p=0.108) were found. **CONCLUSION:** RE appears to be an effective method of improving glucose control, but is less effective in improving blood lipids or blood pressure.

Baseline Cardiac Autonomic Predictors Of Blood Pressure Response To Standardized Endurance Training In Hypertensive Women

Marina Livia Venturini Ferreira, Alex Castro, Silas Gabriel Oliveira Nunes, Rafael Rezende Ferreira, Cláudia Regina Cavagliari, Mara Patricia Traina Chacon-Mikahil. *UNICAMP, Campinas, Brazil.*
Email: marina.lvferreira@gmail.com
(No relevant relationships reported)

Although international recommendations corroborate the antihypertensive effects of regular endurance training (ET), interindividual responses are widely heterogeneous, differing between responders (RE) and non-responders (NR). Previous studies have shown the decrease in the activity of the autonomic nervous system (ANS) is involved in the ET-induced reduction of blood pressure (BP). However, it is not yet known whether this mechanism is related to the variability of BP response. **PURPOSE:** Associate baseline ANS variables with interindividual BP responses in hypertensive women undergoing ET.

METHODS: Forty-four women performed 12 weeks of ET on cycle ergometer (50 min.day⁻¹, 3 days.week⁻¹ at 60-70% heart rate reserve). Pre and post ET 20 min beat-to-beat BP waveforms were recorded by finger photoplethysmography and ANS was assessed by heart rate (HR) variability (HRV) recorded from HR monitor and analyzed in the time and frequency domain. Participants were identified as RE by a magnitude of reduction in systolic BP (SBP) greater than the typical error (TE) of measurement (1xTE=7.4 mmHg) and participants with changes less or increase greater than 1xTE as NR. Associations between baseline HRV variables and changes (Δ) in BP after ET were analyzed using Pearson's correlation coefficient and multiple linear regression. Student's t-test to comparisons RE vs. NR. Receiver operator characteristic (ROC) curve to identify predictors cut-off values for RE and NR discrimination.

RESULTS: Ten individuals were considered RE (Δ=15.6±7.6 mmHg) and 34 NR (Δ=4.3±7.9 mmHg). SBP changes were correlated with: SDNN (r=0.395; p=0.008), RMSSD (r=0.384; p=0.010), LF (r=0.318; p=0.036) and HF (r=0.348; p=0.02). SDNN was able to predict 15.6% of variance in SBP changes (β=0.39, p=0.008). Compared to RE, NR demonstrated greater SDNN (29.6±21.4 vs. 16.1±4.9, p=0.09), RMSSD (32.7±27.3 vs. 17.4±8.6, p=0.013) and LF (591±1380 vs. 110±71, p=0.001) and HF (668±1340 vs. 154±164, p=0.012). For SDNN, a cut-off value of 18.7 discriminated RE and NR with good accuracy (AUC=0.81, sensitivity=80%, specificity=76%, p=0.03).

CONCLUSION: Baseline cardiac autonomic function can predict interindividual SBP responses to ET. Predictors cut-off values could be used to determine whether patients with hypertension are likely to benefit from ET.

Vascular Function Following An Acute Mental Stressor Among Fit Versus Non-fit Young Adults

Gabriel Zieff, Mohammod Alzer, Anthony Kostov, Simon Wahba, Jesse Rackley, Jade Blackwell, Jake Diana, Erik Hanson, Lee Stoner, FACSM. *The University of North Carolina at Chapel Hill, Chapel Hill, NC.* (Sponsor: Lee Stoner, FACSM)
(No relevant relationships reported)

Purpose: Acute mental stress impairs vascular function. The purpose of this study was to investigate if stress-induced vascular impairment is moderated by physical fitness. **Methods:** Nineteen young, healthy adults (21.6±2.7 y, 23.9 ± 3.1 kg/m², 10 F) were classified as fit (n=11) or non-fit according to ACSM physical activity guidelines (75 min vigorous, or 150 min moderate-intensity aerobic exercise). Across two randomized visits, subjects underwent an experimental (stress) and control (non-stress) testing session. A five-min mental arithmetic task was given to induce stress in the experimental session following baseline measurements. Measurements were taken throughout the 60 mins after the stress/control period. Measures included central blood pressure (cSBP), augmentation index (AIx), and brachial-radial pulse wave velocity (PWV). Mixed linear models were used to perform statistical analyses, covarying for baseline measures. **Results:** There was a significant fitness x condition interaction for AIx (p=0.038), such that the greatest AIx of fit individuals following stress exposure

was 3.3 percentage points less than non-fit individuals (95% CI -1.29, -0.09, d = -1.34). There was no interaction of fitness and condition on PWV (p=0.785; 95% CI -0.18, 0.16), but there was an inconclusive effect of fitness (p=0.143), such that fit individuals had a PWV 0.37 m/s less than non-fit individuals (CI: -0.27, 0.04; d=-0.43). For cSBP, there was no fitness x condition interaction (p=0.653; 95% CI: -1.14, 1.83), but there was a main effect of condition (p=0.045) where, regardless of fitness, stress elicited a 3.05 mmHg greater increase in cSBP after the stressor compared to the non-stress condition (95% CI 0.01, 3.06; d=0.69). **Conclusion:** Fitness was associated with a healthier wave reflection profile following a stressor, as well as better overall vascular function. These adaptive effects of fitness on hemodynamic and vascular measures ensued despite stress-induced increases in cSBP occurring regardless of fitness status.

Cardiorespiratory Fitness And Aortic Hemodynamics Are Associated With Brain Volume In Healthy Older Adults

Kathleen B. Miller¹, Anna J. Howerly¹, Adam T. Corkery¹, Marlowe W. Eldridge², Awni Al-Subu², Jill N. Barnes, FACSM¹.
¹University of Wisconsin - Madison, Madison, WI. ²University of Wisconsin - Madison School of Medicine and Public Health, Madison, WI.
(No relevant relationships reported)

Cardiorespiratory fitness (CFR) is positively associated with greater brain volume in older adults; however, the mechanism is unknown. Improved structure and function of the large vessels supplying the brain due to habitual exercise may explain why CFR influences brain volume. **PURPOSE:** The purpose of this study was to determine if aortic hemodynamics modify the association between CFR and brain volume in both young and older adults. **METHODS:** Young (YA; n=27, age =25±5 y, women =15) and older (OA; n =23, age =64±5 y, women =11) healthy adults ranging from sedentary to exercise trained were studied. CFR was assessed using an incremental maximal exercise test on a cycle ergometer (VO₂max). Total brain volume (gray matter + white matter) was determined using a T1 weighted scan on a 3T MRI scanner. Aortic hemodynamics were obtained from applanation tonometry (SphygmoCor) where the aortic pressure waveform was used to calculate aortic augmentation index (AIx). **RESULTS:** Young adults had a larger total brain volume (YA; 1.16±0.02 l vs. OA; 1.10±0.02 l, p<0.05), higher VO₂max (YA; 40±1 ml/kg/min vs. OA; 32±2 ml/kg/min, p<0.05), and lower AIx (YA; 2.9±2.5 % vs. OA; 19.2±2.4 %, p<0.05) compared with older adults. VO₂max was not associated with AIx in young adults (p>0.05); however, VO₂max was negatively associated with AIx in older adults (r =-0.61, p<0.05) such that older adults with higher CFR demonstrated lower aortic hemodynamics. There were no associations between VO₂max, AIx, and total brain volume in young adults (p>0.05 for all). Conversely, both VO₂max (r =-0.51, p<0.05) and AIx (r =-0.64, p<0.05) were associated with total brain volume in older adults. When VO₂max and AIx were entered into the model using multiple linear regression, VO₂max was no longer a significant predictor of total brain volume in older adults (VO₂max; p =0.41, AIx; p =0.03). **CONCLUSIONS:** High CFR and low aortic hemodynamics are associated with larger total brain volumes in older adults. Using multiple linear regression, aortic hemodynamics are a better predictor of total brain volume than CFR in older adults. Improved aortic hemodynamics may be a mechanism by which habitual exercise protects the brain from age-related volume decline. Supported by NIH grant HL118154.

Acute Adolescent Concussion: Cerebrovascular Reactivity, Symptom Burden, And Exercise Response

Stacey E. Aaron¹, David R. Howell², Erin D. Ozturk¹, Rebecca Daniels³, Danielle Hunt³, J. W. Hammer⁴, J. Andrew Taylor¹, William P. Meehan III³, Can Ozan Tan¹. ¹Harvard Medical School, Cambridge, MA. ²University of Colorado School of Medicine, Aurora, CO. ³Boston Children's Hospital, Boston, MA. ⁴Spaulding Rehabilitation Hospital, Cambridge, MA.

(No relevant relationships reported)

Cerebral vasoreactivity (CVR) disruptions have been observed following concussion, which may exacerbate concussion-related symptoms. These CVR disruptions may also influence the cerebral blood flow (CBF) responses during aerobic exercise and thus limit exercise capacity post-concussion. **PURPOSE:** To examine the relationships between concussion-related symptoms, cerebral vasculature's ability to respond to changes in CO₂ (vasoreactivity), and CBF responses during sub-maximal aerobic exercise in adolescents post-concussion. **METHODS:** Adolescents less than two weeks post-concussion completed the Post-Concussive Symptom Checklist (PCSC), cerebral vascular assessments, and a modified YMCA exercise protocol. CVR at rest was estimated from the slope (cm/s/mmHg) of the relationship between the increases in breath-by-breath end-tidal CO₂ and responses of CBF velocity during an air rebreathing task (i.e., increasing end-tidal CO₂). CBF velocity was measured

via transcranial Doppler ultrasonography at the M1 segment of the middle cerebral artery unilaterally during the air rebreathing task and during the aerobic exercise test. Only physical and vestibular-related symptoms were included in analysis: headache, nausea, balance problems, dizziness, fatigue, and % activity level. Two stepwise linear regressions were conducted to test (1) if concussion symptoms are related to CVR and (2) if CVR predicted relative change in CBF velocity during the aerobic exercise test. **RESULTS:** The majority of the variance in CVR was explained by symptoms of nausea, dizziness, as well as current physical activity levels. Age, sex, resting heart rate, balance, and fatigue also contributed to a lesser degree. Exercise caused a significant increase in MCA blood flow ($p < 0.001$). This exercise induced increase in CBF was largely explained by CVR and estimated $\dot{V}O_2$ peak, with resting heart rate, prior concussion(s), and time since injury also contributing. **CONCLUSIONS:** Our findings suggests that symptom burden is related to disruptions in CVR in adolescents in the early weeks after a concussion. In turn, the cerebral blood flow response to exercise was related to both CVR and aerobic capacity, suggesting that disruptions in CVR may impact exercise tolerance post-concussion.

Potential Racial Disparity In Peripheral Vascular Function Regardless Of Menstrual Cycle Phase

Michele N. D'Agata¹, Alexandra E. Hirt¹, Elissa K. Katulka¹, Felicia R. Berube¹, Megan M. Wenner¹, Sushant M. Ranadive², Melissa AH Witman¹. ¹University of Delaware, Newark, DE. ²University of Maryland, College Park, MD.
(No relevant relationships reported)

African American women (AAW) have the highest rates of cardiovascular disease (CVD) across the lifespan compared to women of other races. Vascular dysfunction is a non-traditional risk factor for CVD and is understudied in AAW. Previous studies have reported fluctuations in vascular function across the menstrual cycle (MC) with the changing levels of estrogen, but this relation has never been explored in the context of race. **PURPOSE:** To compare nitric oxide-mediated peripheral vascular function across 3 phases of the MC between AAW and CW using passive leg movement (PLM). **METHODS:** PLM was performed on premenopausal, healthy, female participants not using hormonal contraceptives; 7 AAW (24 ± 2 years, BMI: 21.2 ± 1.4 kg/m², BP: 112 ± 3/74 ± 3 mmHg) and 12 CW (23 ± 1 years, BMI: 23.4 ± 0.9 kg/m², BP: 113 ± 2/70 ± 2 mmHg). Phases of the MC were identified as early follicular (EF) (1-5 days post onset of menstruation; low estrogen), ovulation (OV) (within 1-3 days of luteinizing hormone surge determined by an ovulation test; high estrogen), and mid-luteal (ML) (8-10 days post ovulation; moderate estrogen). Blood velocity and diameter of the femoral artery were measured using Doppler ultrasound. A 2x3 repeated measures ANOVA was used to identify differences in vascular function between AAW and CW across 3 phases of the MC. **RESULTS:** The overall change in leg blood flow from baseline to peak (mL) was significantly lower among AAW compared to CW across the MC phases. EF (AAW: 195 ± 49, CW: 356 ± 64), OV (AAW: 156 ± 47, CW: 451 ± 102) and ML (AAW: 224 ± 65, CW: 369 ± 41) ($p = 0.02$). The hyperemic response to PLM, calculated as area under the curve (mL), was significantly reduced in AAW compared to CW across the MC phases. EF (AAW: 45 ± 21, CW: 131 ± 40), OV (AAW: 49 ± 28, CW: 144 ± 40) and ML (AAW: 67 ± 22, CW: 130 ± 26) ($p = 0.03$). **CONCLUSION:** AAW are experiencing an attenuated peripheral vascular response to PLM compared to CW across the menstrual phases. These preliminary data suggest an overall race-derived disparity in peripheral vascular function regardless of MC phase in young premenopausal women.

In overweight/obese adults, frequent interruptions to sitting time by brief activity bouts can mitigate the impairment of vascular function. However, it is unknown whether the

benefits extend to those with type 2 diabetes (T2D), and whether there is an optimal frequency of activity break. **PURPOSE:** To examine the acute effects on vascular function in those with T2D, of interrupting sitting time with simple resistance activities (SRAs): 3min every 30min; or, 6min every 60min.

METHODS: In a randomised crossover trial, 20 sedentary adults with T2D and overweight/obesity (35-70 yr; 11 males; 9 females) completed three 7-hour conditions (6-14 day washout between conditions): 1) uninterrupted sitting (SIT); 2) sitting with 3-min bouts of SRA every 30 min (SRA3); and, 3) sitting with 6-min bouts of SRA every 60 min (SRA6). Shear rate, blood flow and femoral artery flow-mediated dilation (FMD) were measured at 0h, 1h, 3.5h, 4.5h, 6.5h. Mixed models examined effects of condition and condition-by-time interactions, with adjustment for age, sex, BMI, baseline measurements and treatment order. Post-hoc analyses compared vascular measurements at individual timepoints and were re-run with adjustment for multiple comparisons (Šidák correction).

RESULTS: Mean (±SD) resting shear rate across timepoints was significantly lower in the SIT condition ($32.2 \pm 23.3 \text{ s}^{-1}$) relative to SRA3 ($42.2 \pm 27.9 \text{ s}^{-1}$, $P_{\text{Condition}} < 0.0001$) and SRA6 ($44.6 \pm 29.1 \text{ s}^{-1}$, $P_{\text{Condition}} < 0.0001$). Mean (±SD) resting blood flow, was significantly lower in the SIT condition ($64.7 \pm 45.2 \text{ ml/min}$), relative to SRA3 ($86.1 \pm 77.5 \text{ ml/min}$, $P_{\text{Condition}} < 0.0001$) and SRA6 ($85.0 \pm 61.7 \text{ ml/min}$, $P_{\text{Condition}} < 0.0001$). There were no condition differences in the temporal change in femoral artery FMD measurements across the 7h day ($P_{\text{time} \times \text{condition}} > 0.05$ for all). However, FMD was significantly lower at the 6.5h timepoint in SIT compared with SRA3 ($2.8 \pm 3.5\%$ vs $5.3 \pm 2.7\%$, $P = 0.0007$).

CONCLUSIONS: The results demonstrate that when the volume of activity is the same, one activity break per hour is just as effective as two activity breaks per hour for increasing lower-limb blood flow and shear rate. Interrupting sitting twice per hour was also beneficial for FMD at the final reading, however changes between sitting and activity breaks remained relatively unchanged at earlier timepoints.

The Ascending Aortic Function In Elite Endurance Athletes: An Mri Study

Takashi Tarumi¹, Takayuki Yamabe¹, Marina Fukuie¹, Ryota Kimura², Keigo OHYAMA-BYUN², Seiji Maeda², Jun Sugawara¹. ¹National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan. ²University of Tsukuba, Tsukuba, Japan.
(No relevant relationships reported)

High-intensity chronic endurance training has chronotropic and inotropic effects on the heart; however, adaptations of the ascending aorta which is directly exposed to cardiac pulsations remain unclear. **PURPOSE:** We investigated the functional and structural properties of the thoracic aorta, including the ascending and descending locations, in elite endurance athletes. **METHODS:** Fourteen young endurance-trained men (21 ± 1 years, peak oxygen uptake = 69.6 ± 3.1 ml/kg/min) were compared with 19 sedentary control men (21 ± 2 years). The ascending and descending aortic cross-sectional areas were measured by 2D CINE phase-contrast magnetic resonance imaging (MRI), and the aortic strain, compliance, and distensibility were calculated. Aortic blood pressure was measured during MRI using the general transfer function method. Two-way mixed analysis of variance was used to determine the effects of exercise status and aortic locations. **RESULTS:** Endurance athletes had similar body mass index and aortic blood pressures to sedentary control subjects. At rest, heart rate was slower (58 ± 9 vs. 48 ± 5 bpm, $P = 0.001$) and stroke volume was greater in athletes (82.1 ± 10.8 vs. 95.8 ± 18.5 ml/beat, $P = 0.012$) while cardiac output was similar between the groups. The systolic aortic cross-sectional areas were increased in athletes compared with sedentary subjects (ascending: 6.32 ± 0.99 vs. $6.95 \pm 1.00 \text{ cm}^2$, descending: 4.08 ± 0.64 vs. $4.85 \pm 0.83 \text{ cm}^2$, $P = 0.012$). The diastolic aortic areas ($P = 0.062$) and the aortic compliances ($P = 0.069$) showed a trend of elevations in athletes. The greater ascending aortic strain and compliance were associated with slower heart rate ($r = -0.56$ and -0.43 respectively) and higher stroke volume ($r = 0.44$ and 0.35 respectively) across all participants (all $P < 0.05$). **CONCLUSIONS:** Our findings suggest that endurance athletes have dilated thoracic aorta and better recoiling function of the ascending aorta due to increased systolic expansion and a longer time of relaxation with slower heart rate.

Vascular Dysfunction In The Lower Limbs Of Young Black Males: Evidence From Passive Leg Movement

Stephen J. Ives¹, Meaghan Lynch¹, Brian Lora¹, Tawn Tomasi¹, Gaia Giuriato², Emma Basso¹, Emma Finegan¹, Jack Schickler¹, Massimo Venturelli², Robert Restaino¹. ¹Skidmore College, Saratoga Springs, NY. ²University of Verona, Verona, Italy. Email: sives@skidmore.edu

(No relevant relationships reported)

Cardiovascular morbidity and mortality rates are highest among Black Americans, the mechanisms of which remain elusive. While it has been postulated that exaggerated autonomic reflexes or responsiveness could contribute to elevations in baseline or exercise blood pressure, increasing CVD risk, no studies have explored the movement-induced changes in hemodynamics. **PURPOSE:** Using passive leg movement (PLM), as model of the mechanoreflex (a component of the exercise pressor reflex) and an assessment of lower limb vascular function, the aim of this study was to compare the central and peripheral hemodynamic responses in young healthy Black (BA) and White Americans (WA). **METHODS:** Young (21±4 yr) healthy BA (n = 9) and WA (n = 10) males were instrumented with continuous central hemodynamic monitor (Finger Photoplethysmography), while peripheral hemodynamics were monitored using frequency domain multi-distance near infrared spectroscopy (NIRS) of the vastus lateralis, and ultrasound Doppler of the common femoral artery. After 1 minute of baseline, subjects underwent continuous PLM at 1 hz for two minutes, while tissue oxygen saturation (StO₂), leg blood flow (LBF), cardiac output (CO), heart rate (HR), stroke volume (SV), and mean arterial pressure (MAP) were recorded. **RESULTS:** Resting HR (61±3 vs. 62±3 beats/min), SV (89±5 vs. 92±5 ml/beat), CO (5.4±0.4 vs. 4.4±0.5 L/min), and MAP (92±5 vs. 86±3 mmHg) were not different between BA and WA, respectively (all, p>0.05). The peak PLM-induced changes in HR (6±2 vs. 11±3 Δbeats/min, p = 0.06), SV (7.3±1.6 vs. 11.4±1.9 Δml/beat, p = 0.04), and CO (0.7±0.2 vs. 1.0±0.2 Δl/min, p = 0.09), while MAP (5.3±1.4 vs. 6.0±0.8 ΔmmHg, p > 0.05) was not different. The peak PLM-induced change in StO₂ was significantly attenuated in BA (1.6±0.5 vs. 3.8±0.4 Δ%, p = 0.01). **CONCLUSION:** This research provides novel insights into potential racial differences in mechanoreflex sensitivity and lower limb vascular function. Black American men had an attenuated mechanoreflex response to PLM as compared to White American men; however, Black Americans also had a lower peripheral hemodynamic response, perhaps suggestive of lower limb vascular dysfunction, which might explain a propensity towards greater peripheral vascular disease rates in Black Americans.

The Effects Of 16-weeks Of Exercise Training On Neutrophil Functions In Breast Cancer Survivors

Grace A. MacDonald¹, David B. Bartlett¹, Erik D. Hanson², William S. Evans², Jordan T. Lee², Chad W. Wagoner², Eli Hanson², Paige Harrell², Stephanie Sullivan², Kirsten A. Nyrop², Hyman B. Muss², Brian C. Jensen², Claudio L. Battaglini, FACSM². ¹Duke University, Durham, NC. ²University of North Carolina, Chapel Hill, NC. (Sponsor: Claudio Battaglini, FACSM)

(No relevant relationships reported)

PURPOSE: Following therapy, breast cancer survivors have impaired immune functions which are associated with increased risk of recurrence and infectious diseases. Neutrophils are critical to host protection against infectious diseases. The aim of this study was to use acute exercise as an immunological stressor before and after 16-weeks of exercise training to determine changes in neutrophil functions consistent with a reduced infection risk.

METHODS: 16 breast cancer (BC) survivors completed 45 minutes of intermittent cycling at 60% of peak CPX wattage before (BASE) and after 16-weeks (FINAL) of exercise training. Eleven healthy sedentary women (Control) completed the same acute bout of exercise at BASE. Blood was taken at rest (PRE), immediately after (POST) and 1 hour after (1Hr POST) exercise. Neutrophil phagocytosis and oxidative killing of *E. coli*, and expression of CD16, CXCR2 and TLR4 were assessed by flow cytometry (MFI ± SD).

RESULTS: Compared to Controls, at BASE PRE, BC survivors had lower phagocytosis of bacteria (4250±718 v 3991±1232; p=0.03), and elevated oxidative burst (4495±651 v 6254±1434; p=0.005). At BASE, BC survivors' phagocytic response to acute exercise was impaired. BC survivors PRE to POST phagocytosis was unchanged (p=0.224) while Controls increased 15±20% (p=0.003). BC survivors PRE to 1Hr POST phagocytosis increased by 10±17% (p=0.046) while Controls increased 14±14% (p=0.003). Following training, BC survivor PRE phagocytosis increased from BASE to FINAL by 10% (p=0.08), to similar levels as Controls (p=0.765). BC survivors FINAL PRE to POST phagocytosis increased by 10% (p=0.001) and PRE to 1Hr POST by 11% (p=0.008). Oxidative killing of bacteria was unchanged by acute exercise or exercise training. At BASE, BC survivor expression of CD16 reduced during acute exercise, PRE to 1Hr POST by 9% (p=0.04) which annulled following training.

CONCLUSIONS: Following cancer therapy, BC survivors have impaired neutrophil functions at rest and to a stressor, which are improved by 16-weeks of exercise training. The improved phagocytosis of bacteria in BC survivors may represent an intrinsic improvement in neutrophil functions consistent with reduced risk of infectious disease. *Supported by Breast Cancer Research Foundation (New York, NY).*

Stress-related Genetic Variants Modulate Electrodermal Response To Maximal Exercise

Lisa M. Hernández¹, D. Christine Laver², Marcus K. Taylor, FACSM². ¹Leidos, Inc./Naval Health Research Center, San Diego, CA. ²Innovative Employee Solutions/Naval Health Research Center, San Diego, CA. ³Naval Health Research Center, San Diego, CA. (Sponsor: Marcus K. Taylor, FACSM) Email: lisa.m.hernandez75.ctr@mail.mil

(No relevant relationships reported)

Previous research from our lab established electrodermal activity (EDA) as a valid, surrogate marker of sympathetic nervous system activity during treadmill exercise. We have subsequently reported dose dependent effects of aerobic fitness, combat exposure and blast exposure on the electrodermal response to acute exercise stress. **PURPOSE:** As an extension of our prior work, this study evaluated the effect of stress related genetic variants on EDA during maximal exercise in specialized military men. **METHODS:** Sixty-four male (age = 34.2±7.0 yrs) Explosive Ordnance Disposal operators completed a graded exercise test to assess maximal oxygen consumption (VO_{2max}). EDA was recorded at baseline, during exercise and recovery. Percent change from baseline was calculated for stages of 25, 50, 75 and 100% VO_{2max}, and active and seated recovery. Genetic variants of catechol-o-methyltransferase (COMT), brain-derived neurotrophic factor (Val66Met) and serotonin transporter (5HTTLPR) were determined from saliva. Combination groups of 2 (COMT + Val66Met) or 3 (COMT + Val66Met + 5HTTLPR) variants (2 or 3GCOM) were created and divided into "low" and "high" EDA groups. A 2 or 3 (GCOM) x 6 (STAGE) repeated measures ANOVA evaluated EDA changes across stages for 2 or 3GCOM groups, separately. **RESULTS:** All GCOM groups showed linear increases in EDA percent change throughout exercise. Low 2GCOM response peaked at 75% VO_{2max} and plateaued in recovery. High 2GCOM had a larger change, peaked at 100% VO_{2max} then declined in recovery. There was a borderline main effect of 2GCOM (p=.06, η_p²=.108) and a main effect of STAGE (p<.001, η_p²=.183). Low 3GCOM had a similar pattern as low 2GCOM, but on a smaller scale. High 3GCOM demonstrated the largest change in magnitude, peaked at 100% VO_{2max} and sharply declined in recovery. There was a 3GCOM x STAGE interaction effect (p<.001, η_p²=.352). **CONCLUSION:** When combined, genetic variants implicated in the human stress response modulate EDA during and after maximal exercise. Influence of COMT was expected, as EDA is a proxy of plasma catecholamine levels during exercise. Val66Met and 5HTTLPR have been shown to modulate exercise responses and cardiovascular reactivity, respectively. Future work will comprehensively evaluate biobehavioral characteristics and genetic variants in this sample.

(No relevant relationships reported)

PURPOSE: Asthma is a chronic airway inflammatory disease affecting more than 300 million people around the world. Purinergic signaling via purinergic receptors (mainly P2X7, P2Y2 and P2Y6) are thought play a key role in asthma pathogenesis and severity. High intensity aerobic exercise is known to trigger asthma attacks, while low to moderate intensity training reduces inflammation and improves asthma control. Therefore, this study investigated whether low intensity aerobic exercise reduces asthma phenotype by modulation of purinergic signaling. **METHODS:** Aerobic exercise (AE) was performed in a treadmill at low intensity, 5x/week, 1h/session, for 4 weeks, beginning 2 weeks after HDM administration. HDM (*dermatophagoides pteronyssinus*; 100mg/mouse) was administered 3x/week, for 6 weeks. **RESULTS:** The results demonstrated that AE reduced adenosine triphosphate (ATP) accumulation ($p < 0.001$), IL-1 β , IL-4, IL-5, CXCL1/KC, IL-13, IL-17, IL-23, IL-33 and TNF- α ($p < 0.001$), while increased IL-1ra, IL-2, IL-10 and IL-12p40 in bronchoalveolar lavage (BAL). Total number of leukocytes, eosinophils, lymphocytes and neutrophils in BAL and the number of eosinophils, neutrophils and lymphocytes in the airway wall ($p < 0.01$) were reduced by AE. Airway remodeling (collagen, elastin, smooth muscle and mucus) were reduced by AE ($p < 0.01$). TGF- β , IGF-1 and VEGF levels was reduced by AE ($p < 0.001$). Lung mechanics (Resistance, Elastance, GTIS, HTIS, RAW) and airway hyperresponsiveness (AHR) to methacholine was ameliorated by AE ($p < 0.01$). IL-4, IL-5 and IL-13 production by re-stimulated mediastinal lymph nodes, splenocytes and bone marrow cells was also reduced by AE. The expression of P2X7, P2Y2 and P2Y6 by peribronchial leukocytes ($p < 0.01$) and also by airway epithelial cells ($p < 0.01$) were reduced by AE. **CONCLUSIONS:** Low intensity aerobic training reduces asthma phenotype by inhibiting purinergic signaling and lymphoid organs hyperactivation.

The Immune Response To Cardiorespiratory Exercise Testing In Heart Failure Patients With Reduced Ejection FractionMartin Bahl¹, Aycen Koc², Sabine Kaczmarek¹, Kristin Lehnert¹, Ines Urbaneck¹, Ulf Landmesser², Stephan B. Felix¹, Marcus Dörr¹, Nicolle Kränkel². ¹University Medicine Greifswald, Greifswald, Germany. ²Charité Campus Benjamin Franklin, Berlin, Germany.

(No relevant relationships reported)

PURPOSE: Long-term exercise training reduces systemic inflammation in heart failure patients. However, due to the impaired immune system in these patients, an acute exercise challenge may trigger pro-inflammatory responses. We compared the acute response to a standardized cardiopulmonary exercise test (CPET) in patients with heart failure with reduced ejection fraction (HFrEF) to age and gender matched controls.

METHODS: Patients with HFrEF (n=13; left ventricular ejection fraction [LVEF] < 40%) and controls (n=14, LVEF > 50%) participated in a CPET. Blood samples were taken before, immediately after and 2 hours after CPET. Flow cytometry was used to assess quantitative and morphological alterations in leukocyte subpopulations as well as the formation of leukocyte-platelet aggregates. Only significant findings are reported ($p < 0.05$) and are given as median and inter-quartile range (IQR).

RESULTS: HFrEF (mean LVEF: 36%) and controls (mean LVEF: 57%) were 59 (range: 41 to 80) and 57 (range: 50 to 65) years old, respectively. CPET increased the leukocyte (control: 1.37-fold [IQR: 1.16 to 1.49]; HFrEF: 1.24-fold [IQR: 1.20 to 1.32]), natural killer (NK) cell (controls: 2.11-fold [IQR: 1.30 to 3.13]; HFrEF: 1.67-fold [IQR: 1.56 to 1.71]) and NK-T cell (control: 1.69-fold [IQR: 1.52 to 3.60]; HFrEF: 1.62-fold [IQR: 1.60 to 2.53]) concentration in the HFrEF and control group. CD4+ cells (control: 1.15-fold [IQR: 0.84 to 1.54]; HFrEF: 1.45-fold [IQR: 1.10 to 1.98]) and CD8+ T-cells (control: 1.33-fold [IQR: 1.01 to 1.68]; HFrEF: 1.70-fold [IQR: 1.25 to 2.15]) only increased in HFrEF patients. Aggregation of thrombocytes with monocytes (control: 0.86-fold [IQR: 0.78 to 1.49]; HFrEF: 1.59-fold [IQR: 1.05 to 7.30-fold]), T-lymphocytes (control: 1.27-fold [IQR: 1.05 to 1.68]; HFrEF: 1.49-fold [IQR: 1.03 to 2.64]) and neutrophils (control: 1.08-fold [IQR: 0.87 to 1.25]; HFrEF: 2.13-fold [IQR: 1.62 to 2.19]) increased 2 hour post CPET in patients with HFrEF, but not in controls.

CONCLUSIONS: CPET differentially induced specific immune responses in patients with HFrEF compared to age and gender matched controls. The prolonged immune response in these patients suggests differences in immune resolving mechanisms which deserve further research.

Mitochondrial Characteristics Of Adaptive Immune Cells Associated With Aerobic Fitness

Jessica Alley, Connor McGinness, Josh Borwick, Rudy Valentine, Marian Kohut. Iowa State University, Ames, IA.

(No relevant relationships reported)

Recent findings in immunometabolism have demonstrated that the function of immune cells is largely dictated by their metabolism, with mitochondrial characteristics reflecting distinct metabolic phenotypes. A limitation of previous exercise immunology studies is the failure to describe the effect of exercise on specific immune cell subsets. Since exercise may have differential effects that vary by cell population according to metabolic phenotype, analyzing peripheral blood mononuclear cells as a whole may mask adaptations. **PURPOSE:** To determine the effect of aerobic training on mitochondrial characteristics of specific T cell subsets. **METHODS:** Non-smokers who self-identified as either completing more than six hours of aerobic-type exercise (ACTIVE) or less than 90 minutes of any type of physical activity (INACTIVE) per week were recruited. Blood was collected and participants returned for a later visit to complete a treadmill maximal oxygen consumption ($\dot{V}O_{2max}$) test. Mitochondrial mass and membrane potential (MMP) of CD4⁺ and CD8⁺ naïve (CD45RA⁺ CCR7⁻) and effector memory (CD45RO⁺ CCR7⁺) cells were assessed by geometric mean fluorescence intensity (gMFI) of MitoTracker Green FM and TMRE, respectively. **RESULTS:** Preliminary statistical analyses (n = 11 each group) revealed that ACTIVE had higher cardiorespiratory fitness than INACTIVE (60.0 \pm 9.9 vs. 43.6 \pm 8.2 mL/kg/min relative $\dot{V}O_{2max}$; $p = 0.0004$, independent t-test). There were no differences in cell counts between ACTIVE and INACTIVE T cell subsets. Although gMFI indicating mitochondrial mass of CD8⁺ naïve T cells approached significance between groups (594.7 \pm 127.7 ACTIVE vs. 495.4 \pm 70.9 INACTIVE; $p = 0.0355$, independent t-tests), this difference was not statistically significant after correcting for multiple comparisons. Mitochondrial mass and MMP of CD8⁺ naïve T cells were, however, significantly correlated with relative $\dot{V}O_{2max}$ ($r = 0.5375$ and 0.5343 , $p = 0.0099$ and 0.0104 , respectively, Pearson correlation). **CONCLUSION:** These preliminary data suggest that mitochondrial adaptations in certain adaptive immune cells may be associated with aerobic fitness and lay the groundwork for follow-up studies to directly evaluate differences in cellular respiration of these subsets.

Systemic β_1 -Adrenergic Receptor Blockade Augments NK-Cell Mobilization In Response To Acute Exercise In HumansKyle A. Smith¹, Nadia H. Agha², Forrest L. Baker², Austin B. Bigley², Hawley E. Kunz², Grace M. Niemi¹, Jamie N. Colombo¹, Richard A. Bond², Catherine M. Bollard³, Emmanuel Katsanis¹, Richard J. Simpson, FACSM¹. ¹University of Arizona, Tucson, AZ. ²University of Houston, Houston, TX. ³The George Washington University, Washington, DC. (Sponsor: Richard Simpson, FACSM)

(No relevant relationships reported)

PURPOSE: Recent research has demonstrated that the release of catecholamines, myokines, and the mobilization and redistribution of effector lymphocytes (e.g. NK-cells) with each bout of exercise plays a mechanistic role in the anti-tumor effects provided by regular exercise. We tested the hypothesis that blocking the β_1 -AR in vivo would increase catecholamine signaling toward the β_2 -AR to augment NK-cell mobilization in response to a single exercise bout. **METHODS:** Thirty healthy subjects (ages 22 - 43) completed a single 30-minute bout of steady state exercise on a cycle ergometer at +10 to +15% of their predetermined lactate threshold to determine the number of NK-cells mobilized to blood with exercise. Eighteen of these subjects then participated in a randomized double-blind controlled trial with a cross-over design, whereby a placebo, a non-preferential β_1 / β_2 -antagonist (80 mg nadolol), or a preferential β_1 -antagonist (10 mg bisoprolol) was ingested orally 3 hours before a 30-minute exercise bout performed on separate days. Blood samples were collected before and immediately after exercise for the enumeration of effector lymphocytes (NK-cells, $\gamma\delta$ T-cells and CD8+ T-cells) by flow cytometry. **RESULTS:** The median number of NK-cells mobilized to blood with exercise was $\Delta 524$ cells/ μ L, with those subjects below the median demonstrating a smaller epinephrine response to exercise than those above the median ($\Delta 0.05 \pm 0.03$ vs $\Delta 0.13 \pm 0.08$ ng/mL; $p < 0.05$). Larger numbers of NK-cells were mobilized with exercise in the bisoprolol trial ($\Delta 703.8 \pm 352.2$ cells/ μ L) compared to the placebo trial ($\Delta 573.9 \pm 198.1$ cells/ μ L; $p < 0.05$), both of which were larger than the nadolol trial ($\Delta 285.1 \pm 165.6$ cells/ μ L; $p < 0.05$). Bisoprolol did not augment the mobilization of $\gamma\delta$ T-cells or CD8+ T-cells relative to

placebo. 44% of subjects who mobilized less than $\Delta 524$ NK-cells/ μ L with exercise in the placebo trial were able to mobilize $>\Delta 524$ NK-cells/ μ L after ingesting bisoprolol ($n = 4$). **CONCLUSION:** Systemic β_1 -AR blockade augments NK-cell mobilization in response to acute exercise. These findings may have implications for cancer patients on cardioprotective β -blockers and also provide insights on how certain β -AR antagonists may enhance or inhibit immune responses to exercise.

121 May 27 11:15 AM - 11:30 AM

Intestinal Epithelial Cell-specific Deletion Of Hif1a Affects The Intestinal Barrier Function In High-fat Diet-fed Mice

Beibei Luo¹, Dao Xiang², Xiaoqian Huang¹, Wei Cao¹, Die Wu¹, Peijie Chen¹. ¹Shanghai University of Sport, Shanghai, China. ²Naval Medical University, Shanghai, China.
(No relevant relationships reported)

High-fat diet (HFD) feeding disrupts the intestinal barrier integrity, inducing the translocation of bacteria into the portal circulation, leading to the whole-body inflammation. Intestinal epithelial cells (IEC), producing antimicrobial proteins to prevent the attachment and entry of pathogens, are affected by the tissue hypoxia. The hypoxia-inducible factor (HIF)-1 α is pivotal in the transcriptional response to oxygen flux. **PURPOSE:** To determine the role of HIF-1 α signaling pathway in the regulation of intestinal barrier function on HFD fed mice. **METHODS:** The Villin-Cre mediated, IEC-specific deletion of *Hif1a* (*Hif1a*^{CKO}) and the control *Hif1a*^{fl/fl} mice (male, 8-week) were used in this study. The *Hif1a*^{CKO} and *Hif1a*^{fl/fl} were fed HFD (HFD-*Hif1a*^{CKO} and HFD-*Hif1a*^{fl/fl}, $n=6$ /group) or normal chow for 12 weeks. Immediately after euthanasia, the serum, abdominal fat, intestine and feces were sampled. The intestinal mucus structure was observed by the AB-PAS staining. The intestinal permeability was quantified with FITC-dextran. Fasting plasma glucose, albumin, alanine aminotransferase, aspartate aminotransferase, total bilirubin, triglycerides (TG), total cholesterol (TC), LDL cholesterol (LDL-C), and HDL cholesterol levels were measured. The fecal microbial DNA was extracted and sequenced on an Illumina MiSeq platform. Student's t-tests and one-way ANOVA were used. Differences with $P < 0.05$ were considered significant. All animal experiments were performed in compliance with and approved by the Shanghai University of Sport ethical review board. **RESULTS:** We found that HFD feeding markedly increase the intestinal permeability without significant morphological changes. Compare with HFD-*Hif1a*^{fl/fl}, the HFD-*Hif1a*^{CKO} mice were higher in the body weight (40.55 ± 3.94 vs. 35.06 ± 5.31 g, $p < 0.05$), TG (1.75 ± 0.56 vs. 1.08 ± 0.31 mmol/l, $p < 0.05$), TC (4.28 ± 0.92 vs. 3.74 ± 0.56 , $p < 0.05$) and LDL-C (0.83 ± 0.08 vs. 0.68 ± 0.14 , $p < 0.05$). Principal coordinates analysis based on unweighted UniFrac distances highlighted a clear clustering of the microbial populations of *Hif1a*^{CKO} away from that of *Hif1a*^{fl/fl}. **CONCLUSIONS:** IEC HIF-1 α signaling is involved in the intestinal barrier function maintenance in HFD fed mice. Increasing Mitochondrial Content Does Not Protect Against Disuse-induced Muscle Atrophy

Megan E. Rosa-Caldwell, Seongkyun Lim, Wesley S. Haynie, Lisa T. Jansen, Kirsten R. Dunlap, Tyrone A. Washington, Nicholas P. Greene, FACSM. University of Arkansas, Fayetteville, AR. (Sponsor: Dr. Nicholas Greene, FACSM)

(No relevant relationships reported)

Skeletal muscle mass is maintained by a balance in protein synthetic and degradative pathways. Deteriorations to skeletal muscle health can have significant implications for whole body health and quality of life. This is particularly true for disuse-associated muscle wasting, a common pathology associated with ICU stays, casting and space flight. Mitochondrial aberrations have been hypothesized to underlie these muscle pathologies, as such; improving mitochondrial content is an enticing therapeutic

target. **PURPOSE:** To investigate the sufficiency of increased mitochondrial content on mitigating disuse-induced muscle atrophy. **METHODS:** Mice overexpressing muscle PGC-1 α (PGC-1 α) and WT mice were bred at the University of Arkansas. At 10 wks of age, male and female mice (~8-10/group, ~70 mice total) underwent hindlimb unloading (HU) or normal cage activity (CON) for 7 days. Tissues were then collected, weighed and prepared for mRNA analysis of mediators of proteasomal degradation. Data for males and females were analyzed by 2X2 ANOVA with a Tukey post-hoc. **RESULTS:** In both male and female mice, overexpression of PGC-1 α was not sufficient to protect gastrocnemius, tibialis anterior, or soleus muscle atrophy (~17%, ~13%, ~27% lower muscle weights, respectively). In the gastrocnemius, *MuRF-1* mRNA content was ~2.5-fold greater in male and female WT-HU mice compared to WT-CON; however, both male and female PGC-1 α mice had ~40% less *MuRF-1* content compared to WT-CON, regardless of intervention. Correspondingly, *Atrogin1* mRNA content in the gastrocnemius was ~4-fold greater in male and female WT-HU mice compared to WT-CON; whereas both male and female PGC-1 α mice had no differences in *Atrogin1* content compared to WT-CON regardless of intervention. **CONCLUSION:** Although increased mitochondrial content appears to blunt the induction of the ubiquitin proteasomal degradation system during disuse atrophy, these blunted responses do not appear sufficient to mitigate disuse-induced muscle loss. Aging Blunts The Repeated Bout Effect In Skeletal Muscle

Cory W. Baumann, Dawn A. Lowe, FACSM. University of Minnesota, Minneapolis, MN.
Email: cbaumann@umn.edu
(No relevant relationships reported)

PURPOSE: The ability of skeletal muscle to adapt to eccentric contraction-induced injury is known as the repeated bout effect (RBE), a well-established phenomenon observed in young human and rodent muscle. It has been suggested aged muscle may lack this adaptive potential, which would limit strength gains that could be achieved through training. Therefore, the purpose of this study was to determine if the RBE is blunted in aged muscle when compared to young muscle. **METHODS:** The anterior crural muscles of young (4 mo) and aged (21 mo) female mice were subjected to repeated bouts of eccentric contractions using an *in vivo* model. Specifically, mice performed 50 maximal eccentric contractions with isometric torque being measured immediately pre- and post-injury, and 2 and 7 days into recovery. These procedures were then repeated four times (making five total bouts) with 7 days between each bout. **RESULTS:** Following the initial injury bout, isometric torque of young and aged muscle were reduced to a similar extent ($p=0.12$) and did not differ throughout recovery (2 days, $p=0.15$ and 7 days, $p=0.82$). Over the course of the next four injuries, both young and aged muscle adapted to the prior injuries, experiencing less strength deficits immediately post-injury and an enhanced rate of recovery. However, the adaptive response measured by the fifth injury was less in aged muscle, with strength improvements being only 10-15% in aged muscle while 20-32% in young muscle ($p < 0.05$). **CONCLUSIONS:** The extent of injury and ensuing rate of recovery governs how frequently and how intensely subsequent bouts can be completed. Here, we demonstrate the RBE is blunted in aged muscle compared to young muscle over the course of five injurious bouts of eccentric contractions. These data suggest there is an age-related impairment in the mechanisms underlying the RBE, which could be due to a slowed adaptation rate or a compromised ability to adapt to eccentric contractions.

Intake Of Essential Amino Acids Stimulates Mtorc1 Signaling And Inhibits Autophagy Following Glycogen-depleted Resistance Exercise

William Apró, Oscar Horwath, Jonas Granberg, Marcus Moberg, Eva Andersson, Björn Ekblom. Swedish School of Sport and Health Sciences, Stockholm, Sweden.
Email: william.apro@gih.se
(No relevant relationships reported)

Autophagy is responsible for degrading and recycling cellular proteins under conditions of energetic stress and low nutrient availability. Activation of autophagy is mediated by AMPK which is activated by high-intensity exercise and low glycogen availability and performing resistance exercise with low glycogen levels may result in enhanced autophagy activation which in turn may have negative effects on muscle protein balance. Autophagy is inhibited by mTORC1 which is potently activated by essential amino acids (EAA). The opposing effects of AMPK and mTORC1 on autophagy suggests that any potential negative effects of performing resistance exercise with low glycogen availability may be rescued by EAA intake. **PURPOSE:** To study the effect of EAA intake on autophagy and mTORC1 signaling following resistance exercise with high and low glycogen availability.

METHODS: Using a unilateral study design in which one leg was glycogen loaded and the other leg was glycogen depleted, men and women underwent two experimental trials wherein they consumed either a placebo (PLA) or an EAA drink after resistance exercise. Unilateral differences in muscle glycogen content were achieved through glycogen loading and subsequent one-legged glycogen depleting exercise the evening prior to each experimental trial. Muscle biopsies were collected at baseline, post exercise and 1 and 3 h after drink intake in both legs in both trials.

RESULTS: Mean glycogen content was ~69 % lower in the depleted leg compared to the loaded leg (228 vs 724 mmol/kg dry weight) across all time points in both trials. Phosphorylation of ULK1 at the AMPK-specific site S317 was elevated ~5-fold immediately post exercise in the depleted leg while remaining unchanged in the loaded leg with no differences between trials. In the PLA-trial, S317 phosphorylation remained elevated 60 min post drink ingestion, while in the EAA trial at the same time point, it had returned to baseline values. Phosphorylation of S6K1 at the mTORC1-specific site T389 remained largely unchanged at all time-points in the PLA-trial while being increased by ~33-fold in both legs at 60 min in the EAA-trial.

CONCLUSIONS: Intake of EAA blunt the elevations in autophagy signaling induced by resistance exercise performed in a glycogen-depleted state while simultaneously stimulating the mTORC1 pathway.

Testosterone Supplementation Upregulates Myogenesis And Attenuates Proteolytic Gene Expression During Severe Energy Deficit

Emily E. Howard¹, Lee M. Margolis¹, Claire E. Berryman², Harris R. Lieberman¹, J. Philip Karl¹, Andrew J. Young, FACSM¹, Monty A. Montano³, William J. Evans⁴, Nancy R. Rodriguez, FACSM⁵, Neil M. Johannsen⁶, Kishore M. Gadde⁶, Melissa N. Harris⁶, Jennifer C. Rood⁶, Stefan M. Pasiakos, FACSM⁶. ¹U.S. Army Research Institute of Environmental Medicine, Natick, MA. ²Florida State University, Tallahassee, FL. ³Harvard Medical School, Boston, MA. ⁴University of California at Berkeley, Berkeley, CA. ⁵University of Connecticut, Storrs, CT. ⁶Louisiana State University's Pennington Biomedical Research Center, Baton Rouge, LA. (Sponsor: Stefan Pasiakos, FACSM)

(No relevant relationships reported)

BACKGROUND: Testosterone supplementation promotes whole-body lean mass accretion during severe energy deficit in non-obese, young men. The intramuscular mechanisms mediating this effect remain undefined.

PURPOSE: Determine the effect of supplemental testosterone on androgen receptor (AR), anabolic, proteolytic, inflammatory, and myogenic pathways during energy deficit.

METHODS: Fifty men (mean ± SD; 25 ± 5 y, 25 ± 3 kg/m²) completed a 14-d weight maintenance (WM) phase, followed by a 28-d, 55% diet and exercise-induced energy deficit (ED) with 200 mg testosterone enanthate/week (TEST, n = 24) or placebo (PLA, n = 26). Muscle biopsies (vastus lateralis) from a subset (n = 10 per group) of participants exhibiting the greatest increase or decrease in leg lean mass (DEXA) and total testosterone were assayed to assess phosphorylation status, total protein and gene expression using Western blotting and RT-qPCR. Biopsies were collected at the end of WM and ED at baseline, and at 1 and 6 h after exercise (1 h cycle ergometry matched between phases for power and total work), with a mixed-meal (40 g protein) consumed following the first post-exercise biopsy.

RESULTS: Change (ED – WM) in leg lean mass (1.2 ± 0.7 vs. -0.7 ± 0.4 kg) and total testosterone concentrations (712 ± 159 vs. -193 ± 78 ng/dL) differed between TEST and PLA (*P* < 0.05). Relative to WM, baseline AR total protein was 118 % higher for TEST than PLA (*P* < 0.05) and was associated with changes in leg lean mass and fibroblast growth factor-inducible 14 (Fn14) gene expression (*r* = .540 and -.563, *P* < 0.05). Baseline Fn14 gene expression relative to WM was 52 % lower for TEST than PLA (*P* < 0.05) and tended to associate with changes in leg lean mass (*r* = -.455, *P* = 0.058). After exercise (6 h), muscle atrophy F-box and muscle ring finger-1 gene expression was lower (61 and 44 %) and MyoD expression was 122 % higher for TEST than PLA (*P* < 0.05), relative to WM. Mechanistic target of rapamycin-mediated anabolic signaling was not different between groups.

CONCLUSIONS: The hypertrophic effect of testosterone on lean mass during severe energy deficit may be due, in part, to reduced ubiquitin-mediated proteolysis and increased myogenesis after exercise and feeding, subsequent to modulation of upstream AR and Fn14 signaling. Supported by USAMRDC; authors' views not official U.S. Army or DoD policy.

Skeletal Muscle Raptor And Tsc1/2 Differential Responses To Activity And Fasting In The Tumor Environment

Jessica L. Halle¹, Dennis K. Fix², Brittany R. Counts¹, James A. Carson, FACSM¹. ¹University of Tennessee Health Science Center, Memphis, TN. ²University of South Carolina, Columbia, SC. (Sponsor: James A. Carson, FACSM)
Email: jhalle1@uthsc.edu

(No relevant relationships reported)

Cancer is a debilitating disease that is often accompanied by decreased physical activity and chronic energetic stress that disrupts muscle proteostasis. Skeletal muscle protein turnover is highly sensitive to changes in feeding and activity. Raptor serine 792 and TSC1/2 serine 1387 phosphorylation sites, when activated, can inhibit mTORC1 activation leading to suppressed anabolic signaling, and has been implicated in the regulation of skeletal muscle wasting with cancer. **Purpose:** To examine the effect of a 12-hour fast on the phosphorylation of Raptor and TSC1/2 in male *Apc^{Min/+}* mice, and if voluntary wheel activity can alter the fasting response. **Methods:** Male C57BL/6 (B6, N=24) and *Apc^{Min/+}* (MIN, N=31) mice were either sacrificed under *ad libitum* conditions (B6-fed, M-fed), fasted for 12hrs (B6-fast, M-fast), or fasted for 12hrs following 4wks of voluntary wheel running (B6+W, M+W). TSC1/2 serine 1387 and Raptor serine 792 were measured in the gastrocnemius muscle as phosphorylation to total ratio by western blot. Protein synthesis was measured by puromycin incorporation. **Results:** All MIN mice exhibited body weight loss (*p* < 0.001) and reduced gastrocnemius mass (*p* < 0.001) when compared to all B6 mice. Raptor phosphorylation (pRaptor) was induced in M-fast compared to M-fed (*p* = 0.019), but there was no change in B6+fast compared to B6-fed (*p* = 0.414). TSC1/2 phosphorylation was induced in M-fast compared to M-fed (*p* = 0.001) and in B6-fast to B6-fed (*p* = 0.039). Puromycin was trending to be reduced in M-fast compared to MIN-fed (*p* = 0.070), but there was no change in B6-fast to B6-fed (*p* = 0.323). Raptor phosphorylation was not different in M-fast compared to M+W (*p* = 0.302), however pRaptor was reduced in B6+W compared B6-fast (*p* = 0.028). TSC1/2 phosphorylation (*p* = 0.001) and puromycin (*p* = 0.016) were induced in MIN+W compared to M-fast, with no changes in the B6-fast to B6+W (*p* = 0.360, *p* = 0.196; respectively). **Conclusions:** Our results provide evidence that the cancer environment disrupts anabolic suppression of mTORC1 in skeletal muscle. Interestingly, TSC1/2 phosphorylation was sensitive to fasting independent of the tumor environment. Wheel activity induced protein synthesis independent of Raptor phosphorylation therefore, further studies are warranted to determine this specific mechanism.

Effects Of Lactate Infusion On Resistance Exercise Induced MTORC1-signaling And Protein Synthesis In Human Muscle

Marcus Moberg¹, William Apró¹, Hans-Christer Holmberg², Gerrit van Hall³, Björn Ekblom¹. ¹Swedish School of Sport & Health Sciences, Stockholm, Sweden. ²Swedish Winter Sports Research Centre, Östersund, Sweden. ³Clinical Metabolomics Core Facility, Copenhagen, Denmark.

Email: marcus.moberg@gih.se

(No relevant relationships reported)

Lactate has recently been highlighted as a potential signaling molecule. In myotubes, lactate incubation increase mTORC1-signaling, reduce myostatin expression and induce myotube growth. This indicates that lactate could be a potential mediator of muscle adaptations to resistance exercise. **PURPOSE:** Here we wanted to study the acute molecular response in human skeletal muscle to resistance exercise performed with or without a venous infusion of lactate. The primary outcomes of the study was intracellular signaling, rate of protein synthesis (FSR) and blood/muscle levels of lactate and pH. **METHODS:** 16 healthy females and males participated in the study which consisted of two resistance exercise sessions performed under venous infusion of sodium lactate or saline, in a randomized, blinded and counterbalanced fashion. In the overnight fasted state infusion was employed during ~60 min of rest and unilateral knee-extension exercise. Blood was sampled repeatedly during trials and muscle biopsies were collected at rest and at 0, 90, 180 min and 24 h after exercise. Oral D2O ingestion was used to determine FSR during 24 h of recovery. **RESULTS:** With saline, blood lactate levels reached 3.0 mmol/l post exercise, while lactate infusion resulted in 130% greater lactate levels post exercise that also remained higher than at rest and saline up to 90 min of recovery. Post exercise muscle levels of lactate were 20% higher with lactate compared to saline infusion (32 vs 27 mmol/kg d.w). Lactate infusion had an alkalinizing effect in blood with pH being 7.44 after exercise with lactate and 7.34 with saline. This effect was not noted in muscle where pH was reduced by 0.06 units after exercise in both trials. Exercise increased the phosphorylation of mTOR^{S2448} (~40%), S6K1^{T389} (~3-fold) and S6^{S240/244} (~9-fold) during recovery, without any differences between trials. Effects of exercise without any influence of lactate infusion was also noted for eEF2^{T56}, AMPK^{T172}, PRAS40^{T246} and p44^{T202/T204}. FSR over

24h of recovery did not differ between saline (0.067 %/h) and lactate infusion (0.060 %/h). **CONCLUSIONS:** In this model blood lactate levels did not modulate resistance exercise induced mTORC1-signaling or FSR. As only small differences were noted for muscle levels of lactate, its potential role as signaling molecule should not be discarded.

OXIDATIVE METABOLISM DURING THE TIME-COURSE OF DISUSE ATROPHY IN MALE AND FEMALE MICE

Madeline G. Amos¹, Megan E. Rosa-Caldwell¹, Wesley S. Haynie¹, Kirsten R. Dunlap¹, Seongkyun Lim¹, Lisa T. Jansen¹, Jacob L. Brown¹, David E. Lee¹, Tyrone A. Washington¹, Michael P. Wiggs², Nicholas P. Greene, FACS^M. ¹University of Arkansas, Fayetteville, AR. ²University of Texas at Tyler, Tyler, TX. (Sponsor: Dr. Nicholas Greene, FACS^M)
Email: mgamos@uark.edu
(No relevant relationships reported)

Muscle loss is an important predictor of morbidity and mortality across a variety of diseases. Males and females appear to differ on clinical outcomes in relation to disuse-induced muscle atrophy, however reasons for these different responses have not been investigated.

PURPOSE: To investigate measures of muscle oxidative metabolism during the time-course of disuse atrophy in male and female mice. **METHODS:** Disuse atrophy was induced using hindlimb unloading in 50 male and 50 female mice for 0 (CON), 1, 2, 3, or 7 days (n=10/group). Muscle sections of the tibialis anterior were stained for succinate dehydrogenase (SDH). Cross sectional area (CSA) by SDH staining was used to assess the effect of disuse on different muscle fiber phenotypes. mRNA content of *Ppara* was measured in the gastrocnemius, soleus, and extensor digitorum longus (EDL) muscles. Data were analyzed within each sex by one way ANOVA and trend analysis. A p<0.05 indicated statistical significance. **RESULTS:** CSA of SDH positive fibers progressively decreased in both male and female mice. CON animals (male and female) had SDH positive fiber CSA of ~400 μm² and 7 day unloaded animals had CSAs of ~300 μm². Both male and female mice had an SDH negative CSA of ~650 μm², with no significant differences in fiber CSA noted across groups. In the gastrocnemius muscle, *Ppara* content was ~50-60% lower at 1 day of unloading in males and females and remained depressed in all experimental groups. In soleus muscles of females, *Ppara* was ~60% lower at days 1, 2, and 3 compared to CON, but then recovered back to CON levels. Whereas in males, *Ppara* was ~60% lower with 1 day of unloading and remained depressed in 1, 2, 3, and 7 day groups. In females, there were no differences in *Ppara* content in EDL across all groups. In males, there was ~50-75% lower *Ppara* in EDL content that reached statistical significance at 2 days and remained depressed throughout intervention groups. **CONCLUSION:** Disuse results in muscle loss in males and females and appears to result in similar alterations to oxidative metabolism across multiple tissues. Future studies should investigate if improving oxidative metabolism is protective against disuse atrophy in males and females.

PURPOSE: Evaluate the effects of 6 weeks of unilateral high-intensity resistance training and high-volume resistance training on upper-leg lean tissue mass and mid-thigh lean muscle cross-sectional area. **METHODS:** Well-trained, college-aged males (n = 15) underwent 6 weeks of unilateral resistance training, with one limb training with high-volume (HV), and the other with high-intensity (HI). Dual-energy X-ray absorptiometry (DEXA) scans and peripheral quantitative computed tomography (pQCT) scans were collected both before training (PRE) and after the 6 weeks of resistance training (POST). Upper-leg lean tissue mass (LTM) was quantified by selecting a region of interest to isolate the upper-leg compartment from the whole-body DEXA scan, while lean muscle cross-sectional area (mCSA) of the mid-thigh was measured using pQCT and analyzed through an open source plug-in through ImageJ (NIH). Changes in LTM and mCSA between conditions and over time were evaluated statistically using a 2x2 [CON (HI vs. HV) x TIME (PRE vs. POST)] repeated measures ANOVAs. LSD pairwise comparisons were used as follow-up analyses when a significant interaction was detected. Statistical significance was set at p 0.05.

RESULTS: There were no significant condition * time interactions for lean mCSA or LTM. However, there was a main effect of time for both lean mCSA (p<0.001) and LTM (p<0.001). Both HV and HI increased upper-leg LTM post-training (HV: pre = 8.96 ± 1.07 kg vs. post = 9.24 ± 1.14 kg; HI: pre = 8.95 ± 1.05 kg vs. post = 9.18 ± 1.06 kg). Similarly, both HV and HI increased lean mCSA post training (HV: pre = 185.8 ± 24.0 cm² vs. post = 191.8 ± 24.3 cm²; HI: pre = 185.7 ± 20.0 cm² vs. post = 195.1 ± 25.7). **CONCLUSION:** Six weeks of HV and HI training similarly increased upper-leg LTM and lean mCSA in previously trained college-aged males.

A-25 Clinical Case Slide - Hip I

Wednesday, May 27, 2020, 9:30 AM - 11:30 AM
Room: CC-2005

131 **Chair:** Lauren Elson. *Spaulding/Harvard University.*

RARE CASE OF ACETABULAR FRACTURE FROM BEACH VOLLEYBALL

Priyanka Raju¹, Steven C. Liu¹, Kenneth Vitale, FACS^M. ¹Eastern Virginia Medical School, Norfolk, VA. ²USCD School of Medicine, San Diego, CA. (Sponsor: Kenneth Vitale, FACS^M)
Email: rajup@evms.edu
(No relevant relationships reported)

HISTORY: A 59-year-old beach volleyball player sustained a hip injury during a match. While playing, he landed on soft sand from a jump on his right leg. He felt a 'jolt and pop' in his right hip that radiated to his deep thigh, and felt his leg seemed 'locked out of place.' No past history of hip dysplasia, dislocation, hip surgery. He asked someone to pull on his leg to try and improve symptoms. After the incident, he was able to walk off on his own power, but noted discomfort upon weight bearing and walking.

PHYSICAL EXAMINATION: Examination revealed no focal tenderness, full ROM of the hip, but had discomfort with FABER maneuver. He was able to walk around at the clinic without assistance.

DIFFERENTIAL DIAGNOSIS: Hip dislocation, Acetabular labral tear, loose body, Coxa saltans, Occult fracture

TEST AND RESULTS: X-rays were obtained and suggested a posterior rim acetabular fracture; Same-day CT showed a comminuted intra-articular posterolateral acetabular wall fracture with effusion, femoral head impaction, and irregularity of the central fovea suggested ligamentum teres femoris avulsion

FINAL WORKING DIAGNOSIS: Right posterior wall acetabulum fracture with femoral head impaction

TREATMENT AND OUTCOMES: 1. Referred to Orthopedic Trauma; surgeon recommended evaluation under anesthesia (EUA) due to possibility of transient hip dislocation to evaluate for instability, which he declined. Recommended toe-touch weightbearing with crutches which he also declined as he felt able to ambulate. Hip dislocation precautions given.

2. At 1 month, he ended up using two canes to walk but was able to without significant symptoms. Advanced to weightbearing as tolerated.

3. At 3 months, felt better but still unable to play volleyball or run. X-rays showed interval healing in unchanged alignment.

Case reports unusual etiology of a posterior wall fracture after seemingly 'minor' injury on soft sand, and providers should have a low threshold to proceed with further workup such as CT. Unknown if bystander pulling on leg worsened injury. May even had transient hip dislocation, a rare injury due inherently stable hip bony anatomy.

Case raises awareness to counsel patient on recurrent dislocation, osteonecrosis, and arthritis risks with these injuries, and consider bone density testing if a low-energy injury.

135 May 27 9:50 AM - 10:10 AM

A Busy Adult With Hip Pain

Jaire N. Saunders. *UC Davis, Sacramento, CA.* (Sponsor: Brian A. Davis, FACSM)
 Email: jaire.saunders@gmail.com
 (No relevant relationships reported)

HISTORY:

51yr old F with PMH significant for hip dysplasia. Presented to clinic in June 2017 for recurrent R hip pain. Sxs began in Feb 2016 when her hip subluxed. She had intermittent sharp pains to medial hip that radiated down to the toes with varied hip ROMs; without paresthesias. Prior to eval, dx with anterosuperior labral tear. Tx with PT with home exercise program (HEP), two intra-articular steroid injections, and a greater trochanteric bursa injection. Steroid injections improved pain and relieved some of the "catching," but sxs still persisted.

PHYSICAL EXAMINATION:

Mild valgus knee alignment
 Guarded FADIR, not clearly positive
 Tenderness to palpation, posterolateral troch/ gluteal area

DIFFERENTIAL DIAGNOSIS:

1. Labral tear
2. Snapping hip syndrome (tendon/muscle)
3. Femoroacetabular impingement (FAI) syndrome
4. Hip OA
5. Lumbar referred pain
6. Iliopsoas bursitis
7. Gluteal tendinopathy

TESTS AND RESULTS:

Hip Xray (8/26/2016): WNL
 MR arthrogram (2/28/2017): Degenerative tear, anterosuperior labrum.
 MSK Ultrasound (6/23/2017): Proximal IT band: thickened/hyperechoic. Cortical irregularities at the greater trochanter. Negative snapping hip maneuvers. Positive sonopalpation over posterior hip joint.
 MSK Ultrasound (9/29/2017): No snapping hip sx with log rolling, FABER, or FADIR. RF was observed rolling over the iliopsoas, without snapping. No labrum catching was noted.

FINAL/WORKING DIAGNOSIS:

R hip anterosuperior degenerative labral tear with sx of catching

TREATMENT AND OUTCOMES:

1. R hip intra-articular steroid injection (2/21/18); pain control only.
2. Discussed Platelet Rich Plasma (PRP), prolotherapy, continued steroid injections, and surgery. Did not want surgery due to work schedule/lifestyle. Was agreeable to try prolotherapy.
3. Anterior Superior Labral tear was visualized on Ultrasound in clinic and an ultrasound guided dextrose/lidocaine intra-lesional labral injection was performed (1/23/19) - doing well at 5 mo. follow-up - no pain with ROM, pain level 0.
4. MSK Ultrasound (6/10/2019): R labral tear noted in anterior labrum with improved mild hyperechoic signal.
5. HEP with avoiding of high resistance exercise due to aggravated gluteal tendinopathy

136 May 27 10:10 AM - 10:30 AM

Pelvic Pain- Ballet

Alexandria Joann Haselhorst, Monica Rho. *Shirely Ryan Ability Lab, Chicago, IL.* (Sponsor: Dr. Joe Ihm, FACSM)
 (No relevant relationships reported)

HISTORY: Patient is a 13 yo female pre-professional ballerina who developed pelvic pain during her training. She was doing an arabesque with her leg in single stance with the opposite leg extended. She then moved to a penché position with her torso leaned forward over a leg in single stance with her legs at 180 degrees. She felt an immediate pop in her left groin. She continued to dance through pain during 6 weeks of intensive ballet training prior to presentation to clinic. Pain described as 3/10, aching in left groin and buttock pain at rest. Pain better with rest and worse with walking, leg extensions and entrenchment which is a vertical jump with repeated adduction of feet. She denied any numbness, tingling or weakness. Patient had no prior history of stress fractures, is not menstruating and eats a balanced diet.

PHYSICAL EXAMINATION: Tenderness to palpation over left pubic bone. Full pain free ROM in both hips. Special tests positive on the left side included FABER, FADIR, single leg hop and resisted adduction more than abduction. She had 4/5 hip abduction strength in side lying bilaterally.

DIFFERENTIAL DIAGNOSIS:

1. Ischiopubic stress fracture
2. Pubic apophysitis at adductor insertion
3. Femoral acetabular impingement

4. Hip labral tear
5. Ischiopubic synchondrosis with stress reaction

TESTS AND RESULTS:

Pelvis and hip AP and Dunn radiographs: There is a healing fracture of the left inferior pubic ramus, with a faintly visible fracture line and surrounding periosteal reaction. MRI pelvis w/o contrast: Findings consistent with Asymmetric incomplete fusion of the ischiopubic chondrosis with stress reaction.

FINAL WORKING DIAGNOSIS:

Ischiopubic synchondrosis with stress reaction also known as Van Neck Disease

TREATMENT AND OUTCOMES:

1. Patient was made NWB on crutches for 2 weeks at her MRI follow up appointment.
2. At 2 week follow up patient had decreased pain to palpation over left pubic bone. She was progressed to WBAT, PT, no ballet for 6-8 weeks and continue with the sports nutritionist.
3. At 4 week follow up, patient had no pain on physical examination. Patient was progressed to return to barre class for 10 minutes for one week. She could increase her time each week as instructed by her PT. Patient was not allowed to do speed work, jump or move her leg past 90 degrees in abduction, flexion or extension.
4. Patient will follow up in 6 weeks

137 May 27 10:30 AM - 10:50 AM

Non-remitting Gluteal Pain In An Adolescent Soccer Player

Kristopher Paultre¹, Thomas Best, FACSM². ¹JMH/UM, Miami, FL. ²University of Miami, Miami, FL. (Sponsor: Dr. Thomas Best, FACSM)
 Email: kristopher.paultre@jhsMiami.org
 (No relevant relationships reported)

HPI:

14 y/o male soccer player presents to clinic with 12 months of right gluteal pain when active or sitting for a prolonged time. He described the pain as dull with normal activity and sharp with low levels of exertion particularly in hip flexion. His pain is maximal during soccer while kicking the ball with his opposite foot. In addition, he reports point tenderness over the proximal right hamstring and while sitting down on hard surfaces. He was evaluated roughly 1 year ago by an outside physician with a normal XR of the pelvis. Per patient and father reported an "injury to the Sits bone". Patient was subsequently taken out of sports for 6 months and had a non-US guided corticosteroid injection into the posterior thigh 3 months prior to clinic visit. The injection provided short term relief, no additional treatment (PT) was prescribed.

ROS:

CONSTITUTIONAL: No fevers, chills, sweats, night pain or weight changes.
 CARDIOVASCULAR: No chest pains, palpitations, orthopnea and paroxysmal nocturnal dyspnea.
 RESPIRATORY: No dyspnea on exertion, no wheezing or cough.
 MUSCULOSKELETAL: per HPINEUROLOGIC: No numbness, tingling or weakness.

Physical exam:

Gait: Able to bear weight with a normal gait
 MSK: No swelling, ecchymosis
 ROM: Full ROM intact both actively and passively. There was mild pain with active deep flexion during squat

Straight leg raise: Significant for pain on proximal right hamstring
 Tenderness: Over ischial tuberosity and toward proximal hamstring
 Strength: 4/5 on hip extension remainder of strength testing unremarkable

Log Roll: neg
 FABER/FADIR neg/neg
 Ober Test: neg
 Thomas Test: neg
 Sensation: intact to light touch

Differential Diagnosis:

Chronic hamstring strain
 Bone contusion
 Tumor
 Osteomyelitis

Initial Testing In clinic:

X-Ray Hip AP/lateral:
 Irregular lucency along inferolateral aspect of right ischium. Correlates to insertion of the hamstring. However, the appearance is not typical for an avulsion injury or tendon strain. Femoro-acetabular joints preserved.

MRI: Ill-defined area within the ischium approximately 1.7 x 0.6 x 3.6 cm corresponding to the suspicious area seen on prior x-ray. Findings are likely due to a healing avulsion fracture of the right ischial tuberosity.

Final Working Diagnosis:

Healing avulsion fracture over right ischial tuberosity, clinically improving with PT

138 May 27 10:50 AM - 11:10 AM

Rare Case Of Avascular Necrosis In A Dodgeball Player

Steven C. Liu¹, Alpha Anders², Kenneth Vitale, FACSM.
¹Eastern Virginia Medical School, Norfolk, VA. ²UCSD School of Medicine, San Diego, CA. (Sponsor: Kenneth Vitale, FACSM)
 Email: lius01@evms.edu
 (No relevant relationships reported)

History:

A 27-year-old male presented with left anteromedial hip/groin pain for 2 weeks. He competes in a dodgeball league and plays occasional racquetball as well. After a dodgeball game, he noted onset of hip and groin pain, which became progressively severe, and went to a local Emergency Department. He had x-rays and were told they were normal, however he had significant pain even with weightbearing at this point. No past history of hip dysplasia, dislocation, hip surgery.

Physical Examination:

Hip flexion was 110°, internal rotation 20°, external rotation 60°, abduction 45°; significant pain with flexion, adduction, and internal rotation, and positive FABER. He was able to ambulate without assistance.

Differential Diagnosis:

- Labral tear
- Femoroacetabular impingement
- Femoral neck stress fracture
- Loose body
- Chondral defect
- Athletic pubalgia

Tests and results:

X-rays were obtained and suggested minimal left femoral head collapse, and did suggest mild right femoral head sclerosis; an MRI showed large areas of grade 2 avascular necrosis bilaterally. The left had a joint effusion, edema in addition to necrotic fatty signal in the femoral head compatible with early collapse.

Final/Working Diagnosis:

Bilateral hip avascular necrosis with early left collapse.

Treatment/Outcome:

- Internal Medicine and Rheumatology referral for serological work up.
- Referred to Orthopedic Surgeon; recommended toe-touch weightbearing, counseled on risk of progression. Alendronate was considered as with precollapse Ficat stages 0-II.
- At 8 months, left hip pain was progressing, and noted onset of right hip pain. X-rays showed visible left AVN on the entire weightbearing surface with collapse and flattening of the superior articular surface; right hip now showed subtle sclerosis.
- His only pertinent history included a brief course of oral corticosteroids when he got his wisdom teeth removed, which he did not initially disclose. This case reports an unusual etiology of an avascular necrosis after taking a short-term dose of corticosteroids. Case raises awareness to counsel health providers about collaborating to provide patients with optimal care and avoid potential serious side effects.

139 May 27 11:10 AM - 11:30 AM

Bilateral Hip Pain - Soccer Player

Samantha Lucrezia, Danielle Hirsch, Patrick Mularoni. *Johns Hopkins All Children's Hospital, St. Petersburg, FL.* (Sponsor: Dilipkumar R. Patel, MBBS, MBA, MPH, FACSM)
 Email: slucruz1@jhmi.edu
 (No relevant relationships reported)

History: A 16-year-old Asian male presented with 2 weeks of worsening groin pain. Pain began after a difficult soccer practice, without a specific inciting injury. Patient was evaluated by team's athletic trainer and was referred to orthopedic surgery where x-rays were negative. One week later, patient presented to local pediatric emergency center with intermittent fevers, worsening pain and inability to ambulate. He denied any recent travel outside the US or new exposures.

Physical Exam: afebrile in no acute distress with tenderness to palpation over paraspinal muscles, costovertebral processes L3-L4 and quadriceps musculature. Patient walked with antalgic gait and found to have 2/5 strength hip flexion bilaterally with 5/5 strength in all other muscle groups. Cardiac, pulmonary and abdominal exam were unremarkable. There was no lymphadenopathy present on exam.

Differential Diagnosis:

1. Ankylosing Spondylitis
2. Iliopsoas Abscess
3. Epidural abscess
4. Osteomyelitis
5. Malignancy

Test and Results:

- ESR: elevated at 94 mm/hr, CRP: elevated at 4.57 mg/dL
- CBC: mild normocytic anemia without leukocytosis or thrombocytopenia
- CK, CMP, Uric Acid, LDH within normal limits

- Blood culture: negative
- Rheumatologic studies: ANA, adolase, ANCA were negative
- Testicular US: negative
- MRI of lumbar spine and pelvis: signal enhancement within the bones of pubis symphysis with significant surrounding soft tissue edema
- Bone biopsy: focally degenerated bone, mixed chronic inflammation, fibrosis with reactive changes. No microorganisms present on special stains
- Bone aerobic/anaerobic cultures: negative
- Quantiferon gold: POSITIVE, mycobacterium sputum PCR: POSITIVE
- Chest x-ray: negative

Final/Working Diagnosis:

Tuberculosis osteomyelitis of the pelvis

Treatment and Outcomes:

1. Treatment with ethambutol, isoniazid, pyrazinamide, and rifampin daily until cleared by infectious disease
2. Close follow up with Infectious disease clinic with monitoring labs every 2 weeks
3. Indomethacin PRN for pain
4. Range of motion and strengthening exercises for bilateral hip flexors with physical therapy
5. Regular follow up with local department of health

A-26 Clinical Case Slide - Knee I

Knee Injury- A Tragic Tackle In A Weekend Warrior

Laura A. Shaffer, John R. Deitch. *WellSpan Health, York, PA.* (Sponsor: Mark E. Lavalley, M.D., C.S.C.S., F.A.C.S.M., FACSM)
 Email: lah5089@gmail.com
 (No relevant relationships reported)

History: A 25-year-old male sustained a left knee hyperextension injury while being tackled by a friend in his backyard. He had immediate pain, swelling, and was unable to ambulate. X-Rays in the ED demonstrated an avulsion fracture of unknown origin. Patient was placed in a knee immobilizer and advised to follow up with orthopedics. Three days later, he presented to clinic with pain, swelling, significant instability, numbness and coolness in left foot, and inability to dorsiflex his left ankle.

Physical Exam: Knee examination revealed significant ecchymosis of the posterior-lateral aspect of the knee and positive effusion. Coolness and decreased sensation to distal one third of left leg. He had a positive foot drop. Difficulty palpating dorsalis pedis pulse. Good capillary refill. Significant laxity to lateral collateral ligament in full extension (0 degrees). Positive Lachman's as well as laxity with posterior drawer testing.

Differential Diagnosis:

1. Knee dislocation with peroneal neuropraxia and possible popliteal artery injury 2. Multi-ligament left knee injury with peroneal neuropraxia and possible popliteal artery injury

Tests and Results: CT angiogram- No arterial injury

MRI - Edema and nonorganized hematoma involving gastrocnemius, soleus, popliteus, and tibialis anterior. Detached medial and lateral patellar retinaculum, medial and lateral meniscus tears. Partial tear of PCL, MCL strain, ruptured ACL and LCL. Thin but intact peroneal nerve noted. Avulsion fracture of biceps femoris and tear of popliteus tendon. Medial femoral condyle osteochondral impaction fracture.

Final Working Diagnosis:

Multi-ligament left knee injury. Avulsion fracture of biceps femoris. Meniscal tears. Peroneal nerve injury without arterial injury.

Treatment and Outcomes:

1. Surgical repair 2 weeks after injury.
2. Extensive rehabilitation (0-6 weeks post-op: ROM exercises 0-90; 6-12 weeks post-op: strengthening exercises and advancing weight bearing 25% weekly).
3. Functional brace.
4. Continued monitoring for peroneal nerve improvement in motor and sensation.
5. Had discussion with patient regarding limited outcome and primary goal of function.
5. Unlikely to return to sport.

144 May 27 9:50 AM - 10:10 AM

114 Kilograms Overhead Too Much For This Knee

Erin S. Barnes, MD¹, Joseph Medellin, MD, MPH, MBA², Ryan Rompola, DAT, AT, ATC². ¹Temple University/MossRehab, Philadelphia, PA. ²Henry Ford Allegiance Health Sports Medicine, Jackson, MI. (Sponsor: Mark Lavallee MD, FACSM)
Email: esbarnes89@gmail.com
(No relevant relationships reported)

HISTORY: History: 61 year old male competing in the 102 kg category in the International WeightLifting Federation World Masters Championships, on his third attempt at clean and jerk (114 kg), was able to power clean the bar into the front rack position and subsequently performed a power jerk. As the bar was stabilized overhead, the patient's right knee collapsed medially and he fell to the ground. Medical staff assessed the patient immediately on the platform. **PHYSICAL EXAM:**Right knee exam: no obvious deformity with the leg in extension. Local edema quickly developing superior to patella, passive flexion and extension elicited pain, flexion with notable gapping between the superior pole of the patella and quadriceps muscle bulk. Patella was midline in femoral condyles, no tenderness along the medial or lateral joint lines. There was a palpable defect between the superior pole of the patella and quadriceps muscle bulk. Pulses: palpable DP pulses, good capillary refill Sensation: grossly intact to light touch in the right lower extremity **DIFFERENTIAL DIAGNOSIS:**Tibial-femoral dislocationPatellar dislocationQuadriceps tendon rupture Medial collateral ligament tear ACL tear

TESTS & RESULTS:No immediate imaging available in medical tent, ER X-ray with no fracture, ER CTA without vascular compromise and evidence of complete right quadriceps tendon rupture, which was later confirmed on pre-surgical MRI. **FINAL DIAGNOSIS:** Complete right quadriceps tendon rupture **TREATMENT & OUTCOMES:**EMS was called and the patient's knee was immobilized. Pulses were palpable throughout the duration of the exam. While in the ER there was concern for vascular injury therefore CTA was obtained. Once vascular injury was ruled out, patients' knee was placed in a knee immobilizer and he was cleared to travel home. Patient underwent surgical repair one-week post-injury in his native state. He began physical therapy several days after surgery and rehab is ongoing. Return to sport estimated at 9-12 months post-injury.

145 May 27 10:10 AM - 10:30 AM

LEG BUMP- SOCCER

George Ross Malik, Samuel Chu. *Shirley Ryan Ability Lab, Chicago, IL.* (Sponsor: Dr. Joseph Ihm, FACSM)
Email: gmalik@sralab.org
(No relevant relationships reported)

HISTORY:

A 12-year-old male with a past medical history of Celiac's disease and growth deficiency on hormone supplementation presented to sports medicine clinic with a large, painless bump on the medial aspect of his left knee. He noticed it three months prior, but reported enlargement over the last few weeks. He described it as firm and non-mobile. He denied any trauma or inciting event to the knee. He reported playing soccer 8 hours and squash 2 hours per week with both school and club teams. He did not describe any swelling around the knee itself and there was no history of locking or buckling of the knee. The bump did not limit his ambulation or mobility. He endorsed a mild decrease in his ability to flex the knee. He denied any other bumps or masses, fevers, chills, weight loss, erythema, ecchymosis, or edema.

PHYSICAL EXAMINATION:

Examination revealed an approximately 1x2cm firm, non-mobile mass over the superomedial aspect of the left tibia. No knee effusion was noted bilaterally. The left knee was non-tender to palpation along the medial and lateral joint lines as well as the patellar facets. There was no crepitus in the bilateral knees. The range of motion was minimally restricted in flexion on the left compared to the right. Full extension was intact without pain bilaterally. Sensation to light touch and motor strength was normal in the lower extremities. There was no varus or valgus laxity. McMurray's and Lachman's tests were negative bilaterally.

DIFFERENTIAL DIAGNOSIS:

1. Tumor (Osteosarcoma)
2. Ganglion Cyst
3. Parameniscal Cyst
4. Soft Tissue Sarcoma

TESTS AND RESULTS:

Left Knee X-ray: No acute fracture or traumatic malalignment. No bone mass visualized
Left Knee Bedside Ultrasound: Hypoechoic mass superficial to medial joint line and posterior to MCL
Left Knee MRI: 1.1 x 2.3 x 1.9cm multi-loculated parameniscal cyst. Tear in the posterior horn of the medial meniscus connecting to the parameniscal cyst

FINAL/WORKING DIAGNOSIS:

Multi-loculated parameniscal cyst secondary to a medial meniscus tear

TREATMENT AND OUTCOMES:

1. Referred to orthopedic surgery to rule out any surgical intervention
2. Consideration of ultrasound-guided percutaneous drainage of the parameniscal cyst
3. Instructed to current activity and exercise as tolerated
4. Counseled to report any pain or changes in symptoms
5. Follow up in 2 months

146 May 27 10:30 AM - 10:50 AM

Knee Injury Football

Michelle L. Walls. *Michigan State University, East Lansing, MI.* (Sponsor: Susan M. Ott, FACSM)
(No relevant relationships reported)

HISTORY: 14 year old male football athlete sustained an unwitnessed injury to his left knee at football practice. He presented to the emergency room and subsequently to the orthopedic department. CO left knee pain and swelling with difficulty bearing weight

PHYSICAL EXAMINATION: Moderate effusion. ROM 0-40 degrees, no joint line pain, stable to varus and valgus stress testing at 0 and 30 degrees of flexion. Positive lachmans. Unable to do further testing due to pain and decreased ROM

DIFFERENTIAL DIAGNOSIS: 1-ACL injury 2-locked knee due to bucket handle meniscus tear 3-fracture 4-patella dislocation/subluxation

TEST AND RESULTS: Plain radiographs : skeletally immature, displaced tibial spine fracture CT: same with the center of the physis closed MRI: Same no other intra-articular pathology and further definition of the size of the intra-articular fragment

FINAL WORKING DIAGNOSIS: tibial spine fracture

TREATMENT AND OUTCOMES: arthroscopically assisted fixation of fracture, non weight bearing for 4 weeks in post operative brace ROM 0-30, Gradual return to full weight bearing and full ROM in post operative brace over the next 2 weeks. Placed in hinged knee sleeve and into ACL protocol physical therapy at 6 weeks PO. Negative lachmans achieved and maintained from immediately post op onward. Radiograph union of the fracture at 6 weeks PO. Anticipate return to basketball with brace at 3 months post op

147 May 27 10:50 AM - 11:10 AM

Knee Injury-Football

Alexander A. Spiewak. *Western Michigan University School of Medicine, Kalamazoo, MI.* (Sponsor: Robert J Baker, FACSM)
Email: Alexander.spiewak@gmail.com
(No relevant relationships reported)

HISTORY: A 17-year-old senior high school football quarterback sustained a right knee injury during the third quarter of a game. During the third quarter while the player was attempting to cut and change directions he planted hard on his right leg and attempted to push off. He subsequently fell to the ground screaming in pain. There was no contact with another player. Athletic trainers and the team physician ran onto the field to aid him.**PHYSICAL EXAMINATION:** Examination demonstrated a deformed right knee. The tibia was displaced laterally in relation to the femur. The patella was midline. His sensation was intact, no dorsalis pedis pulse was palpable. His range of motion was severely limited. Reduction of his true knee dislocation was performed on the field due to the lack of palpable DP pulse. His knee was easily reduced on the field and his dorsalis pedis pulse was then easily palpated. He was carried to the sideline. On sideline he had a grade II Lachmans with his exam being limited by pain. He was placed in a straight leg immobilizer and taken to the emergency department.**DIFFERENTIAL DIAGNOSIS:**1. Knee dislocation2. Patellar dislocation3. Ligamentous injury **TEST AND RESULTS:**CT Angiography lower extremity right-Normal vascular structures with normal pop. Artery-Moderate right knee effusion -No visualized fractures seenKnee complete 4 view right-Skeletally mature with physiologic valgus alignment-Large knee effusionMR right knee without contrast-Complete tear of ACL-Lateral femoral condyle cortical impaction fracture with deepened femoral notch-Large joint effusion-Suspected longitudinal tear of the posterior horn of the lateral meniscus **FINAL/WORKING DIAGNOSIS:**True knee dislocation with complete ACL tear and lateral meniscus tear as well as lateral femoral condyle impaction fracture**TREATMENT AND OUTCOMES:**1. The patient was kept in hinged knee brace for 4 weeks to allow for capsular healing2.Patient underwent right knee arthroscopic ACL reconstruction with bone-tendon-bone autograft and lateral meniscus repair. No posterolateral corner injury was noted on

arthroscopy.3.Patient began physical therapy. He demonstrated significant quadriceps atrophy which improved throughout his course.4.Patient returned to sport with a functional brace, but did not return to football

148 May 27 11:10 AM - 11:30 AM

Bone Injury In A Gymnast

Philip Zhang¹, Jacob Joseph², Jorge Rojas¹, Edward G. McFarland¹, Brian J. Krabak³. ¹The Johns Hopkins University, Lutherville, MD. ²The Johns Hopkins University, BALTIMORE, MD. ³University of Washington, Seattle, WA. (Sponsor: Brian J Krabak MD MBA FACSM, FACSM)
Email: phzhang@augusta.edu

Bone Injury - Gymnastics

HISTORY: A 14-year old female level 10 USGA gymnast presented with right knee pain and swelling after hyperextending her knee during a landing while competing on vault. She did not feel or hear a pop but was unable to walk due to pain. The knee subsequently swelled and she sought medical treatment at a local facility. Radiographs were negative but she continued to have pain while walking with loss of motion. She had no previous knee injuries and did not complain of any paresthesias. She otherwise was in good health with no history of illnesses or medical conditions
PHYSICAL EXAM: The patient was in no distress but could not weight bear on her leg. She had a 2+ effusion and her knee motion was limited from 20 to 125 degrees. She was neurologically intact for sensation and motor strength in the extremity. She was tender only on her proximal tibia near the patellar tendon attachment. Her patellar tendon and quadriceps mechanism was intact. She had no laxity to varus or valgus stress testing of the collateral ligaments with the knee extended or flexed 30 degrees. A McMurray's test was too painful to perform. She had a negative Lachman's and posterior drawer test. Her vascular examination (pulses, color, capillary refill, temperature) of the extremity were all normal.

DIFFERENTIAL DIAGNOSIS:

1. Patellar dislocation
2. Partial tear patellar tendon
3. Meniscal tear
4. Cartilage contusion
5. Occult fracture - tibial plateau

TESTS AND RESULTS:

Plain radiographs of the knee (sunrise, true AP and lateral): Normal
MRI of the Knee: Normal ACL and PCL. Moderate knee effusion. Contusion of the lateral femoral condyle and the anterolateral tibial plateau.
CT scan of the Knee: Cortical break in the lateral tibial plateau anteriorly

FINAL WORKING DIAGNOSIS:

TREATMENT AND OUTCOMES:

1. Non-operative treatment: crutches until free of symptom (3 weeks) then progressive weight bearing
2. Ibuprofen 800 mg up to three times per day prn for two weeks; cryotherapy daily
3. Conditioning only at gymnastics with no WB on extremity for 6 weeks followed by slow progression back to sport
4. Returned to gymnastics at 3 months?

A-27 Clinical Case Slide - Neurological

Wednesday, May 27, 2020, 9:30 AM - 11:30 AM
Room: CC-2022

152 May 27 9:30 AM - 9:50 AM Isolated Infraspinatus Weakness Due To Suprascapular Neuropathy In A National Level Volleyball Player

Jason Lou¹, Daniel Krasna¹, Terry Nicola, FACSM². ¹Schwab Rehabilitation Hospital/University of Chicago, Chicago, IL. ²University of Illinois, Chicago, Chicago, IL.
(No relevant relationships reported)

HISTORY: 15-year-old female national-level volleyball player with no PMH who presented for nagging right shoulder pain and subjective right arm weakness for 1.5 years. The patient did not endorse a specific inciting injury. The pain was located at the anterolateral aspect of the deltoid with radiation down the arm without numbness or tingling, made worse with volleyball activity and made better with rest. Due to her continued pain and right shoulder weakness, she was held from participating in volleyball matches. MRI arthrogram was negative for pathology, so she was referred for EMG.

PHYSICAL EXAMINATION: General Appearance: Young Caucasian female in no acute distress

Musculoskeletal: 4 out of 5 strength at right shoulder external rotation. 5 strength in bilateral upper extremities otherwise. No atrophy of the bilateral shoulder muscles. Normal bilateral scapulothoracic movement. Full range of motion at the bilateral upper extremities. Bilateral shoulders non-tender to palpation over the anterior, lateral, or posterior aspects. Neck non-tender to palpation. No pain noted with cervical neck flexion, extension, or rotation.

DIFFERENTIAL DIAGNOSIS: 1) Labral Tear 2) Rotator Cuff Tendinopathy 3) Suprascapular nerve palsy at the spinoglenoid notch

TEST AND RESULTS: Bilateral upper extremity EMG: On nerve conduction studies, no response obtained from the right infraspinatus, response normal at the suprascapular when stimulating at Erb's point. On needle EMG, 4+ fibrillations and no recruitment seen at the right infraspinatus; normal suprascapular. Electrodiagnostic evidence suggestive of a right suprascapular nerve neuropathy selectively affecting the infraspinatus. Findings compatible with suprascapular nerve palsy proximal to or at the spinoglenoid notch.

FINAL WORKING DIAGNOSIS: Suprascapular neuropathy selectively affecting the infraspinatus due to repetitive overhead activity.

TREATMENT AND OUTCOMES: The patient was prescribed a 4-week course of physical therapy for range of motion exercises and shoulder rotator cuff muscle strengthening. She was advised to initiate a return-to-play graduated exercise program after completion of PT based on strength and tolerance to pain. The patient's pain significantly improved with PT and rest. She was able to return to competitive play within 8 weeks.

153 May 27 9:50 AM - 10:10 AM

Unilateral Pectoralis Atrophy

Stefanie Lewis. *Maine Dartmouth, Augusta, ME.* (Sponsor: James Dunlap, MD, FACSM)
(No relevant relationships reported)

History:

A 49 year old male, right hand dominant, referred for evaluation of right sided pectoralis weakness and atrophy first noted incidentally 2 months prior at routine physical. He subsequently noted weakness as he was no longer able to do bench press or even a single push-up which were standard exercises in his workout routine. He

denied any history of specific injury or inciting event. Further questioning revealed numbness of the 2nd and 3rd fingers on the right. Notably he did not have any neck or shoulder pain.

Physical Examination:

Visual inspection revealed right sided pectoralis atrophy and winging of the inferior border of the scapula on the right. There was no tenderness to palpation in the cervical spine or shoulder girdle. There was full active cervical and shoulder range of motion without pain. Strength testing was normal and symmetric aside from weakness with forearm supination on the right compared to the left. Spurling test of the cervical spine was negative bilateral. Patient noted mild sensory deficits in the 2nd and 3rd digits on the volar aspect on the right. Normal radial and ulnar pulses bilateral.

Differential Diagnosis:

- 1) Pectoral nerve entrapment
- 2) Brachial plexopathy
- 3) Cervical radiculopathy

Test and Results:

EMG/NCS

-Electrodiagnostic evidence of multiple right cervical radiculopathy, mostly involving C5 and C6 roots. Incidental finding of mild right ulnar neuropathy.

MRI C spine

-Right-sided hypertrophic changes are seen about the Luschka joints at C3-C4, C5-C6 and C6-C7. Most prominent at C5-C6 where there is moderate to severe narrowing. No evidence of disc herniation, canal stenosis or cord effacement.

Final Working Diagnosis:

Cervical radiculopathy, primarily of the C6 nerve root. As the imaging findings did not fully correlate with physical exam findings and EMG findings, patient was referred to neurosurgery for consultation and second opinion which is currently pending.

Treatment and Outcomes:

Provided neurosurgery recommends non-operative treatment patient will be referred to physical therapy to regain appropriate strength in hopes of returning to his prior workout routine.

154 May 27 10:10 AM - 10:30 AM

Arm Weakness In A Recreational Weightlifter

Ashkan Alkhamisi. *University of Florida, Gainesville, FL.*

(Sponsor: Jason L. Zaremski M.D., FACSM)

Email: ashkan.alkhamisi@ufl.edu

(No relevant relationships reported)

HISTORY:

A 47-year-old RHD male presented to sports medicine clinic with 3-4 month history of left shoulder weakness. He first noticed the weakness while working out, specifically during overhead shoulder press. He denied any specific injury or trauma of his left shoulder. He reported intermittent pain extending from the posterior shoulder to his neck. Pain was described as dull. Pain was 2/10 at rest and 4/10 with overhead activity. The patient noticed progressive muscle atrophy in his posterior shoulder region since the onset of symptoms. He denied any numbness or tingling of the left arm. Denied any recent illnesses. He denied prior treatment for this issue, including PT, injections, or surgeries.

Physical Exam:

General: No acute distress. Left shoulder: No swelling or erythema. Notable atrophy of body of infraspinatus. Sensation intact to light touch. Normal range of motion in all directions. Strength 5/5 with shoulder abduction, forward flexion, and internal rotation. Strength 3/5 with external rotation with elbow at side. Negative Empty Can, Drop Arm, Hawkins', Neer, O'Brien, and Speed's tests.

Differential Diagnoses:

1. Rotator cuff tendinopathy
2. Ganglion cyst at spinoglenoid notch
3. Subacromial impingement syndrome
4. Cervical radiculopathy
5. Brachial plexopathy
6. Parsonage-Turner Syndrome

Initial Test and results:

AP, Axillary, lateral xray views of left shoulder were normal. MRI left shoulder indicated supraspinatus and infraspinatus muscle edema without tendon tear without space-occupying lesion. EMG/NCS indicated focal conduction abnormality of the suprascapular nerve proximal to the level of the supraspinatus muscle and distal to the brachial plexus.

Final Diagnosis:

Suprascapular Nerve Entrapment

Treatments and Outcomes:

Patient was referred to orthopaedic surgery and recommended shoulder arthroscopy for suprascapular nerve release. During the case the surgeon noted a small cyst at the spinoglenoid notch (not apparent on MRI imaging). 2 weeks post-op, the patient reported doing light daily activities with no pain or weakness. 4 weeks post-op patient was asymptomatic performing home exercises up to 5x/week. He returned to activities as tolerated with no restrictions.

155 May 27 10:30 AM - 10:50 AM

Foot Drop In A Runner: A Novel Treatment For An Uncommon Problem

Ross Quinn Osborn. *The Center for Health and Sports Medicine, Fruit Cove, FL.* (Sponsor: James Churilla, PhD, MPH, MS, FACS, FACS)

Email: ross@jaxfamilysportsmed.com

(No relevant relationships reported)

History: A 59-year-old recreational runner presented to the office with right sided foot pain and weakness, which began insidiously 3 weeks prior and mostly noticed with plantar flexion while running and improved but not resolved by non-weightbearing. He noticed diffuse, minimal swelling around the foot, but no bruising or numbness. Celecoxib offered minimal relief and he had no history of injury to the foot nor was he complaining of any pain in the knee or opposing foot. He underwent a 6-week course of physical therapy and home exercise program. He returned 5 weeks later with worsening weakness in the foot, to the extent of having foot drop in the foot. There was no significant history of injury to the back or knee, nor was he complaining of pain in either. He was referred to a neurologist, who performed a nerve conduction study, revealing a peroneal nerve entrapment, prompting referral for MRI of the right knee. **Physical Examination:** Initial exam revealed diffuse mild swelling around the ankle. His active dorsiflexion lacked 20 degrees when compared to the left and he reported pain with resisted eversion and dorsiflexion of the foot. His resisted dorsiflexion was 3/5 and eversion was 4/5.

Follow up exam 5 weeks later demonstrated 1/5 strength with resisted dorsiflexion and 3/5 with eversion, but normal sensation and patellar and Achilles reflexes. Examination of the lumbar spine was negative. There was no atrophy.

Differential Diagnosis:

1. Peroneal nerve entrapment
2. Anterior tibial tendonitis
3. Peroneal tendon strain
4. Osteoarthritis

Tests and Results:

X-ray, right ankle/foot - minimal osteoarthritic changes diffusely in the tarsal bones. Calcifications within the Achilles tendon.

Ultrasound - swelling around the anterior tibial tendon and hypochoic signal in the peroneal tendon.

NCS - peroneal nerve entrapment

MRI - periarticular ganglion extending into proximal calf

Final Working Diagnosis: peroneal nerve palsy secondary to periarticular ganglion

Treatment:

1. Ultrasound guided aspiration of the ganglion, with corticosteroid injection following aspiration
2. Repeat physical therapy course following aspiration
3. Medical weight loss program
4. Gait assessment prior to return to running

The patient experienced a full recovery 3 months after aspiration and has resumed running at his previous level.

156 May 27 10:50 AM - 11:10 AM

Arm Pain And Weakness In A Soccer Player

Melissa Lau, Jeffrey Strakowski. *Ohio State University,*

Columbus, OH.

(No relevant relationships reported)

HISTORY Patient is a 17 year old right hand dominant male soccer player with history of infectious mononucleosis. He complains of spontaneous, progressive distal right upper limb weakness and cramping for one year. His cramping pain is 1-4/10 in severity, worse with exercising. He has early fatigue and approximately 30% of his baseline strength in his elbow, wrist and finger extensors; he denies neck pain, numbness, paresthesias or history of stingers. He reports no lower limb involvement, incontinence or gait disturbances.

PHYSICAL EXAMINATION: MSK:-ROM: Neck, bilateral upper limb ROM intact -Strength: **RUL:** 5/5 SAb; 5/5 EF; 5/5 EE; 4+/5 WE; 3+/5 FE; 5/5 FF LUL, RLL, LLL: 5/5 in all muscles -Palpation: No palpable mass, edema in forearm/arm

Neuro: -Provocative: +Tinel along dorsal aspect of RUL brachium -Sensation: grossly intact -Cranial nerves: grossly intact -Reflexes: 1+ biceps, triceps, brachioradialis bilaterally

DIFFERENTIAL DIAGNOSIS: -Radial nerve neuropathy -Posterior cord brachial plexopathy -Peripheral nerve sheath tumor (eg schwannoma, neurofibroma) -Diffuse neuritis -Soft tissue mass

TEST AND RESULTS: -MRI R wrist, forearm, arm (with and without contrast): Area of mild enlargement around the spiral groove (possible cyst vs tumor) -PET scan: No suspicious focal uptake or other evidence of malignancy -NCS/EMG 4/2018: severe right radial neuropathy proximal to the brachioradialis and distal to the triceps brachii/anconeus innervation -Ultrasound 4/2018: Enlargement of the radial nerve near the

spiral groove. Hypochoic central fascicles (ie the motor axons); normal appearing peripheral fascicles (ie the sensory axons). Fascicle enlargement is consistent with a demyelinating process, not an axonal process

FINAL WORKING DIAGNOSIS: Neuralgic amyotrophy AKA Parsonage-Turner Syndrome

TREATMENT AND OUTCOMES: He underwent physical therapy without improvement in symptoms. However, NCS/EMG revealed a demyelinating process that was consistent with spontaneous or autoimmune process such neuralgic amyotrophy; ultrasound revealed mostly motor axonal involvement. He opted for conservative management, monitoring for spontaneous improvement. He did not seek further follow up.

157 May 27 11:10 AM - 11:30 AM

Hockey Player With Weakness In His Extremities

Ima Vera Jonkheer, D.O., MSc, Philip F. Skiba, D.O., Ph.D.
Advocate Lutheran General Hospital, Park Ridge, IL.

(No relevant relationships reported)

HISTORY: A 63 yo M hockey player w/ PMhx of OA, HLD, kidney stones, & chronic pupillary anisocoria presented to the ED after 24 hours duration of LE weakness & paresthesias in both hands. He also reported difficulty ambulating. He denied trauma, new ingestions, pain, visual disturbances, incontinence of bowel/bladder, or recent travel. He admitted to recent sick contacts in his family & a personal hx of preceding flu-like illness 2 weeks prior from which he recovered with no apparent sequelae.

PHYSICAL EXAMINATION: Vitals: HR 120s, BP 160-275/100-175. Gen: NAD. Neck: No bruits, full ROM w/o pain/meningeal signs. HEENT: B/L pupils reactive to light; L>R pupil. CV: Tachycardic. Chest: Clear, non-labored. Abd: Soft, BSx4. Back: No tenderness. Skin: No rash. Neuro: A&Ox3, no facial droop, uvula midline, speech clear, neg pronator drift, tone normal. Strength test: deltoid 5 R&L, bicep 4+ R&L, tricep 4+ R&L, hand intrinsic 5- R&L, psoas 4+R, 5-L, quad 5- R&L, hamstring 4+ R&L, tibialis 5 R&L, gastroc 5 R&L. Light touch/vibratory/pinprick sensations intact. Reflexes 2-. Difficulty lifting R>L leg to walk.

DIFFERENTIAL DIAGNOSIS: 1. Acute inflammatory demyelinating polyradiculoneuropathy 2. Acute inflammatory myopathy 3. Myasthenia gravis
TEST AND RESULTS: LABS: Hgb 18.9 gm/dL, Hct 51.5%, Total protein 9.2 gm/dL, CK: 625 units/L, DDimer: 0.70 mg/L, IMAGING: CXR Neg, CT Head Neg, CT Chest/Abd/Pelvis Neg

FINAL WORKING DIAGNOSIS: Acute Inflammatory Demyelinating Polyradiculoneuropathy (Guillain-Barré Syndrome)

TREATMENT AND OUTCOMES: 1. Neurology assessed in the ED, w/ hx of antecedent URI, progressive weakness, preserved sensation w/areflexia, novel hypertension/tachycardia representing dysautonomia, recommended LP. 2. LP consistent w/ AIDP w/ elevated protein, admitted & started on IVIG 2g/kg divided over 3 days monitored in Neuro Tele Unit. 3. PT/OT while inpatient & PM&R admission after hospitalization. 4. Underwent prolonged course of PT for LE/UE weakness for 1 year initially requiring assistive devices including walker/cane, slowly normalizing gait over time. 5. Completed PT, assessed by Sports Med for gradual return to sport program focused on strength training, cardiovascular conditioning, & diet modification w/ inc protein. 6. Continues to follow w/ Neuro, Sports Med, & PM&R for intermittent weakness.

EFFECTS OF CONTRAST WATER THERAPY ON THE RECOVERY OF HEART RATE VARIABILITY FOLLOWING ECCENTRIC EXERCISE

Hsing Yu Kang, Wei Chin Tseng, Szu Kai Fu, Yen Min Teng, Jo Ning Chang, Cheng Hsiu Lai. *University of Taipei, Taipei City, Taiwan.*

(No relevant relationships reported)

Abstract

Purpose: The aim of this study was to compare the effects of hot/cold immersion therapy and passive recovery following maximal eccentric exercise of the bilateral knee extensors on heart rate variability.

Methods: 14 health college males (18-22 yrs) were recruited and randomly assigned into the contrast water therapy (CWT) or passive recovery (CON) group (n=7 per group). Each participant performed 10 sets of 10 maximal isokinetic (30°/s) eccentric contractions (MaxECC) of each knee extensors. Contrast water therapy (8°C × 1 min and 45°C × 4 minutes, 3 reps), or the passive recovery interventions (15-min

consecutive rest) were taken at 30 minutes post-MaxECC. Heart rate variability (HRV) parameters were collected by the portable heart rate monitor at 5 mins before, and 0-5, 10-15 and 25-30 mins after interventions.

Results: During the first 5 mins after interventions, mean HR (95.4 ± 11.1 bpm) and the normalized units of high frequency power (23.6 ± 10.3 nu) of the CWT group showed significantly higher value than the CON group (81.5 ± 11.6 bpm, 18.5 ± 9.0 nu; $P < 0.05$), the mean R-R intervals (636.8 ± 78.8 ms), the standard deviation of normal R-R intervals (26.1 ± 6.6 ms) and the square root of the mean squared differences between adjacent R-R intervals (17.2 ± 7.7 ms) for CWT showed significantly lower than that of CON (749.3 ± 105.4 ms, 46.1 ± 17.7 ms, 33.0 ± 12.8 ms; $P < .05$). However, 10-15 and 25-30 mins after interventions, all HRV parameters between the two groups showed no significant difference ($P > .05$).

Conclusion: These findings supported the hypothesis and suggested that one session of 15 mins CWT after eccentric exercise could be increased parasympathetic-related activation in cardiac autonomic regulation, but the effect only lasting for 10 mins.

Keywords: autonomic nervous system, parasympathetic activation, normalization of high-frequency power

The Effects Of Contrast With Compression Therapy On Muscle Recovery Post Exercise

Shabnam Lateef, Ryan Oakley, Vinny Colantuno, Robert Lavellee, Anders LaFortune, Disa L. Hatfield, Jonathan McLinden, Jacob E. Earp. *University of Rhode Island, Kingston, RI.*

Reported Relationships: S. Lateef: Industry contracted research; Solid State Incorporated.

Intense eccentric exercise causes muscle damage that leads to a decrease in subsequent performance. Accelerating muscle recovery between bouts of exercise minimizes the risk of injury and is essential for optimal athletic competitive performance.

PURPOSE: The purpose of this study was to determine if the contrast with compression (CwC) therapy proprietary device by Solid State Inc was able to improve muscle recovery post intense eccentric exercise. **METHODS:** Ten physically active men (age = 21.3 ± 2.1 years; height = 182 ± 8.5cms; weight = 88 ± 19.5kg; body fat = 17.2 ± 7%) completed two separate single-arm elbow flexor workouts on an isokinetic dynamometer. After one workout each participant received contrast with compression (CwC) therapy immediately after, 24h and 48h after the workout. After the other workout the same person received no treatment (CON). Post-exercise recovery of selected characteristics were measured at 1h, 24h, 48h and 72h. Comparisons were made between the CwC and CON groups using a Mixed Model ANOVA with repeated measures to identify time effects and an ANCOVA was used to identify interaction effects. A Bonferroni post-hoc test was used to assess timepoint differences in between interventions in recovery post eccentric exercise. A $p \leq 0.05$ was used for all analysis.

RESULTS: CwC therapy post exercise resulted in a significantly faster recovery rate of strength and power to baseline levels ($p = 0.00$) as well as a greater recovery of overall relative strength ($p = 0.004$). Treatment with CwC significantly suppressed the post-exercise inflammatory response ($p = 0.05$) and significantly reduced the secondary muscle damage response as measured by levels of Creatine Kinase post exercise. CwC therapy also resulted in a significantly quicker recovery of the maximal elbow flexion range of motion ($p = 0.00$) within the hour post exercise. Lastly, participants experienced significantly less soreness 48 hours and 72 hours post-exercise with CwC therapy. **CONCLUSION:** Contrast with compression therapy significantly increases the recovery rate of muscle strength and power post eccentric exercise. CwC is also effective at reducing exercise associated muscle damage, delayed onset muscle soreness and mitigates the loss of range of motion post intense exercise.

187 Board #3 May 27 9:30 AM - 11:00 AM

An Examination Of The Effects Of Various Procedures To Improve Delayed Onset Muscle Soreness

Michael Vela, Amanda Skaggs, Andrew Gutierrez, Caitlin Tagle, Kevin Canales, Mayra Limas, Gabriel Figueroa, Ulku Karabulut, Murat Karabulut, FACSM. *University of Texas Rio Grande Valley, Brownsville, TX.*

Email: michael.vela02@utrgv.edu

(No relevant relationships reported)

PURPOSE: To examine the acute effects of various recovery methods on delayed onset muscle soreness (DOMS). **METHODS:** Following intense DOMS-inducing exercise, nine males (age = 23.6 ± 2.4 years) were exposed to three treatment conditions (foam rolling (FR); body tempering (BT); blood flow restriction (BFR)) or control in a random order. Resting blood pressures were observed and recorded each laboratory visit. Subjects warmed up with a 5-minute treadmill walk at a speed of 3.5 mph at 0% grade and performed three vertical jump (VJ) tests. The DOMS protocol consisted of 5 sets of leg extensions at 85%1RM until failure. Each repetition required a one-second of concentric contraction followed by a four-second of eccentric contraction. Soreness levels were objectively (Force Gauge; FG) and subjectively

(Likert Scale; LS) measured. Participants received a randomized treatment 24 and 48 hr. after their respective exercise session for a 20-minute period. VJ tests identical to the pretest were executed prior to treatment and 24 and 48 hr. after each treatment. A leg extension endurance test was performed until failure 48 hr. after treatment. **RESULTS:** Significant time main effects ($p < .05$) were indicated for subjective and objective pain perception. VJ values were significantly lower 48 hr. after inducing DOMS compared to the values recorded on the first day ($p < .05$). Our results also demonstrated that FR significantly increased muscular endurance performance when compared to the BFR treatment ($p < .05$) and there was a trend for improved endurance performance for FR compared to control ($p = .06$). Furthermore, a trend for a better endurance performance existed when using BT treatment as opposed to control ($p = .06$). **CONCLUSION:** This study suggests that FR was a more effective treatment method compared to BFR. Prior research suggests that applying external pressure to muscle following DOMS may aid in muscle adhesion separation, promote vasodilation and O₂ delivery, and stimulate mitochondria and energy production due to increased blood volume. Therefore, our findings also indicate that FR and BT may serve as practical modes of treatment for DOMS due to one or a combination of factors such as improved O₂ delivery, increased waste product removal from the muscle, and augmented restoration of the muscles' length-tension relationship.

188 Board #4 May 27 9:30 AM - 11:00 AM
Effects Of Different Non-pharmacological Methods On Recovery From Delayed Onset Muscle Soreness

Tabitha Abraham, Zulema Mendez, Roel Ruiz, Marcos Cruz, Robert Martinez, Sael Elizondo, Concepcion Chapa, Ulku Karabulut, Murat Karabulut, FACSM. *University of Texas Rio Grande Valley, Brownsville, TX.*
 Email: tabithabraham5@gmail.com
 (No relevant relationships reported)

PURPOSE: To investigate the effects of diverse recovery methods on delayed onset muscle soreness (DOMS) and muscle performance. **METHODS:** Ten healthy males (age = 24.1 ± 3.2 years; height = 173.3 ± 7.7 cm; weight = 81.5 ± 17 kg) participated in a crossover study with three randomized recovery treatment methods that were foam rolling (FR), Theragun (TGUN), or vibration platform (VP). The first session started with a 5-min seated rest, followed by the recording of the subjects' resting systolic blood pressure (RSBP) and heart rate (HR) values. The subjects warmed-up on a treadmill at 4.5 mph, 0% gradient, for 5-min. Three trials of vertical jump (VJ) test were performed and the best jump performance was recorded. Subjects continued to leg extensions, which consisted of 1 warm-up set and then 4 sets at 80-85% of one repetition maximum (1-RM) until failure to induce DOMS. Rep tempo involved 1-sec concentric and 3-sec eccentric contractions. Subjects returned on day 2, which included 5-min rest followed by RSBP and HR measurements, then soreness levels were measured with Likert scale and Forge Gage. The subjects warmed-up on a treadmill, followed by the recovery method chosen for that session. VP consisted of 10 1-min sets with 1-min rest in between. FR and TGUN were used for 10-min on each side of the lower limb with 1-min rest in between. Following recovery methods, subjects repeated VJ test and leg extension exercises and number of reps were recorded. The exact procedure of day 2 was performed on day 3. **RESULTS:** A significant main effect for condition with the VP method showing higher RSBP values than the TGUN ($p < 0.01$). There were significant condition*time interaction and condition and time main effects for the total number of reps ($p < 0.03$). A higher number of reps performed following TGUN compared to VP and higher number of reps were performed on day 1 compared to day 2 ($p < 0.03$), with no contrast between day 1 and day 3. Significant time main effect was also seen in VJ values, suggesting day 1 values were higher compared to day 2 ($p < 0.05$) and day 3 values ($p < 0.05$). **CONCLUSION:** The results suggest that TGUN is an effective recovery method for reducing soreness, which can be attributed to higher muscle adhesion breakdown, and/or increased blood flow and O₂ delivery to the muscle, and/or reduced pain perception due to inhibition of nociceptor activity.

189 Board #5 May 27 9:30 AM - 11:00 AM
The Influence Of Flotation Restricted Environmental Stimulation Therapy On Recovery From High Intensity Resistance Exercise

Lydia K. Caldwell, Emily M. Post, Matthew K. Beeler, Brian C. Focht, FACSM, Jeff S. Volek, Carl M. Maresh, FACSM, William J. Kraemer, FACSM. *The Ohio State University, Columbus, OH.*
 (Sponsor: William J. Kraemer, FACSM)
 Email: caldwell.713@osu.edu
 (No relevant relationships reported)

Flotation-restricted environmental stimulation therapy (flotation-REST) attenuates afferent nervous system signaling to promote relaxation of the body and mind. Despite limited research, the intervention has become increasingly popular among high performance populations (e.g., athletes, military) seeking to accelerate recovery and enhance performance readiness. **PURPOSE:** to determine whether flotation-REST

augments recovery from high intensity resistance exercise known to induce significant metabolic, adrenergic and mechanical stress. **METHODS:** Eleven resistance trained males (age: 22.5± 2.3 years; height: 176.4±6.0 cm; weight: 85.7±6.2 kg; back squat 1RM: 153.1±20.1 kg; strength to weight ratio: 1.8±0.2) participated in a randomized, crossover-controlled research study. In one testing block high intensity resistance exercise (6 x 10 back squats at 80% 1RM, 2 min rest) was followed by a one-hour flotation-REST session, while recovery in the remaining block consisted of a sensory stimulating control. Markers of neuroendocrine signaling (catecholamines, cortisol, testosterone), structural damage (myoglobin, creatine kinase), inflammation (IL-6, TNF-alpha) and psychological perception (soreness, mood, fatigue) were measured before exercise (PRE), immediately post exercise (IP), post 1-hour recovery (1R), twenty-four hours post exercise (+24) and forty-eight hours post exercise (+48). Mean differences were assessed using repeated measures ANOVA with pairwise post-hoc comparisons ($p \leq .05$). Effect sizes (ES) were calculated to evaluate magnitude of significant treatment differences. **RESULTS:** Flotation-REST significantly decreased soreness across the 48-hour recovery period (ES, 1R: 0.68, +24: 0.47, +48: 0.28). Immediate improvements in positive affect (ES, 1R: 0.74), negative affect (ES, 1R: 1.03) and fatigue (ES, 1R: 1.13) were accompanied by differences in neuroendocrine signaling. Norepinephrine was significantly reduced (ES, 1R: 0.99) and testosterone significantly increased (ES, 1R: 0.32) in flotation-REST compared to control. No treatment differences were displayed for structural damage or inflammation. **CONCLUSION:** The data suggest a positive impact of flotation-REST in the first 48 hours of recovery, particularly where psychological appraisal is involved.

Note. AC = simulated Ammunition can Carry; CC = Cover to Cover sprint; s = seconds; SC = Stair Climb; SR = Shuttle Run
[†]statistically slower than baseline, ^{*}statistically slower than foam roll, α = < .05

PURPOSE: Evaluate the effects of post-exercise foam rolling (FR) and passive recovery (PR) on short-term symptoms of delayed-onset muscle soreness (DOMS) and military performance tasks (MPT). **METHODS:** Twenty participants (23.6 ± 4.1 years) completed a baseline session that included four MPTs: 1) stair climb, 2) cover-to-cover sprint, 3) ammunition can carry, and 4) 200-yd shuttle run. All tasks were completed while participants wore a 12-kg weighted vest and timed using photocell laser timing gates. Participants then completed two experimental sessions that included a DOMS-inducing exercise protocol followed by either a 20-min FR or 20-min PR, and a follow-up MPT test 24 hours later. Ratings of perceived exertion (RPE) were measured after each MPT. Ratings of muscle pain (RMP) were assessed prior to MPT and after FR and PR. A one-way repeated measures ANOVA was used to compare peak and mean MPT times across baseline, FR and PR sessions. If necessary, a post-hoc pairwise comparison with least significant difference was performed. Friedman test compared perceptual variables between the three sessions. Wilcoxon matched-pairs signed-ranks test evaluated post-recovery RMP between FR and PR. **RESULTS:** MPT times after PR were slower than baseline or post-FR measurements (Table 1). MPT mean and peak times differed for all but two tasks. In addition, a medium-large effect size was found for all variables. Post-recovery RMP approached significance ($p = .06$) showing a slightly lower median of 3.0 (IQR 2.3 - 4.0) for FR compared to a median of 4.0 (IQR = 3.0 - 6.0) for PR. There was no difference ($p = .21$) in RPE across the sessions. Similarly, no difference ($p = .09$) was found for RMP assessed before each MPT session. **CONCLUSION:** FR appears to be an effective and practical recovery

method for mitigating the negative performance effects associated with DOMS. Given the importance of military readiness, practitioners should consider including FR after strenuous exercise.

The Effects Of Foam Rolling On Exercise Induced Muscle Damage

Lauren M. Visconti, Brandon Beimborn, Kurt Escobar, Joshua A. Cotter, FACSM, Evan E. Schick. *California State University, Long Beach, Long Beach, CA.*

(No relevant relationships reported)

Exercise-induced muscle damage (EIMD) occurs following strenuous and unaccustomed exercise. EIMD is associated with elevated creatine kinase (CK) blood concentrations, limitations in range of motion (ROM), and cellular swelling. EIMD may negatively affect training quality and performance thus methods to mitigate EIMD may be useful to resistance training populations. Self-myofascial release, in particular foam rolling (FR), has been utilized by competitive and recreational athletes to ameliorate the effects of EIMD. However, the effect of FR on EIMD has yet to be established. **PURPOSE:** The purpose of this study is to investigate the effect of FR on markers of EIMD after an acute bout of high volume resistance exercise. **METHODS:** Eight participants (five males and three females), between the ages of 18 and 35, completed two acute resistance exercise bouts (10 sets of 10 repetitions barbell back squat at 60% 1RM) separated by a minimum of seven days. Following one exercise bout, subjects performed FR targeting the thigh (i.e. hamstrings and quadriceps), the shank (i.e. calf and tibialis anterior), and the gluteus maximus immediately post, 24, and 48 hours post exercise, while no FR was performed following the alternate bout (CON). In both conditions, participants were asked to refrain from additional recovery methods following exercise. Outcome measures included serum CK, hip ROM, knee ROM, and thigh circumference. All measurements were pre-exercise, immediately post, 24, and 48 hours post. **RESULTS:** There was a significant increase in serum CK from pre to 24 hours post ($p = 0.04$), as well as 24 and 48 hours post ($p = 0.04$). Hip ROM ($p = 0.02$) and knee ROM ($p = 0.03$) decreased and thigh circumference ($p = 0.03$) increased 48 hours post exercise. No significant differences between FR and CON were found for any measures. **CONCLUSION:** FR does not attenuate markers of muscle damage (i.e. serum CK, hip ROM, knee ROM, and thigh circumference) after an acute bout of high volume resistance training. This study suggests that despite its common practice, FR may not be an effective strategy for mitigating EIMD.

Artificial CO₂-water Immersion Facilitates Recovery From Muscle Fatigue Caused By High Intensity Anaerobic Exercise

Noriyuki Yamamoto¹, Tadashi Wada², Fumiko Takenoya³, Masaaki Hashimoto⁴. ¹Japanese Red Cross College Of Nursing, Kitami, Japan. ²Kokushikan Univ., Tokyo, Japan. ³Hoshi Univ., Tokyo, Japan. ⁴Teikyo. Univ. Sci., Tokyo, Japan.

(No relevant relationships reported)

In response to the CO₂-water (CO₂ ≥ 1000 ppm) immersion, the reduction of sympathetic nerve activity may imply the facilitation of muscle fatigue recovery. **PURPOSE:** In the present study, we investigated whether the whole body bath with CO₂-water influences recovery of the muscle fatigue after high intensity exercise. **METHODS:** The healthy male college students ($n=6$, 18-21yrs, 171.3±6.7cm, 73.6±13.0kg) participated in this study. The cycle ergometer work tests lasting 30 seconds were used to estimate anaerobic power with leg pedaling exercises. Exercise loads of the tests were 0.075kp per body weight. Anaerobic power was determined by measuring the highest power output during 30 seconds. Core temperature (CoreT) and ECG were recorded continuously throughout the experiment. The subjects performed 30-s maximal pedaling exercise, and took bath in tap- or CO₂-water at 35 °C for 10 minute after exercise. Subjective thermal sensation (TS) in the body bath was also recorded. Vastus lateralis (VL) dominant muscle hardness using the elastography, muscle pain by visual analog scale (VAS), and blood lactate (BLa) and were evaluated at pre- and immediately after-exercise, and at 10 min after exercise. **RESULTS:** The strain ratio (SR) between the VL and a reference material was calculated. TS in the CO₂-water was significantly higher than in the tap-water (tap-water vs. CO₂-water, $-0.17±0.76$ vs. $1.17±0.41$, $p<0.01$). At 10 min in recovery, in the CO₂-water compared with the tap-water, SR significantly decreased quicker ($0.49±0.25$ vs. $0.91±0.25$, $p<0.01$). However, there was no significant difference in CoreT, BLa and VAS between these two water kinds. **CONCLUSIONS:** We reported previously that the muscle blood flow in the immersed part was larger in CO₂-water than tap-water of a same temperature. In addition to a local effect of CO₂, suppression of muscular sympathetic activity may also contribute to the increase in local blood flow. Facilitation of muscle hardness recovery shown in this study might be caused by the increased muscle blood flow. The present results suggested that CO₂-water immersion may contribute to rapid recovery from the muscular hardness induced by high intensity exercise.

Neuromuscular, Endocrine, And Perceptual Recovery Following A Youth American Football Game

Jon K. Davis, Anthony S. Wolfe, Steven A. Basham, Eric C. Freese. *GSSI Frisco, Frisco, TX.*

Reported Relationships: J.K. Davis: Salary; Gatorade Sports Science Institute, PepsiCo Inc. The views expressed in this abstract are those of the authors and do not necessarily reflect the position or policy of PepsiCo, Inc..

PURPOSE: American football is a high-intensity intermittent sport consisting of various movements and repeated collisions which makes recovery from a game challenging to adequately prepare for the next competition. Therefore, the purpose of this study was to determine the time course of recovery assessed by neuromuscular function, salivary biomarkers, and perceptual fatigue following a youth American football game. **METHODS:** Thirteen male American football youth athletes were monitored for 7 days following a single football game. Baseline measures were taken at 28h pre-game for lower body neuromuscular function via countermovement jumps (CMJ) to determine peak power (PP), jump height (JH), flight time (FT), and takeoff velocity (TOV). Saliva was analyzed for cortisol, testosterone, and C-reactive protein (CRP). Perceptual recovery was assessed by modified profile of mood states (POMS), perceived recovery status (PRS), and a daily wellness questionnaire consisting of four 10-point Likert scale questions examining stress, muscle soreness, sleep quality, and energy. These measures were repeated immediately post-game (30min), and at 20h, 44h, 68h, 92h, 116h, 140h post-game. **RESULTS:** Compared to baseline values there was a significant decrease ($p<0.05$) in CMJ PP, JH, TOV up to 68h post-game and FT 44h post-game. No significant difference existed among time points for salivary testosterone and CRP. Salivary cortisol concentration significantly increased following the game (baseline $0.12±0.09\mu\text{g/dl}$, post-game $0.34±0.25\mu\text{g/dl}$; $p<0.05$). Daily wellness ratings for energy were significantly decreased (baseline $7.2±1.6$, post-game $4.7±2.4$; $p<0.05$) while daily wellness ratings for soreness were significantly increased (baseline $4.6±2.6$, post-game $6.3±1.3$ ($p<0.05$) immediately following the game. POMS total mood disturbance, significantly increased (baseline $-1.5±7.0$, post-game $15.6±9.4$; $p<0.05$) following the game. Athletes PRS exhibited a significant decrease in recovery up to 44h post-game ($p<0.05$), similar to the decrease in neuromuscular function. **CONCLUSION:** Neuromuscular function and PRS are impaired for up to 44-68h post-game. Coaches should consider the time course of post-game recovery when implementing practices and strength training to ensure adequate recovery from competition.

194 Board #10 May 27 9:30 AM - 11:00 AM
Effects Of Respiratory Impedance On Performance And Recovery

Ro-Anne Khrystel Galleta, Julia C. Robbert, Peggy A. Plato. *San Jose State University, San Jose, CA.* (Sponsor: Craig J. Cisar, FACSM)

(No relevant relationships reported)

Respiratory impedance has been studied as a possible countermeasure against fatigue during repeated bouts of high-intensity exercise. By creating resistance during inspiration, an impedance threshold device (ITD) decreases intrathoracic pressure and pulls more blood back to the heart, resulting in increased stroke volume and cardiac output. This increased blood flow may enhance exercise recovery by clearing metabolites and increasing tissue perfusion. **PURPOSE:** To examine the effects of breathing with an ITD during recovery between repeated bouts of high-intensity exercise. **METHODS:** Eleven participants (8 men, 3 women, 19-29 years-of-age) performed a total of 9, 20 s bouts of high-intensity exercise interspersed with 3 min of active recovery on an electronic bicycle ergometer. Participants were instructed to perform each exercise bout at an intensity that would elicit a rating of approximately 7 (very strong) on the Borg Category-Ratio scale of perceived exertion. The same exercise protocol was performed on different days, with and without the ITD during recovery. **RESULTS:** As expected, the exercise protocol significantly increased blood lactate (1.7 ± 0.2 mM pre-exercise vs. 11.5 ± 0.6 mM after bout 9, $p < .001$). Ratings of perceived exertion also increased across exercise bouts (4.9 ± 0.4 after bout 1, 7.5 ± 0.2 after bout 5, and 9.0 ± 0.2 after bout 9, $p < .001$). Participants rated their perceived recovery lower as the number of exercise bouts increased ($p < .001$). There were significant differences in peak and mean power output, as well as total work between exercise bouts, with the highest values recorded during the 9th bout (total work: 7434 ± 380 joules during bout 1, 8015 ± 266 J during bout 5, and 8391 ± 303 J during bout 9, $p < .01$). Thus, participants paced themselves during early bouts and gave a near maximal effort during the last bout. However, results were not significantly different between the control and ITD conditions. **CONCLUSION:** Use of an ITD during recovery periods between repeated, high intensity exercise bouts that required pacing did not positively impact subsequent performance. Results may be different if individuals perform repeated, high-intensity exercise that requires a maximal or near maximal effort during each exercise bout rather than a pacing strategy.

The Effects Of Foam Rolling On Fatigue-induced Performance Decrements In Trained Females: A Sham-control Study

Jennifer Rivera¹, Lee E. Brown, FACSM², Christian V. Ison¹, Gabriela Juache¹, Matthew R. Rodriguez¹, Edward Jo¹.
¹California State Polytechnic University, Pomona, Pomona, CA.
²California State Polytechnic University, Fullerton, Fullerton, CA. (Sponsor: Lee Brown, FACSM)
 Email: jrivera3@cpp.edu
 (No relevant relationships reported)

It remains commonplace for athletes to utilize self-myofascial release techniques like foam rolling during muscular fatigue situations to acutely support or at least preserve subsequent performance capacities. However, currently, there is limited evidence to support this specific application of foam rolling. **PURPOSE:** The purpose of this investigation was to examine the effects of foam rolling vs. a sham ultrasound control treatment following fatiguing exercise on subsequent performance in trained female subjects. **METHODS:** Twenty female subjects (age = 21.4 ± 1.1y) participated in this crossover design study. Subjects were tested for reactive strength index (RSI), peak isometric mid-thigh pull (IMTP) force, and fatigue perception followed by an exercise fatigue protocol. Then, subjects underwent either a foam rolling (FR) or sham ultrasound (CTL) treatment which was followed by repeat testing. A repeated measures ANOVA was used to examine the interaction of treatment (FR vs. CTL) x time (pre-vs. post-fatigue protocol) for each outcome measure. A dependent student T-Test was used to make comparisons between treatments on the pre- to post-fatigue protocol Δ score for each outcome measure. **RESULTS:** There was a significant treatment x time interaction for fatigue perception (p=0.03) and RSI (p=0.03) but not peak IMTP force. Both treatments resulted in a significant (p<0.05) increase in fatigue perception (FR: +3.2 ± 1.8 cm; CTL: +4.1 ± 2.1 cm) and decrease in RSI (FR: -8.9 ± 6.9 %; CTL: -11.9 ± 7.5%) from pre- to post-fatigue protocol. Further analyses revealed that the increase in fatigue perception following FR was significantly less than CTL (p=0.03). Additionally, the decrease in RSI following FR was significantly less than CTL (p=0.02). The fatigue-induced decrease in peak IMTP force did not differ between treatments. There was no significant correlation between the pre- to post-fatigue change in RSI and fatigue perception (p=0.10; r = -0.3). **CONCLUSIONS:** In conclusion, this study corroborates a prior non-sham-controlled investigation in that foam rolling during neuromuscular fatigue situations may aid in the preservation of performance while reducing perception of fatigue.

Soreness And Fatigue As The Key Perceptual Indicators For Previous Day Workload In Athletes

Hanna Gardner, William Adams, Travis Anderson, Eleni Karras, Stacey Walton, Laurie Wideman, FACSM. *University of North Carolina at Greensboro, Greensboro, NC.* (Sponsor: Laurie Wideman, FACSM)
 Email: hmgardne@uncg.edu
 (No relevant relationships reported)

PURPOSE: As monitoring of athletes has become prominent throughout competitive sport, objective and subjective methods have proven valuable in informing of an athlete's physical condition and preparedness. However, it remains unclear how objective load metrics are reflected in self-reported subjective indices. Thus, the purpose of this study was to examine the relationship between objective markers of workload and subjective assessments of soreness, fatigue, and stress the following day. **METHODS:** Twenty-six collegiate male soccer players (mean±SD; 20±1y; 75.83±5.90kg; 178.5±6.8cm) wore GPS-enabled heart rate monitors during every training session and match within the 2017 season. Objective load variables (total distance covered (TD), number of sprints (SP), number of accelerations (AC), number of decelerations (DC), and training load (TL)) were collected each day. Subjective load (soreness, fatigue, and stress) were reported on a 1-10 Likert scale the following morning. Mixed models tested the relation between subjective metrics and the objective metrics of the previous day's training or match. **RESULTS:** Training load and deceleration numbers from the day before showed significant relevance to reported scores of soreness and fatigue. Heavier training loads resulted in higher soreness and fatigue scores (TL P<0.001), just as lighter training loads resulted in lower soreness and fatigue scores. A similar positive correlation was found with the number of decelerations to reported soreness and fatigue (DC P=0.023). **CONCLUSIONS:** Lasting physiological impacts of the previous day's training load and decelerations were reflected in player-reported soreness and fatigue the following morning. This information may be utilized by coaching staff to; 1) adjust training based on subjective metric scores and 2) inform tapering strategies to maximize performance in matches.

Self-reported Sleep Habits During A Professional American Football Season

Steven A. Basham¹, Anthony S. Wolfe¹, Eric C. Freese¹, Bridget C. Sopena², Timothy J. Roberts³, Jon K. Davis¹, Melissa L. Anderson³. ¹Gatorade Sports Science Institute, Frisco, TX. ²Gatorade Sports Science Institute, Barrington, IL. ³Gatorade Sports Science Institute, Bradenton, FL.
 Email: steven.basham@pepsico.com

Reported Relationships: S.A. Basham: Salary; Gatorade Sports Science Institute, PepsiCo Inc. The views expressed in this abstract are those of the authors and do not necessarily reflect the position or policy of PepsiCo, Inc...

American football is physically and psychologically demanding, thus highlighting the potential need for adequate sleep for recovery. **Purpose:** To investigate self-reported sleep habits over the course of a seven-week football season and determine how game load may impact sleep. **Methods:** Professional football players (n = 24; 25.9 ± 2.7 y) were recruited from the Alliance of American Football league. A customized sleep survey was used to ask about sleep duration (SLD), "How many hours of sleep did you get last night?" and sleep quality (SQ), "What was your quality of sleep", while a total sleep score (TSS) was calculated using SLD and SQ, with higher scores meaning better sleep. Players completed the sleep survey sent via automated text message at 0800h the day before each game (GD-1), game day (GD) and each day following game day (GD+1, GD+2, GD+3, GD+4, and GD+5) during the seven-week season. Game load was recorded and defined as total snaps played for each game. A mixed-effects model was used to measure changes in all variables, while a Pearson's correlation coefficient was used to assess relationships between game load and sleep variables. Two, three, and four-day averages for all sleep variables were calculated and correlated with the respective game load. **Results:** A significant interaction for GD x time (p < 0.05) for SLD was observed, where players slept less on GD (6.1 ± 1.3 h) and GD+2 (6.7 ± 0.7 h) compared to GD-1 (8.5 ± 0.9 h) for week three, and GD+5 (6.3 ± 0.8 h) compared to GD-1 (8.4 ± 0.6 h) for week seven. Overall, SLD was higher on GD-1 (8.1 ± 0.9 h) than all other time points (p < 0.05). No significant main effect or interaction was found for SQ (p > 0.05). Overall, the TSS was significantly higher on GD-1 (7.0 ± 1.8 AU; p < 0.01) compared to GD, GD+2, GD+3, and GD+4 (5.4 ± 2.2; 5.6 ± 1.6; 5.8 ± 1.4; 6.1 ± 0.9 AU; respectively). Significant positive correlations for game load were found with SQ for two (r = .34, R² = 0.119, p < 0.05), three (r = .39, R² = 0.155, p < 0.01) and four (r = .50, R² = 0.247, p < 0.01) day averages and the TSS for two (r = .29, R² = 0.083, p < 0.05), three (r = .29, R² = 0.084, p < 0.05), and four (r = .37, R² = 0.139, p < 0.01) day averages, but not for SLD. **Conclusions:** Professional football players reported impaired SLD and TSS up to 5 days following a football game. Higher game load was associated with better SQ in the days following the game.

198 Board #14 May 27 9:30 AM - 11:00 AM
Effects Of Percussion Massage On Delayed Onset Muscle Soreness

Michael E. Rogers, FACSM, Nicole L. Rogers. *Wichita State University, Wichita, KS.*
 Email: michael.rogers@wichita.edu
 (No relevant relationships reported)

Delayed-onset muscle soreness (DOMS) is common 24-72 hr after engaging in resistance training. Manufacturers of percussion massage devices have stated that such devices decrease muscle soreness. **PURPOSE:** To determine the effects of percussion massage on pain and performance in those with DOMS. **METHODS:** 25 untrained college-aged adults (16 women and 9 men; 22.9±0.9 yr; 69.1±7.2 kg; 155.0±14.6 cm) participated in the study and were instructed to refrain from exercise and consuming or applying any type of anti-inflammatory medication 24 hr before, and throughout the duration of, the study. Participants initially rated leg pain using a scale ranging from 0 (no pain) to 10 (pain as bad as it could be) and performed a vertical jump test. Then, after determining 1-RM, they performed 10 sets of 10 repetitions of barbell back squats at 60% of their 1RM to elicit DOMS. Squats were performed to a predetermined depth using stacked 5-cm spacers so the femurs were parallel to the floor at the end of the eccentric phase. 48 hr later, participants, rated leg pain, performed the vertical jump test, and then had percussion massage applied to each leg (5 sets of 1 min per quad for 10 min total). Following this, participants again rated leg pain and repeated the vertical jump test. **RESULTS:** Participants reported no pain (0.0) and had a vertical jump height of 61.33 cm at baseline. 48 hr later, pain was rated as 6.55 (severe pain) and had 8.0% lower (p<0.05) vertical jump height (56.42 cm) compared to baseline. After percussion massage, pain declined (p<0.01) to 5.38 (moderate pain) and vertical jump height increased (p<0.05) by 4.2% to 58.77 cm, although this was still lower (p<0.05) than baseline. **CONCLUSIONS:** This study supports previous studies that have found that a single bout of resistance training can inflict severe DOMS. Results also indicate that percussion massage reduces pain and improves performance in those with DOMS. However, additional studies are needed to determine the effects of percussion massage on other types and levels of pain as well as on other types of performance measures.

199 Board #15 May 27 9:30 AM - 11:00 AM
Effects Of Percussion Massage On Hamstring And Low Back Flexibility

Nicole L. Rogers, Michael E. Rogers, FACSM. *Wichita State University, Wichita, KS.* (Sponsor: Michael E. Rogers, FACSM)
 Email: nicole.rogers@wichita.edu
 (No relevant relationships reported)

The sit and reach (SR) test is a common field test used to measure hamstring and low back flexibility. It is believed that hamstring and low back flexibility may prevent acute and chronic musculoskeletal injuries. Manufacturers of percussion massage devices have stated that such devices increase range of motion (ROM). **PURPOSE:** To determine the effects of percussion massage versus traditional static stretching on hamstring and low back flexibility. **METHODS:** 25 untrained college-aged adults (16 women and 9 men; 22.9±0.9 yr; 69.1±7.2 kg; 155.0±14.6 cm) participated in the study. Percussion massage and static stretching were performed on two separate days in random order with 48 hr between trials. At baseline on each day, participants performed the SR test. Participants then had vibration massage applied to the hamstrings and low back (1 min for each leg and low back in alternating fashion for 3 sets) or performed static stretching of each hamstring using a stretch strap and a low back stretch (1 min for each leg and low back in alternating fashion for 3 sets). Participants then performed the SR test again. The best of three SR test trials in each of the four testing conditions was used for analysis. **RESULTS:** Static stretching resulted in an improvement ($p=0.03$) of 7.2% (pre=13.1±4.4 cm; post=14.0±4.7 cm). Percussion massage did not affect ($p=0.13$) ROM (pre=13.4±4.4 cm; post=13.7±4.7 cm). **CONCLUSIONS:** Results indicate that percussion massage does not affect hamstring and low back flexibility. However, additional studies are needed to determine if longer applications of percussion vibration may improve ROM.

200 Board #16 May 27 9:30 AM - 11:00 AM
The Efficacy Of Prolonged Cooling Using Phase Change Material For Enhancing Recovery Following A Marathon

Susan Y. Kwiciec¹, Malachy P. McHugh, FACSM¹, Kirsty M. Hicks², Karen Keane², Glyn Howatson, FACSM². *Lenox Hill Hospital, New York, NY.* ²*Northumbria University, Newcastle upon Tyne., United Kingdom.* (Sponsor: Malachy P McHugh, FACSM)
 Email: susan@nismat.org
 (No relevant relationships reported)

PURPOSE: Athletes often utilize cryotherapy interventions following exercise to mitigate muscle damage, inflammation and feelings of soreness. The literature has shown only small benefits from cryotherapy on accelerating recovery from exercise. The practical utility of modalities such as cold water immersion is questionable. Phase change material (PCM) packs can provide prolonged cooling while simultaneously allowing the wearer to continue with activities of daily living and, thus, is a more practical alternative to other cryotherapy modalities. The aim of this study was to test the efficacy of a single prolonged cooling treatment using PCM following completion of a marathon on soreness, strength, muscle damage and inflammation on the days after running a marathon.

METHODS: Twenty-four participants (8 male, 16 female) completed a marathon and were randomized to receive the post-race intervention (3 h of 15°C PCM covering the quadriceps) or recover without an intervention (control). Soreness, knee extension strength, vertical jump height, creatine kinase (CK), and high sensitivity c-reactive protein (hsCRP) were recorded at baseline, 1, 2, and 3 days following the marathon. **RESULTS:** Soreness increased following the marathon ($P < 0.0001$) in both groups, but was lower in the PCM group (treatment effect $P = 0.028$) and resolved faster (treatment by time $P < 0.044$; D3 soreness: 1.1 ± 0.9 PCM vs 2.7 ± 1.6 control). Strength decreased following the marathon in both groups ($P < 0.0001$) with no difference between groups. Although not significant, by Day 3 strength recovered more in the PCM (98.6 ± 15.6%) vs. control group (90.4 ± 7.6%). PCM had a beneficial effect on jump height (treatment effect $P = 0.037$, treatment by time $P = 0.031$); over the 3 days post-race, jump height averaged 101 ± 10% of baseline in PCM treatment versus 89 ± 10% in the control condition ($P = 0.037$). CK and hsCRP increased over time (both $P = 0.0001$) peaking on D1, with no difference between groups.

CONCLUSIONS: Prolonged post-marathon PCM cooling accelerated resolution of soreness and recovery of vertical jump performance, but had no effect on other indices of damage or inflammation. PCM cooling is a practical, wearable cryotherapy modality that can facilitate recovery following excessive exercise stress.

The Effect Of Percussive Massage Versus Foam Rolling On Recovery Between Two 91 Meter Swims

Ryan Mullin, Casey Spor, Jessica Diaz, Peter Byrne, Jacob Virginia, Robert Otto, FACSM, Michele Aquino, John Petrizzo, John Wygand, FACSM. *Adelphi University, Garden City, NY.* (Sponsor: Robert Otto, FACSM)
 Email: ryanmullin@mail.adelphi.edu

Reported Relationships: R. Mullin: Industry contracted research; Theragun®.

Swim competition often requires repeat bouts of the same event, as well as several different events for each swimmer. Multiple events during the competition may influence subsequent outcomes, thus various strategies are employed to enhance recovery and reduce fatigue. The search for the optimal recovery is never ending. Two of the more popular recovery techniques include foam rolling massage and percussive massage. There is a paucity of research to support the efficacy of either. **Purpose:** The purpose of this study was to assess the effect of no massage (NM), foam roller massage (FM) and percussive massage (PM) on repeated swim performance separated by 30 minutes of recovery. **Methods:** 8 male and 12 female college-aged swimmers (age: 20.9 ± 2.8 yr., height: 171.7 ± 8.6 cm., weight 70.3 ± 10.9 kg.) volunteered to participate in three 91 meter repeat swim trials. Blood lactate (BL) was measured two minutes pre-swim and three minutes post-swim. A randomized, single blind crossover application of FM, PM, or NM was conducted between each of the two 91meter maximal velocity swims. For both FM and PM the treatment was applied bilaterally for a total of 16 minutes with 2 minutes per muscle group (calves, hamstring, quadriceps, and upper arms). **Results:** For the first vs second bout of each trial, male times were 52.3 ± 2.5 vs 52.7 ± 2.7 sec, 52.2 ± 2.7 vs 52.3 ± 2.8 sec, and 52.5 ± 2.3 vs 52.4 ± 2.6 sec and female times were 63.7 ± 3.6 vs 63.9 ± 3.8 sec, 63.4 ± 3.9 vs 63.8 ± 3.8 sec and 63.9 ± 4.0 vs 63.0 ± 3.8 sec for FM, PM, and NM trials, respectively. Statistical analysis by dependent T-test ($P < .05$) revealed NSD ($p > .05$) pre vs post between trials, except that the second swim was slower than the first swim in the male FM trials. Mean BL values post first swim were 8.5 ± 3 mmol, 8.8 ± 2.56 mmol, 9.1 ± 2.2 mmol, and pre second swim lactate values were 3.4 ± 1.8 mmol, 3.9 ± 1.6 mmol, 4.0 ± 1.7 mmol for FM, PM, and NM respectively. Statistical analysis of BL by ANOVA revealed no significant difference across all trials ($p > .05$). **Conclusion:** The mode of recovery did not improve velocity in repeat 91 meter swim bouts or alter the time course for post-swim BL recovery. Supported, in part by a grant from Theragun®.

The Effect Of Percussive Massage Versus Foam Rolling On Recovery Between Two 1000 Meter Runs

Casey Spor, Jessica Diaz, Peter Byrne, Ryan Mullin, Jacob Virginia, John Petrizzo, Robert Otto, FACSM, Michele Aquino, John Wygand, FACSM. *Adelphi University, Garden City, NY.* (Sponsor: Robert Otto, FACSM)
 Email: caseyspor@mail.adelphi.edu

Reported Relationships: C. Spor: Industry contracted research; Theragun®.

Interest in effective methods to reduce recovery time related to athletic performance is an area of interest in competitive sports. Many of the methods purported to enhance recovery and improve repeat performances are unproven. These methods include foam rolling and more recently, percussive massage. **Purpose:** The purpose of this study was to compare repeated running performance under the conditions of no massage (NM), foam rolling (FR) and percussive massage (PM) when implemented during the rest period between two running trials. **Methods:** 20 recreationally active college-age students (age: 22.5 ± 2.8 yrs., height: 176.2 ± 8.0 cm, body mass: 70.8 ± 11.1 kg, 11 ♂) volunteered to participate in a randomized, single-blind, crossover design study. Three trials consisting of two repeat 1000m runs separated by 30 minutes of rest were conducted with a minimum of 48 hrs. between trials. The 30 minute recovery was to simulate the time between races in a track event. Finger stick blood lactates were taken three minutes post run, as well as before the second run. During the 30 minute recovery the subjects received one of the three treatments NM, FR, and PM. For PM the treatment was applied bilaterally, for a total of 12 minutes with two minutes per muscle group (calves, hamstrings, and quadriceps). FR trials followed the same protocol. Run time(sec) and lactate values(mmol) were recorded for all trials. **Results:** Statistical analysis by ANOVA ($P < .05$) revealed no significant difference in run performance time among all conditions. Mean pre-intervention times were: 245 ± 24, 244 ± 23, and 246 ± 24 and post-intervention times were: 246 ± 22, 245 ± 23 sec, and 247 ± 23 for NM, FR, and PM respectively. Blood lactate significantly decreased from post first run: 11.2 ± 2.3, 11.7 ± 2.3, and 10.7 ± 2.0 to the pre-second run with values of 5.1 ± 2.1 mmol, 5.5 ± 2.2mmol, and 5.1 ± 1.7 mmol for NM, FR, and PM respectively, with no significant difference among conditions. **Conclusion:** Although subjects reported enhanced recovery with the interventions, the results of this study suggest that

percussive and non-percussive massage do not affect performance time in a 1000m run nor do they alter the time course for blood lactate attenuation. Supported, in part by a grant from Theragun®.

Test-retest Reliability And Performance Differences Between Traditional Upper Quarter Y-balance Test And Two Modifications**

Tal Amasay. *Barry University, Miami Shores, FL.*
Email: tamasay@barry.edu
(No relevant relationships reported)

The traditional Upper Quarter Y-Balance Test (TUQYBT) tests mobility and stability of the shoulder. The TUQYBT is performed in a push-up position, while the contralateral arm is pushing a reach indicator maximally in the medial, superolateral, and inferolateral directions. The TUQYBT has proven to be beneficial in analyzing shoulder function, specifically for athletic and active populations. It has not been proven to be suitable for the older adults and obese populations. Research shows that 67% of bodyweight is carried during the up position of push-up. During the TUQYBT this weight is shifted to one shoulder, which place a lot of stress on it. A decrease of 15% of the body load was found during a modified push-up (knees down) position. Moreover, load will further be reduced when performing a push-up in standing position on the wall.

PURPOSE: To determine test-retest reliability of two modified UQYBTs (modified push-up and standing positions) and to identify performance differences with respect to TUQYBT. **METHODS:** Twenty-five students (nine men, 16 women; mean age 24.4±3.3 and 23.6±3.3 years), performed three variations of the UQYBT. Cronbach's Alpha test-retest reliabilities were performed to analyze data consistency. Two separate one-way repeated measures ANOVAs were performed to determine the effect of the three starting UQYBT positions on the composite reach scores for each side, followed by post-hoc analyses. **RESULTS:** Findings revealed consistency for the two UQYBT modifications in all three reach directions, Cronbach's Alpha values 0.87-0.99. Significant main effects were found on the right ($F(2,72) = 6.19, p = 0.003$) and left ($F(2,72) = 4.12, p = 0.004$) sides. Post-hoc analyses revealed that the standing UQYBT composite scores were significantly higher for both sides (right 73.1±7.5 cm, left 73.1±7.2 cm) than the modified push-up (right 68.5±7.5 cm, left 69.5±7.9 cm) and TUQYBT (right 65.2±9.0 cm, left 66.5±9.0 cm) scores ($p < 0.05$). The modified UQYBT composite scores, for both sides, were significantly higher than TUQYBT scores ($p < 0.05$). **CONCLUSION:** It appears that the modified UQYBTs may be suitable for populations such as older adults and obese, who may have difficulty holding themselves up during the TUQYBT. Future research is needed to determine applicability in these populations.

Measuring Energy Expenditure Independent Of The Respiratory Quotient During Rest And Exercise**

Seif A. Alshakah¹, John R. Macaulay¹, Paul Gerges¹, Stella Crall¹, Marshall D. McCue², Derek C. Monroe¹. ¹University of California Irvine, Irvine, CA. ²Sable Systems International, Las Vegas, NV.
(No relevant relationships reported)

Widely used measures of energy expenditure (EE) are based on Weir's (1949) equation that relies on oxygen utilization and carbon dioxide production to derive a respiratory quotient (RQ). However, Weir's RQ-free equation, presented in the same article, was only recently validated to measure home-cage EE in rodents. It has not yet been used to measure EE in humans.

PURPOSE: To evaluate an RQ-free method for measuring EE at rest and during submaximal and maximal intensity treadmill running. **METHODS:** A convenience sample of 27 physically-active college students (17 women) were recruited to perform a maximal treadmill test until volitional exhaustion (Bruce protocol). EE (kcal/min) was measured continuously at 10 Hz using an open-flow respirometry system (Sable Systems Intl.; Las Vegas, NV). EE was down-sampled and averaged at rest (EE_{Rest}), during the first stage (EE_1), during the last completed stage (EE_{Submax}), and during the final stage (EE_{Max}). The intensity (VO_2 ; ml/kg*min) of the last completed stage and the final stage were calculated based on speed and incline using ACSM equations. Heart rate (HR) was measured at rest and every minute during the test. Participants rated their perceived exertion (RPE) at the end of each stage. VO_{2max} was estimated based on the total time spent walking/running on the treadmill. Four multiple regression models were used to predict EE from participant traits (PT;

gender, age, weight), stage intensity, HR, RPE, and estimated VO_{2max} (EE_{Max} only). A repeated-measures ANOVA was used to test the degree to which changes in EE were explained by changes in HR (treated as a time-varying covariate).

RESULTS: EE_{Rest} was predicted by PT and resting HR [$p < .001, R^2 = .658$]. EE_1 was predicted by PT and HR and RPE in Stage 1 [$p < .001, R^2 = .871$]. EE_{Submax} was predicted by PT, the intensity of, and HR and RPE response to, the last completed stage [$p < .001, R^2 = .844$]. EE_{Max} was predicted by PT, VO_{2max} , and the intensity of, and HR and RPE response to, the final stage [$p < .001, R^2 = .746$]. 83% of the increase in EE, from rest to the final stage, was explained by increasing HR.

CONCLUSIONS: The reliability (R^2) of our models for predicting EE at rest and during exercise are comparable to published RQ-dependent models, supporting the utility of an RQ-free method for measuring EE during submaximal exercise.

Comparison Of Sweat Vs. Serum Lactate And Glucose Concentrations During Exercise**

Corey T. Ungaro, Kelly A. Barnes, Adam J. Reimel, Ryan P. Nuccio, Shyretha D. Brown, Lindsay B. Baker, FACSM. *Gatorade Sports Science Institute, Barrington, IL.*
Email: corey.ungaro1@pepsico.com
(No relevant relationships reported)

Research has been equivocal on whether or not sweat lactate ([Lac]) and glucose ([Gluc]) are related to serum [Lac] and [Gluc]. **Purpose:** To determine the relationship between sweat [Lac] and [Gluc] versus serum [Lac] and [Gluc] during cycling exercise in the heat for 90 min. **Methods:** Twelve moderately-trained recreational athletes (38 ± 6 y, 75.6 ± 14.5 kg, $VO_{2max} 45.6 \pm 7.7$ ml/kg/min) completed 90 min of cycling at $78 \pm 5\%$ HR_{max} in the heat ($31^\circ C, 50\% RH$). Prior to exercise, the forehead was cleaned with alcohol and deionized water, then three absorbent patches (10 cm² absorbent pad, 3M Tegaderm™ + Pad) were applied sequentially (at 0, 30, and 60 min) and each patch was removed after 30-min increments of exercise alongside a synchronous blood draw. The forehead was re-cleaned with deionized water between each patch removal/application. Sweat and serum [Lac] and [Gluc] were measured using ion chromatography. Descriptive statistics were conducted across all collection time points for sweat and serum [Lac] and [Gluc]. Pearson's product-moment correlations were performed to assess the relation between sweat and serum [Lac] and [Gluc] at the 90-min collection period. Due to limited sample volume the final n was 10 for each marker. Data are shown as mean \pm SD. **Results:** Forehead sweat [Lac] was $13.88 \pm 3.29, 11.49 \pm 3.13, 11.91 \pm 4.08$ mM and serum [Lac] was $2.89 \pm 1.33, 2.84 \pm 0.64, 3.09 \pm 1.13$ mM, at 30, 60, and 90 min, respectively. Forehead sweat [Gluc] was $0.425 \pm 0.417, 0.270 \pm 0.239, 0.357 \pm 0.284$ mg/dL and serum [Gluc] was $69 \pm 15, 73 \pm 16, 73 \pm 13$ mg/dL, at 30, 60, and 90 min, respectively. There was a moderate, but non-significant, positive correlation between sweat and serum [Lac], $r(8) = 0.485, p = 0.155$ and a minimal, but non-significant, positive correlation between sweat and serum [Gluc], $r(8) = 0.186, p = 0.606$. **Conclusion:** Sweat [Lac] and [Gluc] explain only 24% and 3% of the variation in serum [Lac] and [Gluc], respectively; suggesting other factors (aside from serum) impact sweat [Lac] and [Gluc]. Further research is warranted to understand the presence of lactate and glucose in the sweat and their applicability and relevance for use as biomarkers.

Elite Athletes Have Mildly Elevated Serum Bilirubin Concentrations**

Jana Woronyczová¹, Miroslava Nováková², Martin Leniček³, Emil Bolek², Renata Cífková⁴, Libor Vítek³. ¹Ist Faculty of Medicine, Charles University and Sports Research Institute of Czech Army Forces, Prague, Czech Republic. ²Sports Research Institute of Czech Army Forces, Prague, Czech Republic. ³Ist Faculty of Medicine, Charles University, Prague, Czech Republic. ⁴Center for Cardiovascular Prevention, Ist Faculty of Medicine and Thomayer Hospital, Prague, Czech Republic.
Email: jana.woronycz@seznam.cz
(No relevant relationships reported)

Bilirubin is a potent endogenous antioxidant and immune system-modulating substance, which is implicated also in the cell signaling and in various metabolic pathways. Mild elevation of its systemic concentrations seems to provide substantial protection against numerous pathological conditions such as atherosclerotic and inflammatory diseases. Scarce reports in the literature suggest that serum bilirubin might have relevance also to the physical performance. **Purpose:** The aim of the current study was to assess serum bilirubin concentrations in the Czech elite athletes and to compare them with the Czech general population. **Methods:** The study was performed in 145 consecutive healthy Czech elite athletes (M:F ratio=1.78) and in 2597 individuals (M:F ratio=0.91) of the Czech post-MONICA study randomly selected from the Czech general population. Serum bilirubin concentrations as well as prevalence of benign hyperbilirubinemia >17 $\mu mol/L$ (1 mg/dL, a phenotypic sign of Gilbert's syndrome) were evaluated. **Results:** The medians of serum

bilirubin concentrations in the elite athletes were substantially higher compared to the general population (11.75 vs. 9.6 $\mu\text{mol/L}$, $p < 0.001$), and this substantial difference was observed in both men (13.02 vs. 11.3 $\mu\text{mol/L}$, $p = 0.006$) and women (10.29 vs. 8.3 $\mu\text{mol/L}$, $p < 0.001$). Compared to the general population, the prevalence of a phenotypic Gilbert's syndrome (known also as benign hyperbilirubinemia) was significantly higher in both male (18.4% vs. 31.1%, $p = 0.004$) and female athletes (7.4% vs. 17.3%, $p < 0.001$). **CONCLUSIONS:** Elite athletes have significantly higher serum concentrations of bilirubin, the most potent endogenous antioxidant substance. Simultaneously, also the prevalence of Gilbert's syndrome is higher in elite athletes, suggesting that the presence of Gilbert's syndrome may predispose to better physical performance. This study was supported by grant No. SVV 260156/2019 provided by Charles University.

Salivary Hormone Critical Difference And Biological Variation In A Professional American Football Season

Anthony S. Wolfe¹, Steven A. Basham¹, Bridget C. Sopena², Melissa L. Anderson³, Timothy J. Roberts³, Jon K. Davis¹, Eric C. Freese¹. ¹Gatorade Sports Science Institute, Frisco, TX. ²Gatorade Sports Science Institute, Barrington, IL. ³Gatorade Sports Science Institute, Bradenton, FL.

Reported Relationships: **A.S. Wolfe:** Salary; Gatorade Sports Science Institute, PepsiCo Inc. The views expressed in this abstract are those of the authors and do not necessarily reflect the position or policy of PepsiCo, Inc..

Although a large body of research has investigated various hormonal and immunological responses to exercise, few studies have assessed the biological significance of those responses utilizing critical difference values (CDV) and biological variation (BV) in the context of monitoring biomarkers in professional athletes. **Purpose:** To assess salivary hormone changes over a professional American football season and determine if individual monitoring of these biomarkers is valuable. **Methods:** Professional American football players ($n = 24$) were recruited to provide weekly saliva samples over the course of a seven week season. Saliva samples were collected between 0600 and 0800 hours following an overnight fast and a mouth rinse with distilled water. Eight samples (two baseline and six weekly samples) were collected per player and analyzed for salivary testosterone (T), cortisol (C), uric acid (sUA), and immunoglobulin A concentration (SIgA). Player data were included for analysis if they provided samples at $\geq 70\%$ of all collection time points ($n = 17$). Data were analyzed using parametric statistics after confirmation of normality by Shapiro-Wilk and Reed's Criterion tests. The within-subject biological variation, CDV, and index of individuality (II) were calculated in accordance with the methods of Frasier and Harris. Lastly, relative percent change from baseline for each weekly collection was assessed using repeated measures one-way ANOVA. **Results:** The CDV for salivary T, C, sUA, and SIgA were 27.5%, 61.3%, 48.0%, and 59.2%; while BV was 10.8%, 26.1%, 20.5%, and 25% respectively. II was calculated as 0.93, 0.52, 0.59, and 0.65 (arbitrary units) for T, C, sUA, and SIgA, respectively. All hormones exhibited significant differences between players ($p < 0.001$), however were not significantly different between weeks ($P > 0.05$). **Conclusion:** These data suggest that individual players experience week-to-week variation in salivary hormone response over a professional American football season, however team-wide fluctuations are minimal. Furthermore, the relatively low II values may imply that these salivary biomarkers are useful in terms of monitoring meaningful individual changes across a season.

208 Board #24 May 27 9:30 AM - 11:00 AM
Validation Of The Humon Hex Lactate Threshold Estimate

Tyson Trainor¹, Bryson Carrier², Brayden Jolley³, Andrew Creer¹. ¹Utah Valley University, Orem, UT. ²University of Nevada, Las Vegas, Las Vegas, NV. ³Tulane University, New Orleans, LA.

(No relevant relationships reported)

Fitness trackers track a wide range of fitness and physiological metrics, including muscle oxygen saturation and lactate threshold (LT). The Humon Hex (HH) is a low-cost wearable device that uses continuous-wave near-infrared spectroscopy (NIRS) to determine muscle oxygen saturation. The HH is unique in its ability to estimate LT based on muscle oxygen saturation during a threshold test. **Purpose:** The purpose of this study was to determine the validity and accuracy of predicting LT from continuous-wave NIRS compared to lab-based measurements. **Methods:** 15 healthy, recreational runners (6 male, 9 female, 26.1 ± 6.4 yrs, 67.9 ± 16.3 kg, 173.3 ± 9.5 cm, 31.6 ± 21.5 km/week) participated in a single threshold test on a treadmill. The protocol was dictated by the HH device ("Threshold Test" in the app) and involved increasing treadmill velocity by 0.22 m/s (0.5 mph) every 3 min until volitional exhaustion. At the end of each stage, participants would straddle the treadmill while researchers collected and analyzed the blood lactate levels using a Lactate Scout portable lactate analyzer (Lactate.com). The HH LT estimate was provided by the Humon website.

Blood lactate levels were recorded and graphed, and LT was derived by identifying the point immediately prior to where lactate levels had a greater than 1 mmol/L jump from the previous stage that also placed the total lactate concentration above 4 mmol/L. A 2-tailed, paired t-test, mean absolute percentage error (MAPE), single measures Intraclass Correlations (ICC), and Bland-Altman analysis with accompanying bias and Limits of Agreement were performed, calculated and plotted. **Results:** There was no difference between the HH estimated LT velocity compared to the lab-based methods (12.5 ± 2.0 km and 12.7 ± 1.3 km/hr, respectively). There was a MAPE of 9.00% and an ICC of 0.652 with a 95% confidence interval of -0.222 to 0.869 ($F(15,15) = 4.546$, $p = 0.004$) when comparing the variables. **Conclusion:** Although there was no difference between HH estimated LT velocity compared to laboratory testing, the MAPE was above 5% and ICC slightly below 0.7 with a significant relationship. This data suggests that the HH does not produce a completely valid estimate of LT compared to lab-based tests; however, it still may be useful in situations where laboratory testing may not be available or practical.

209 Board #25 May 27 9:30 AM - 11:00 AM
Exercise As A Tool For Evaluation Of A Novel Subcutaneous Lactate Monitor

Nitsan Dror, John Weidling, Shlomit Radom-Aizik, Sean White, Francesca Ortenzio, Elliot Botvinick. University of California Irvine (UCI), Irvine, CA. (Sponsor: Bareket Falk, FACSM)

Email: nitsand@uci.edu

(No relevant relationships reported)

BACKGROUND: Lactate levels are commonly used as an indirect measure to assess metabolic stress both in exercise (e.g., anaerobic threshold and exercise intensity) and clinical conditions like sepsis. The current method for measuring blood lactate does not meet the need in clinical settings. Multiple blood draws and long processing preclude timely decision-making in clinical practice. A minimally invasive, blood free, continuous lactate monitor can improve clinical decisions and patient care.

PURPOSE: To evaluate continuous lactate measurements of a novel enzymatic, Continuous Lactate Monitor (CLM), that was developed in our laboratory, during incremental cycling exercise challenges.

METHODS: Five healthy individuals 18-45 y/o (3 males, 2 females) participated in the study. Two CLM devices were inserted subcutaneously in the lower back flank an hour before the exercise challenge. Each exercise challenge consisted of a 12-minute warm up and up to 7, 4-min incremental workload bouts separated by rest intervals. Continuous lactate measures obtained from CLM were compared with commercial lactate analyzer (Abbott iSTAT) measures taken at 12 time points from venous blood, drawn from the antecubital vein: before, during exercise, and up to 120 minutes post exercise. Area under the curve (AUC), and delay time were calculated to compare the CLM readings with blood lactate.

RESULTS: Average blood lactate increased from 1.02 to 16.21 mM/L. Ratio of AUC derived from CLM to blood lactate was 1.09 (1.01-1.22). Average difference between CLM and blood lactate, with linear interpolation between blood lactate measurement, was 1.4 mM/L (0.878-2.37). At the lower levels of lactate (baseline), CLM sensitivity was lower. Average delay time between CLM readings and blood lactate was 6.16 minutes (3.70-11.21).

CONCLUSIONS: The newly developed CLM has shown to be a promising tool to continuously measure lactate in a minimally invasive fashion. Results indicate the CLM can provide needed trends in lactate over time. Such a device may be used in the future to improve treatment in clinical conditions such as sepsis, assess the response to endurance exercise in both clinical and athletic settings, and guide exercise prescriptions. Supported by PERC Systems Biology. *N.D. and J.W. equal contribution

Effect Of Exercise Setting On Energy Expenditure And Enjoyment During Active Virtual Reality Gaming

Trenton Huynh Stewart, Kirsten Villanueva, Amanda Hahn, Julissa Ortiz, Chandler Wolf, Randy Nguyen, Nicole D. Bolter, Marialice Kern, FACSM, James R. Bagley. San Francisco State University, San Francisco, CA. (Sponsor: Marilice Kern, FACSM)

Email: tstewart1@sfsu.edu

(No relevant relationships reported)

PURPOSE: Recent work by our lab (Gomez, et al., 2018) has shown that active virtual reality games (AVRGs) can elicit exercise intensities that meet American College of Sports Medicine (ACSM) recommended exercise guidelines for preventative health benefits. However, much of the work focusing on this topic has been limited to laboratory settings. The purpose of this study was to investigate differences in energy expenditure (VO_2) and enjoyment of college-aged students while playing AVRGs in different settings (i.e., lab, gym, home). **METHODS:** A repeated measures design was used with 32 participants (16 males, 16 females, Age = 22.6 ± 2.6 years), all of whom completed two 45-minute AVRG sessions in the lab and gym. A subset of 4 participants completed an additional AVRG session at home. **RESULTS:** Significant differences

in $\dot{V}O_2$ were observed among the three AVRGs ($F(1, 28) = 9.128, p = .005$; range = 13.53 - 23.04 ml/kg/min). However, there were no differences between settings in $\dot{V}O_2$ or enjoyment ($p > .05$). **CONCLUSIONS:** Different AVRGs elicit varying exercise intensities, yet the setting in which they are played does not affect $\dot{V}O_2$ or perceived enjoyment. These results suggest AVRGs can be studied reliably across multiple settings (lab, gym, and home) without having to consider environmental influences. As VR systems become more accessible and affordable, future research should continue investigating the effects of AVRGs during at-home play.

A Superjump® Into ACSM Guidelines

Cristina Cortis¹, Alice Iannaccone¹, Salvador J. Jaime², Giovanna Vozza¹, Maria Gessica Diana¹, Annalisa Iodice¹, Sara Baldassano³, Jill Cooper³, Patrizia Proia³, Andrea Fusco¹.
¹University of Cassino e Lazio Meridionale, Cassino, Italy. ²University of Wisconsin-La Crosse, La Crosse, WI. ³University of Palermo, Palermo, Italy. (Sponsor: Carl Foster, FACSM)
Email: c.cortis@unicas.it
(No relevant relationships reported)

SuperJump® (SJ) is a fitness activity combining aerobic and anaerobic exercises performed on a mini trampoline. The exercise intensity can be modified by changing countermovement depth, jump height, and frequency. Although it has been hypothesized that practicing SJ may contribute to daily physical activity recommendations, no study has quantified intensity. **PURPOSE:** To investigate heart rate (HR) and perceived exertion responses of a SJ workout. **METHODS:** Seventeen (Males: n=9; Females: n=8) young adults (age: 25.8±2.7 years; height: 1.7±0.1 m; weight: 66.2±12.1 kg) volunteered for the study. The intensity of the activity was assessed by means of HR monitors during a SJ session (30-min). At the end of each bout of exercise, session ratings of perceived exertion (sRPE) on a CR10 scale were recorded. Percentages of age-predicted maximal HR (%HRmax) were utilized to quantify intensity. %HRmax data were categorically separated according to the American College of Sports Medicine (ACSM) classes of intensity (very light: <57%HRmax; light: 57-63%HRmax; moderate: 64-76%HRmax; vigorous: 77-95%HRmax; near maximal to maximal: ≥96%HRmax). Repeated measures ANOVA was used to evaluate differences ($p < 0.05$) in relation to gender and exercise intensity. *Post hoc* analysis was applied using Bonferroni correction. **RESULTS:** No difference emerged for gender for HR and sRPE data. Frequency of occurrence of %HRmax was significantly higher ($p < 0.005$) for the moderate intensity (48.9±34.9%) with respect to very light (5.5±9.5%), light (16.5±24.4%) and vigorous (29.1±37.7%) intensities, while none of the subjects experienced near maximal to maximal values. According to sRPE values (3.1±1.2) subjects rated the SJ session as moderate. **CONCLUSION:** Findings indicate that SJ can be classified as moderate physical activity according to ACSM guidelines. Therefore, SJ may contribute to meet daily physical activity recommendations by representing an alternative form of low-impact aerobic exercise. Further studies should investigate the long-term effects of SJ training on health-related physical fitness parameters.

A Lower Limb Functional Screening Tool For Predicting Lower Limb Injury: A Prospective Cohort Study

Shimeng Shi¹, Xiaojian Shi¹, Zonghan Yang¹, Peng Song², Gordon Waddington³, Roger Adams⁴, Jeremy Witchalls³, Doa El-Ansary⁵, Oren Tirosh⁵, Sam Wu⁵, Jia Han¹. ¹Shanghai University of Sport, Shanghai, China. ²Dr.Sport Sport Physio Center, Chengdu, China. ³University of Canberra, Canberra, Australia. ⁴University of Sydney, Sydney, Australia. ⁵Swinburne University of Technology, Melbourne, Australia.
(No relevant relationships reported)

PURPOSE: The purpose of the current study was to assess the usefulness of the lower limb functional screening tool (LoLiFST) for predicting low back and lower limb injury in active athletes.

METHODS: Fifty athletes (32M,18F; mean age: 19.4 ± 2.5 yrs) from six different sports volunteered. Athlete injury history and general information were recorded. The LoLiFST is based on five lower limb movements in different movement planes, directions, modes, and at varying intensities. Both legs were assessed in a random order and each athlete was given both technique and symptom scores. Intra-rater and inter-rater reliability was evaluated. Participants were followed up for 12 months, and their exposure to sport and injuries were recorded. Independent samples t-tests were performed to determine if a significant difference existed in LoLiFST scores between those injured and non-injured athletes. Receiver operating characteristic (ROC) analysis was employed to assess the instrument's capacity to predict injury.

RESULTS: The inter-rater reliability was 0.900 and the intra-rater reliability was 0.955. Fourteen participants experienced injury within the following 12 months. Injured athletes had significant lower scores than non-injured in both technique and symptom scores of the LoLiFST ($df=48, t=4.149, P<0.05; df=16.402, t=2.979,$

$P<0.05$). When technique or symptom score alone was included in the ROC analysis, the area under the ROC curve (AUC) scores were 0.793 ($P<0.05, 95\%CI: 0.649-0.936$) and 0.761 ($P<0.05, 95\%CI: 0.599-0.923$), respectively. When technique and symptom scores combined, the AUC discrimination score was 0.835 ($P<0.05, 95\%CI: 0.709-0.962$). When injury history was added into the variable set, the AUC discrimination score was 0.860 ($P<0.05, 95\%CI: 0.746-0.974$), resulting in 86.0% of cases being correctly predicted as low back or lower limb injured/non-injured.

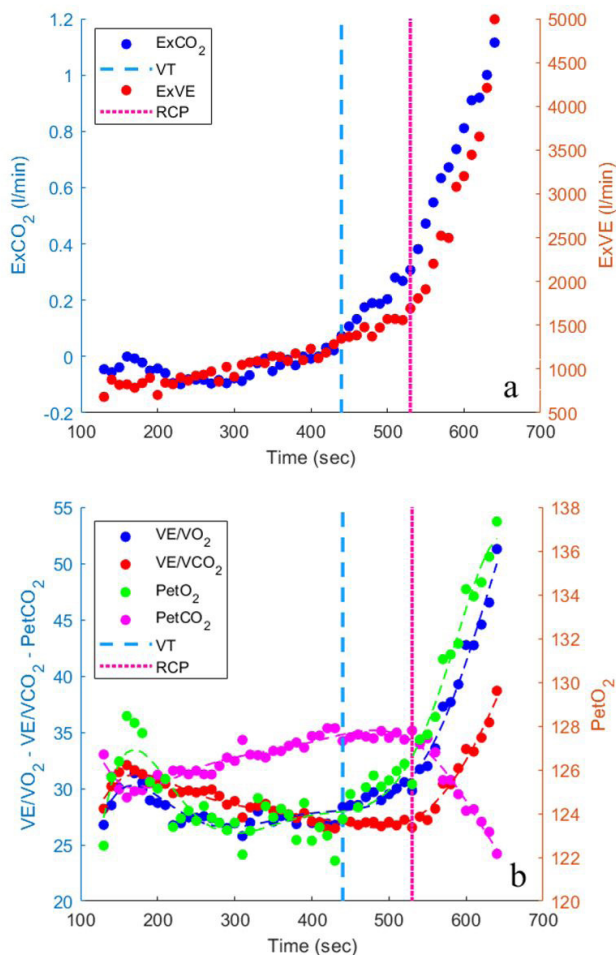

CONCLUSIONS: The new functional assessment tool LoLiFST had excellent intra-rater and inter-rater reliability. The findings from the current study suggest that the technique, reported symptoms, and injury history should be used in combination to maximize its capacity for predicting injuries. Future larger sample size research is warranted to explore the validity of the LoLiFST in predicting low back and lower limb injury in various sports.

An Automated Excess Minute Ventilation Method To Detect The Respiratory Compensation Point

Kyoung Jae Kim¹, Roxanne Buxton², James Crowell³, Meghan Downs⁴, Andrew Abercromby⁴. ¹KBR, Houston, TX. ²University of Houston, Houston, TX. ³MEI Technologies, Houston, TX. ⁴NASA Johnson Space Center, Houston, TX.
Email: kyoungjae.kim@nasa.gov
(No relevant relationships reported)

Ventilatory changes during incremental exercise to maximum effort are represented as two inflection points: the ventilatory threshold (VT) and the respiratory compensation point (RCP). RCP is not frequently reported and detection methods have not been well validated. **PURPOSE:** To introduce an automated excess minute ventilation (ExVE) method to detect the RCP. **METHODS:** 171 peak cycle tests were performed by 96 healthy subjects (M/F) of varying body weight and training status. Expired air was collected for metabolic gas analysis (ParvoMedics TrueOne™). We compared RCPs from the proposed ExVE and the V-slope method (Davis, et al. 1985). Novel method: We extended the excess $\dot{V}CO_2$ (Ex $\dot{V}CO_2$) concept used to detect VT (Gaskill et al. 2001) and calculated ExVE as $(\dot{V}E^2/\dot{V}CO_2) - VE$ to determine RCP. The V-slope method may not be capable of providing automatic solutions (Panteleimon et al. 2008). Thus we applied a parametric global method (Lavielle, 2005) to automatically find the first sustained rise in the Ex $\dot{V}CO_2$ and ExVE curves. **RESULTS:** The detected RCP in the ExVE curve (Figure a) was located at the point of an increase in both the $VE/\dot{V}O_2$ and $VE/\dot{V}CO_2$ and a decrease in end-tidal CO_2 (Pet CO_2) (Figure b) (Jesús et al. 2016). There were extremely strong positive correlations in both RCP Time and RCP $\dot{V}O_2$ between the ExVE and V-slope methods (0.934, 0.920). There was no significant difference between the ExVE and V-slope methods in both RCP variables (0.610 and 0.162) (Table). **CONCLUSION:** The ExVE method can determine the RCP. Our novel and automated protocol may increase the methodological consistency in both research and clinical practice.

Result of Pearson correlation and independent two sample t-test								
Variables	Pearson Corr.	t	df	Sig. (2-tailed)	Mean Diff.	Std. Error Diff.	95% CI (lower)	95% CI (upper)

Effect Of Scapular Dyskinesis On Scapular Functionality And Back Endurance In Elite Women Handball Players

BUNYAMIN HAKSEVER¹, MEHMET MICOOGULLARI¹, OZGE OZALP¹, GUL Y. BALTACI, FACSM². ¹International Cyprus university, Nicosia, Turkey. ²Private Guven Hospital, Ankara, Turkey. (Sponsor: Y. GUL BALTACI, FACSM)
 Email: yasbun@hotmail.com
 (No relevant relationships reported)

Purpose: In professional handball players, accurate scapulohumeral rhythm is crucial for the prevention of overhead shoulder injuries. Additionally low back strength and endurance transfer power to scapular and upper part of body via posterior fascia chain. The aim of this study was to investigate the difference between handball players with scapular dyskinesia and without scapular dyskinesia regarding to functionality and back endurance. **Methods:** Forty-one elite female handball players were included in the study. Sixteen women (mean age: 22.5±6.4yrs BMI: 22.5±2.7kg/m²) who has scapular dyskinesia according to lateral scapular slide test (LSST) as Group 1, 25 women (mean age: 22.5±6.4yrs, BMI:21.8±2.0kg/m²) who has no scapular dyskinesia according to LSST as Group 2 divided into groups. Davies Test and Closed Kinetic

Chain Upper Extremity Stability Test (CKCUEST) were used for the measurement of scapular functionality and Sorensen Test for the measurement of back extensor endurance. Mann-Whitney U test was used to compare the mean values between the groups. **Results:** There were no statistically significant differences in CKCUEST and Davies tests between both groups (p> 0.05). There was statistically significant difference in favor of Group 2 according to Sorensen test between both groups (p = 0.026). **Conclusion:** Endurance of the trunk extensor muscles seems to have influence in scapular dyskinesia in elite female handball players. Besides, functionality of upper extremity in scapular dyskinesia needs to future studies for handball players.

Fitness Readiness For Yoga Poses Scale (fryps): Development And Validation
 Liwen Ju. Nanjing sport institute, nanjing, China. (Sponsor: Weimo Zhu, FACSM)
 (No relevant relationships reported)

Background/Purpose: While yoga is quickly becoming one of the most popular exercises, some significant yoga injuries were also reported. Lack of needed fitness for a specific yoga post is often the reason to get injured. Yet, no tool is available to assess participants' fitness readiness for yoga practice. This study was to address this need by developing a Fitness Readiness for Yoga Poses Scale (FRYPS) and collected its psychometric evidence.

Methods: After a comprehensive literature search and consulting with a number of experts, 101 healthy college students (male = 27.72%, age = 20 ± 3 yr.) were recruited for the study. Specifically, their performance of 7 common yoga poses was evaluated, including mountain pose, bend back, bend forward, riding horse, upward facing dog, downward facing dog and flowing cobra, and their fitness were tested by 6 fitness tests, including sit-up, push-up, squat, cow-face, leg-lifting, and back-up, on the same day. The fitness scores were used to create a draft of FRYPS. The participants were then categorized into 3 groups basing on their yoga performance (poor, fair, good). Using stepwise regression, FRYPS' scores as the independent variable, the yoga pose rating as the dependent variable, the relationship between FRYPS and yoga pose performance level was established. Additional analysis, such as receiver operation curve (ROC), were performed to help setting cutoffs for FRYPS.

Results: The results of regression analysis indicated that a 7-level FRYPS can be used to evaluate the fitness readiness for yoga posture practice, including mountain standing, standing back bend, standing forward bend, riding type, snake strike type and upper dog type.

Conclusion: Consisting of six fitness tests (sit-ups, push-ups, squats, shoulder-flexibility tests, active knee-lifting and back-ups), a yoga fitness readiness scale called FRYPS was developed and its psychometric evidences were collected and confirmed.

Novel Surface Mechanomyography Sensor Assessment Of Hamstrings Contraction During A Neuromuscular Control Screening Task

Shannon E. Linderman¹, Donna Moxley Scarborough¹, Ryan T. Aspenleiter², Hannah S. Stein¹, Eric M. Berkson¹. ¹Massachusetts General Hospital, Boston, MA. ²Figur8, Inc, Boston, MA.
 Email: slinderman@mgh.harvard.edu
 Reported Relationships: S.E. Linderman: Salary; Figur8, Inc.

PURPOSE: Hamstring strain is a common injury among athletes. Asymmetries in muscle balance and activation are potential injury risk factors. Surface mechanomyography (sMMG) sensors are wearable devices that when applied across a muscle group provide a novel measurement of physical muscle output during a contraction. The purpose of this study is to assess 1) the relationship of sMMG's muscle bulk displacement measurement to force generation and 2) sMMG detection of hamstrings contraction timing compared to the clinical standard method of electromyography (EMG).

METHODS: Healthy, active individuals (mean age= 30.0 ±10.77 y, n=9, 6 males, 3 females) underwent hamstrings neuromuscular control assessment with simultaneous recording of EMG and sMMG by sensors applied to the right hamstrings. Subjects performed a series of 3 resisted "make-test" isometric hamstring curls against a hand-held dynamometer (HHD). Raw sMMG data and 6th order Butterworth filter and TKEO processed EMG data were used in timing analyses. Paired T-tests and a Pearson correlation assessed relationships between measurement modalities.

RESULTS: Peak hamstrings muscle bulk displacement detected by sMMG (mean= 4.02 ±1.04 mm) positively correlated with HHD maximum force generation (mean= 28.84 ±12.13 lb), r²= 0.850. There was no significant difference in the timing duration of muscle contraction between EMG (mean= 4.443 ±0.573 s) and sMMG (mean= 4.469 ±0.623 s), p= 0.279.

CONCLUSIONS: Results are consistent with physiologic expectations that increased physical muscle bulk displacement during a contraction is associated with greater force. Similarity in time signatures with EMG support findings of successful sMMG

detection of hamstrings contraction (Figure 1). The sMMG sensor may be helpful for assessing hamstrings muscle performance of both force output and timing as part of neuromuscular control screening for injury prevention, rehabilitation monitoring, or return-to-sport readiness.

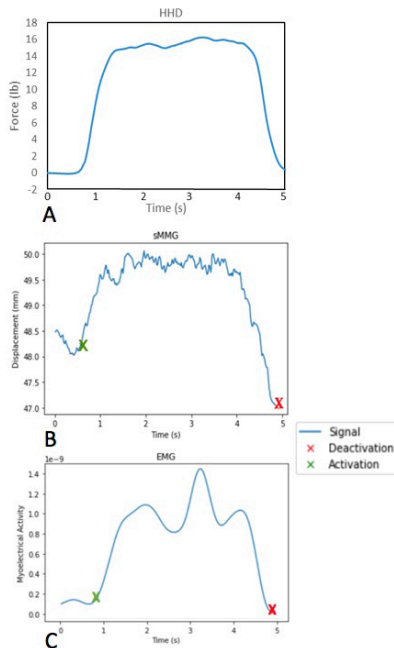

Figure 1. Example comparison of surface mechanomyography (sMMG) sensor output to hand-held dynamometry (HHD) and electromyography (EMG) during a resisted isometric hamstrings curl. Raw sMMG hamstrings muscle displacement (B) aligns with HHD force output (A) and processed EMG data (C) for muscle contraction duration. The timing activation threshold was set at 3 times above the standard deviation of a resting trial for each modality (Solonik et al., 2010).

THE WINFIGHT TEST: PROPOSAL OF A PUNCHING FATIGUE AND ANAEROBIC TEST FOR COMBAT SPORTS ATHLETES

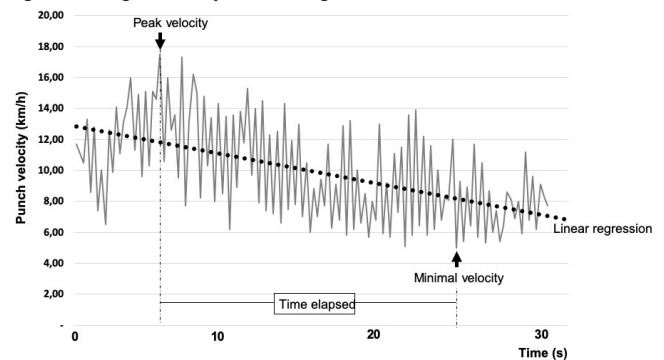

Renata RT Castro¹, André Marinho Fernandes². ¹Care Club, Rio de Janeiro, Brazil. ²CareClub, Rio de Janeiro, Brazil. Email: castrort@gmail.com (No relevant relationships reported)

PURPOSE: The principle of specificity states that training and testing should be relevant and appropriate to the sport in order to achieve better performance. The Wingate test measures anaerobic power and fatigue in a 30-seconds bout of all-out cycling. Despite the importance of anaerobic power analysis for performance in combat sports, there is no specific test for its evaluation in fighters. We propose the Winfight test, for analysis of fatigue and anaerobic capacity in professional combat sports athletes.

METHODS: 10 professional combat sports athletes (6 males; age: 28±6 years) performed a 30-seconds bout of all-out exercise, punching a heavy bag, while wearing punch trackers (Hykso, USA). Velocity of each punch was recorded and plotted against time (Figure). Linear regression analysis was performed, and punch velocity x time slope was calculated. Peak (PeakVel) and minimal (MinVel) punch velocity were used to calculate velocity drop-off (VDO). Fatigue index (FI = VDO/time elapsed between peakV and minV) were calculated. Data presented as mean ± standard error.

RESULTS: Peak V (27,5±7,9 km/h) was achieved at 4±3 s. MinV (5,5±1,3 km/h) was achieved at 23±4s. VDO was 22,08±7,5 km/h, a drop of 78,7±7,7%. When time was considered, FI = 1,2±0,4 km/h/s; %FI=4,4±1,2%/s. Punch velocity x time slope = -0,08±0,04. **CONCLUSIONS:** Due to the predominance of anaerobic metabolism, professional combat sports athletes cannot keep very high punching velocity for more than a few seconds. The Winfight test enabled the analysis of punching fatigue. This data can be used for training and tactics during fight camps. Studies are currently being done to evaluate Winfight test's results reproducibility and correlation to performance.

Figure 1. Winfight test of a professional fighter

Reliability Of A Submaximal Cycle Ergometer Verification Phase To Confirm VO_{2max}

Kirsten Thornhill, MS, Brandon Sawyer, PhD. Point Loma Nazarene University, San Diego, CA. (Sponsor: Robert Pettitt, FACSM) Email: kthornhi@pointloma.edu (No relevant relationships reported)

Purpose: To test the reliability of a submaximal cycle ergometer VO_{2max} test with a 90% power output verification phase (VP) test in active male and female participants. **Methods:** 20 active (BMI = 22.7±2.9 kg/m²; age = 25.5±4) men (n = 10) and women (n = 10) completed 3 ramp VO_{2max} graded exercise tests (GXT) on a cycle ergometer followed by 10 minutes of active recovery, then performed a constant-load verification phase test at 90% of maximum power output achieved on the ramp VO_{2max} tests to verify attainment of a 'true' VO_{2max}. **Results:** Maximum attained VO₂ did not differ between the two verification phase tests (verification phase test 2: 3.01±0.69 L/min, verification phase test 3: 3.04±0.69 L/min; P=0.55). Likewise, VO_{2max} achieved on the verification phase was similar to the ramp VO_{2max} test (verification phase test 2: 3.01±0.69 L/min, verification phase test 3: 3.04±0.69 L/min; GXT 2 = 3.03±0.71 L/min, GXT 3 = 3.04±0.69 L/min; P > 0.05). ICCs and CVs for the group showed excellent consistency for VP VO_{2max} (ICC = 0.991; CV = 2.68 ±2.52%). ICC and CV for female participants VP VO_{2max} demonstrated excellent consistency (ICC = 0.987; CV = 2.5%). Male participants VP VO_{2max} displayed excellent consistency (ICC = 0.941; CV = 2.2%). Bland-Altman Plots showed no bias between VO_{2max}. **Conclusions:** The verification phase proved to be reliable with low variability and showed no bias based on VO_{2max} value. A 90% submaximal verification phase is a reliable test to confirm a 'true' VO_{2max}.

219 Board #35 May 27 9:30 AM - 11:00 AM

Comparison Of The Wingate Anaerobic Test And The New Power Bike Test On Anaerobic Power

Sukho Lee¹, Kyoungho Seo¹, Jungbo Ko¹, Jiyeon Kim², Jonathan Martinez¹, Cindy Trinh¹, Michael Miller¹, Hyejung Choi¹. ¹TEXAS A&M UNIVERSITY-SAN ANTONIO, San Antonio, TX. ²University of Houston, Houston, TX. (Sponsor: Minsoo Kang, FACSM) Email: slee@tamusa.edu (No relevant relationships reported)

Anaerobic power (AP) is the one of the most important factors influencing athletic performance in many sports. Although the Wingate anaerobic test (WAT) has been the most representative measurement for assessing AP, exhaustive testing procedure limits its use in the lab. Recently, the New Power Bike test (NPT) was developed and can measure anaerobic power with maximal pedaling for only four seconds without load. **PURPOSE:** The purpose of this study was to 1) compare the power output between the WAT and the NPT and 2) examine relationships among WAT, NPT, and vertical jump test (VJT). **METHODS:** Thirty-seven participants (age, 26.65±4.16 years; height, 169.2±9.56 cm; weight, 84.49±20.10 kg) went through AP measurements using the WAT, NPT, and VJT. The participant conducted VJT and either WAT or NPT randomly on the first visit. Participants then performed either WAT or NPT via a counterbalanced design on second visit with one-week interval. The Pearson correlation coefficient were computed among the WAT, NPT, and VJT scores and the effect size was evaluated with Cohen's d. Variance between the variables was calculated with the coefficient of determination (r²). The statistical significance was set at 0.05. **RESULTS:** There were

significant positive correlations between the WAT and NPT in the mean of peak power (MPP) ($r = 0.727, p < 0.001$) and mean of relative peak power (MRPP) ($r = 0.388, p = 0.018$), respectively. The MPP (976.18 ± 344.17 W) and MRPP (11.47 ± 2.60 W/kg) of the NPT were significantly higher than the MPP (705.67 ± 249.30 W) and MRPP (8.34 ± 2.55 W/kg) of WAT. There were positive correlations in MPP between NPT and VJT ($r = 0.620, p < 0.001$) between the WAT and VJT ($r = 0.399, p = 0.015$). Also, there were significant correlation ($r(35) = .25, p = .014, d = 5.1$) in MRPP between WAT and VJT, with shared variance between the variables at 0.6%. **CONCLUSION:** There were significant positive correlations between the WAT and NPT in MPP and MRPP. The NPT also showed greater correlation with field test (VJT). So, the NPT can be a good alternative measurement with lesser efforts for assessing anaerobic power and predict athletic performance in the field.

Can Cognitive Training During Exercise Improve Performance On A Time To Exhaustion (TTE) Test?

Nicholas J. Hanson, Rachel M. Dykstra, Michael G. Miller.
Western Michigan University, Kalamazoo, MI.

(No relevant relationships reported)

Mental fatigue can negatively affect our drive to continue exercise. A recent study showed that a training intervention combining exercise and a cognitive task was able to improve performance on a time to exhaustion (TTE) test, which is a challenging task where individuals are required to exercise at a set workload for as long as possible. The duration of the training needed to improve TTE is unknown. **PURPOSE:** To determine if an 8-week cognitive training intervention can improve TTE performance by delaying mental fatigue. **METHODS:** Subjects were 28 recreationally active individuals, with a mean \pm SD age of 22.1 ± 2.6 years. They were randomly assigned to one of three intervention groups: a control group (CON) that was asked to exercise normally at home, and two groups that exercised in the laboratory either once (1X) or twice (2X) per week. Groups were designed to have nearly equal men and women. All subjects were asked to complete a graded exercise test (GXT) to exhaustion and a TTE before and after an 8-week intervention. All tests were completed on a cycle ergometer. The GXT consisted of cycling at a beginning workload of 70-85W and the workload increased every minute by 25-55W, depending on sex and training status. The TTE included a set workload corresponding to 75% VO_{2max} . Training sessions included 1hr of cycling at 65% VO_{2max} while continuously performing the AX-CPT task on a laptop computer. One-way ANOVAs were used to determine the effect of intervention group on change in TTE and VO_{2max} values. **RESULTS:** CON had no change in VO_{2max} (-0.8 ± 4.5 ml·kg⁻¹·min⁻¹) and the experimental groups both had a small increase (1X: 2.8 ± 5.4 , 2X: 2.5 ± 5.9 ml·kg⁻¹·min⁻¹); however, none of these were significant. There was not a difference between groups in VO_{2max} change ($p = 0.313$) or change in TTE (CON: -1.5 ± 9.0 , 1X: -1.8 ± 15.8 , 2X: 6.3 ± 12.2 min; $p = 0.257$). **CONCLUSION:** Although the 2X group saw an increase in TTE it was not significantly different from the other groups. This method has promise, however, as four individuals in the 2X group improved TTE compared to only two subjects in 1X, and one subject in CON. Some individuals may be non-responders to this type of intervention; this would explain the large variability. Alternatively, the lack of significant findings may suggest that the intervention should be longer or include more sessions each week.

Reliability Of Cycling Time Trials Performed At Maximal And Submaximal Intensities

Andrew W. Subudhi, FACSM, Philip M. Batterson, Elizabeth D. Hubbell, Robert A. Jacobs. *University of Colorado, Colorado Springs, CO.*

Email: asubudhi@uccs.edu

(No relevant relationships reported)

Maximal time trial efforts provide reliable assessments of exercise performance, yet are exhaustive in nature and thus must be used judiciously. **Purpose:** To determine whether a time trial performed at a submaximal, non-exhaustive pace, akin to a "tempo" workout, could provide an equally reliable index of exercise performance. **Methods:** Twenty-two volunteers (14 male, 8 female; age 29 ± 8 years) completed three submaximal (TT_{SUB} ; $n = 14$) or three maximal (TT_{MAX} ; $n = 8$) 250kJ time trials on a cycle ergometer over a period of four weeks. TT_{SUB} was completed at a self-selected work rate to maintain Rating of Perceived Exertion (RPE) between 13 and 17 (Somewhat Hard to Very Hard) throughout the trial. TT_{MAX} was completed as fast as possible to simulate a race effort. Reliability across trials was assessed using the Intraclass Correlation Coefficient (ICC) and the coefficient of variation (CV), calculated as the quotient of standard deviation and mean time to completion of each individual's trials. Independent t-tests were used to assess mean differences between TT_{SUB} and TT_{MAX} . Fisher r-to-z transformation was used to compare ICCs ($\alpha = 0.05$). **Results:** Time to complete 250kJ at submaximal effort (RPE 15.2 ± 0.5 vs. 16.5 ± 0.7 ; $P < 0.001$) was longer than for maximal effort (1961 ± 558 vs. 1463 ± 607 s; $P = 0.035$). However, there were no differences in TT_{SUB} and TT_{MAX} reliability as assessed by ICC

(0.92 vs. $0.97, P = 0.352$) or CV of time to completion (7.3 ± 5.3 vs. $6.7 \pm 4.0, P = 0.807$). **Conclusion:** This study supports the concept that a tempo-style workout may be used as a reliable index of exercise performance. Future studies will be completed to evaluate the sensitivity of the non-exhaustive time trial to changes in aerobic capacity.

Differences Between Pointe Shoe And Barefoot Jumping In A Professional Ballet Dancer: A Case Study

Sarah K. Perry, Lorraine R. Brilla, FACSM. *Western Washington University, Bellingham, WA.* (Sponsor: Lorrie Brilla, FACSM)

(No relevant relationships reported)

Ballet is an art form that requires highly trained athletes to perform specialized movements specific to their field. Some of the most unique aspects of ballet training that sets it apart from other athletics are the use of pointe shoes, the emphasis on bilateral training, and the full body aesthetic requirements of every movement. **PURPOSE:** To determine how wearing pointe shoes alters full body kinematics during ballet temps levé jumps on both the preferred stance leg and the non-preferred stance leg, to compare the left and right side to determine the effectiveness of bilateral ballet training, and to observe the contribution of upper extremity movement to jump execution. **METHODS:** One professional female ballet dancer (23 yrs) with 17 years of ballet training performed various jumps in two footwear conditions. She was instrumented with 39 reflective markers, and a 10-camera motion capture system was used to collect three dimensional marker position data at 250 Hz. Sagittal plane upper and lower extremity angles were calculated and compared between conditions as well as between left and right sides. **RESULTS:** During single leg jumps, ankle range of motion (ROM) was slightly larger *en pointe* ($79.1^\circ \pm 1.31^\circ$) than barefoot ($56.4^\circ \pm 0.68^\circ$) due to an increase in plantarflexion, regardless of preferred takeoff leg. Conversely, knee ROM was slightly smaller due to a decrease in knee flexion *en pointe* ($45.8^\circ \pm 2.43^\circ$) than barefoot ($56.1^\circ \pm 6.33^\circ$) for single leg jumps, regardless of preferred takeoff leg. A bilateral jump revealed no distinct differences between left and right sides. Upper extremity angles did not show clear trends between left and right sides or between footwear conditions, however, the ipsilateral shoulder ($114.7^\circ \pm 6.69^\circ$) had slightly greater ROM than the contralateral shoulder ($103.4^\circ \pm 8.49^\circ$) during single leg jumps. **CONCLUSIONS:** Wearing pointe shoes causes alterations to lower limb angles during single leg jumps, altering the demand on the dancer's body during these movements. The increase in ipsilateral shoulder ROM implies ballet dancers utilize the upper extremity to accurately execute single leg jumps. The lack of obvious differences between left and right side joint angles indicates that bilateral ballet training is effective at the professional level.

DECREASE IN PHYSICAL FITNESS IN SOUTH CHINA COLLEGE STUDENTS FROM 2015 TO 2018

Chunbo Qin¹, Xi Jin², Daixi Xie¹, Yang Wen¹, Mark Loftin, FACSM². ¹Shenzhen University, Shenzhen, China. ²The University of Mississippi, University, MS. (Sponsor: Mark Loftin, FACSM)

Email: 6796054@qq.com

(No relevant relationships reported)

Physical fitness (PF) is important for human health and movement throughout the lifespan. **PURPOSE:** The aim of this study was to explore changes in physical fitness in college students from the first year of college to the third year of college. **METHODS:** 3606 Chinese college students aged from 16 to 23 years old (1810 males) were recruited from Shenzhen University in China. The subjects participated in PF tests in 2015 and 2018. Physical characteristics and PF tests included body weight (BW), body height (BH), body mass index (BMI), vital capacity, 50-meter running, long distance jumping, sitting body flexion, 800-meter running (only for females), 1000-meter running (only for males), sit-up (only for females) and pull-up (only for males). All students were tested by facilities TSN200 (produced by Physical Fitness Science and Technology Company). Dependent T-tests were used to compare variables responses and a two-way ANCOVA was used to examine gender by time at post-test with pre-test scores serving as a covariate ($p < 0.05$). **RESULTS:** In females, significant differences were noted for BH, VC, 50-meter running, long distance jumping, sitting body flexion, 800-meter running, and sit-ups. In males, significant differences were found for BW, BMI, VC, 50-meter running, long distance jumping, sitting body flexion, and 1000-meter running. **CONCLUSION:** The results indicated that many PF performance tests decreased over the time frame noted. Moreover, it appears that limited performance time was dedicated to PF. Therefore, we suggest that strategies should be enacted by the University or government to improve the condition of PF for college students in China.

A Comparison Of Step Tests To Predict Maximal Oxygen Consumption
 Taylor Rowley¹, Chris Cho², Ann Swartz, FACSM², Scott Strath, FACSM². ¹Saginaw Valley State University, Saginaw, MI. ²University of Wisconsin-Milwaukee, Milwaukee, WI. (Sponsor: Scott Strath, FACSM)
 Email: trowley@svsu.edu
 (No relevant relationships reported)

Introduction: Of the many methods to estimate maximal oxygen consumption (VO_{2max}), step tests provide a quick estimation of VO_{2max} without expensive equipment. Few studies have investigated varied step height and cadence speed across a broad sample population. The purpose of this study was to generate and validate models to predict VO_{2max} using three different step tests. **Methods:** A sample of 162 adults, aged 18-79 years, completed a graded exercise test to assess VO_{2max} . All three step tests were completed on a later day. The step tests differed in duration, number of stages, and step height. Test 1 (T1) was a two-stage, six-minute test, and had a six-inch step height, Test 2 (T2) was a three-stage, nine-minute test, and had a six-inch step height, and Test 3 (T3) was a three-stage, nine-minute test, and had an eight-inch step height. Stepping cadence increased with each stage and was prescribed based on age group (<40 years, 40-60 years, and >60 years). Recovery heart rate (HR_{rec}) was measured every 30-seconds for two-minutes after each test. Model equations were obtained using hierarchical multiple regression analysis. Covariates for each model included age, sex, body mass, stepping cadence, and HR_{rec} at all measured time intervals. The baseline model for each test consisted of age, sex, and body mass. Stepping cadence was entered in step two but was only significant for T3. Thirty-second HR_{rec} was entered in the final step and was significant for all three tests. Validity was assessed using a Jackknife cross-validation method, allowing for root mean square error (RMSE) and percent bias to be calculated. **Results:** The baseline model accounted for ~72% of the variance for predicting VO_{2max} . Each model accounted for ~83% of VO_{2max} variance and had an error ~4.15 ml $kg^{-1}min^{-1}$. The results of the jackknife analysis found that bias for all three tests was minimal (<0.001%) and the resulting bias-adjusted R^2 was 0.825, 0.826, and 0.834 for T1, T2, and T3, respectively. Adjusted RMSE was 4.259, 4.223, and 4.102 ml $kg^{-1}min^{-1}$ for T1, T2, and T3, respectively. **Discussion:** All three step tests account for ~83% of the variance of VO_{2max} with an error around 4.2 ml $kg^{-1}min^{-1}$. As there is a minimal difference between tests, there is flexibility in the utilization of these step tests based on the need of the administrator and ability of the client.

Biomechanical Analysis Of The Closed Kinetic Chain Upper Extremity Stability Test
 Ethan S. Welch, Matthew D. Watson, George J. Davies, Bryan L. Riemann. Georgia Southern University - Armstrong Campus, Savannah, GA.
 Email: ew09516@georgiasouthern.edu
 (No relevant relationships reported)

PURPOSE: The closed kinetic chain upper extremity stability test (CKCUEST) involves counting alternate touches of each hand to the contralateral hand while maintaining a push-up position. The purpose of this study was to compare kinematic and ground reaction force (GRF) patterns between the dominant (DOM) and nondominant (NDOM) limbs. **METHODS:** Healthy college-aged males (n=16) and females (n=16) completed three 15s trials of the CKCUEST test with 45s rest between trials. DOM and NDOM GRF and hand kinematics were captured using an electromagnetic tracking system and two forceplates. Contact and flight times were computed separately for each limb. For both the medial-lateral (ML) and 3-dimensional (3D) composite vectors, the average hand travel distance, hand velocity, and peak and average GRF per touch were computed and statistically compared between limbs. **RESULTS:** There were no significant limb differences for contact (DOM=.97±.28s, NDOM=.98±.28s, P=.679) and flight (DOM=.69±.19s, NDOM=.69±.19s, P=.305) times. ML distance was statistically equal (P=.866) between the NDOM (1.38±.13m) limb compared to DOM (1.38±.14m), as well as the 3D distance (DOM=1.36±.14m, NDOM=1.34±.13m, P=.189). There were no significant differences for ML (DOM=2.08±.44m/s, NDOM=2.08±.45m/s, P=.728) and 3D (DOM=2.30±.50m/s, NDOM=2.30±.49m/s, P=.734) velocities. Peak ML GRF was significantly (P<.001) greater for the NDOM (186.7±77.2N) limb compared to DOM (166.6±65.7N). Average ML GRF was significantly (P<.001) greater for NDOM (130.3±51.1N) limb compared to DOM (112.6±44.5N). There were no significant limb differences for either peak 3D GRF (DOM=475.6±163.6N, NDOM=474.7±163.8N, P=.840) or average 3D GRF (DOM=362.1±121.1N, NDOM=362.0±121.7N, P=.974). **CONCLUSIONS:** Although there were significant findings with ML GRF, the differences may not be clinically meaningful. Future research will consider patients with shoulder pathologies being assessed during rehabilitation progression and at discharge.

Validity And Reliability Of Small Respiratory Chamber To Assess Exercise Energy Expenditure
 Elvis Alvarez Carnero, Christopher Bock, Steven R. Smith, Bret H. Goodpaster. AdventHealth Translational Research Institute, Orlando, FL.
 Email: Elvis.Alvarezcarnero@AdventHealth.com
 (No relevant relationships reported)

The recently created small respiratory chambers (FLEX rooms) permit a more affordable solution and faster response time than the larger traditional whole room respiratory chambers. Despite the potential for FLEX to be employed to assess acute energy expenditure (EE), it has never been validated for submaximal exercise. **PURPOSE:** To perform concurrent validation and reliability analysis of indirect calorimetry of FLEX against metabolic carts (Cart) during submaximal cycling. **METHODS:** Ten healthy participants were included in this study (41.5±15.2 years; BMI=25.8±3.3 kg/m²). Energy expenditure was evaluated on FLEX and mixing chamber Cart, simultaneously. FLEX is an 11,000-liter room operated by a push-pull system and mass flow controllers. Participants performed two submaximal exercise bouts of 30-minutes the same day with a 30-minute resting period between bouts, each bout had a light and a moderate load; they repeated the same protocol after two days. Oxygen uptake (VO_2) and CO_2 production (VCO_2) were derived with the same equation. EE, Net EE, gross efficiency (GE) and net efficiency (NetEF) were calculated for each load (L1 & L2). FLEX within and between-day reliability was calculated by the standard deviation of the differences in kcal/min and %. Repeated measures analysis was utilized to explore differences between Cart and FLEX. **RESULTS:** EE and NetEE were not significantly different between cart and FLEX technologies (EE_{L1} , FLEX= 4.29 vs. Cart= 4.13 kcal/min, EE_{L2} , FLEX= 6.2 vs. Cart=6.0 kcal/min, P>0.05 for both; $NetEE_{L1}$, FLEX= 2.7 vs. Cart=2.7 kcal/min, EE_{L2} , FLEX= 4.63 vs. Cart=4.57 kcal/min, P>0.05 for both). GE and NetEF were similar between both systems for all loads (GE_{L1} , FLEX= 11.8% vs. Cart= 12.3%, GE_{L2} , FLEX= 16.3% vs. Cart= 18.9%, P>0.05 for both; $NetEF_{L1}$, FLEX= 18.8% vs. Cart=18.9%, $NetEF_{L2}$, FLEX= 22.0% vs. Cart= 22.4%, P>0.05 for both). FLEX assessments of EE were highly reliable within-day (L1= 0.11 kcal/min (2.5%) and L2= 0.07 kcal/min (1.1%)) and between-days (L1= 0.10 kcal/min (2.4%) and L2= 0.14 kcal/min (2.2%)). **CONCLUSION:** FLEX is a valid and reliable technique to assess energy metabolism during exercise without the cumbersome mouthpiece or mask required by metabolic carts.

A Comparison Of Predictive Equations Versus Measured Resting Metabolic Rate In Healthy Individuals
 Ben Pike¹, Grace O'Connor¹, Jeremy Ducharme², Brian Miller³, Jakob D. Lauver¹, Justin P. Guilkey¹, Christine M. Mermier², Kelly E. Johnson¹. ¹Coastal Carolina University, Conway, SC. ²University of New Mexico, Albuquerque, NM. ³Mary Baldwin University, Staunton, VA. (Sponsor: William G. Lyster, FACSM)
 Email: bnpike@coastal.edu
 (No relevant relationships reported)

Established prediction equations, such as the Mifflin-St. Jeor (MSJ), Harris-Benedict (HB), World Health Organization (WHO), and Nelson provide an estimate of resting metabolic rate (RMR). However, these prediction equations should be reinvestigated to determine if an update is needed. **PURPOSE:** To examine several well-known RMR prediction equations ($RMR_{predict}$) against measured (RMR_{meas}) values in healthy adults. **METHODS:** Twenty-four participants (35.2 ± 15.4 yrs, 171.8±3.9 cm, and 71.5±33.2kg) participated in this study. Each participant followed standard pre-test guidelines and underwent a single RMR assessment (RMR_{meas}) using a metabolic cart calibrated before each test. Each participant laid motionless in a supine position under a ventilated canopy for 25-30 minutes. The most stable 5 minutes of resting data within ≤5% of coefficient of variation was defined as the measured resting metabolic rate. A two-factor mixed methods ANOVA was used to compare the measured RMR against other prediction equations (HB, WHO, and MSJ) by sex. Additionally, sex-adjusted Bland Altman Limits of Agreement (LA) were reported as frequency of subjects outside of agreement compared to RMR_{meas} . For significant differences, Cohen's d effects sizes were reported. All results are expressed as M ± SD with significance set at p ≤ 0.05. **RESULTS:** On average males had 498±137kcal/d higher RMR than females (p≤0.001). The HB (1609.7 ± 300.5 kcal/d) and WHO (1620 ± 302.8 kcal/d) prediction equations did not differ from the RMR_{meas} (1703.5 ± 349.5 kcal/d) (p > 0.05). However, significant differences were observed for MSJ (1529.4 ± 284.5 kcal/d; d = 0.92) and Nelson (1515.7 ± 352.9 kcal/d; d = 1.05) prediction equations when compared to RMR_{meas} (1703.5 ± 349.5 kcal/d). The Mifflin-St. Jeor and Nelson significantly underestimated RMR when compared to RMR_{meas} by 9.3 ± 10.5% and 10.9 ± 9.8%, respectively. MSJ and Nelson had the largest frequencies outside of the LA at 20% and 36% under-predicted for females, respectively. **CONCLUSIONS:** Preliminary data shows that MSJ and Nelson RMR equations

WEDNESDAY, MAY 27, 2020

may need to be interpreted with caution, especially for female populations. Since no significant differences were observed between HB and WHO compared to RMRmeas, their continued use in estimating RMR in a healthy population of adults is supported.

 (No relevant relationships reported)

Many law enforcement agencies, fire departments and military branches often require members to complete a muscular strength and endurance physical fitness test for entry or as a yearly test to assess their ability to perform essential job duties. Push-ups are common components of a muscular fitness assessment, especially in tactical settings. These tests require a certain level of muscular strength, however, the level of strength needed to be successful in essential job duties is widely debated. Because multiple raters are used to test large groups, scoring inconsistencies can occur due to a lack of proper movement standard knowledge between raters. **PURPOSE:** The primary purpose of this study was to evaluate interrater reliability of the 1-minute push-up test using video motion capture application across a group of fitness professionals and health science students. **METHODS:** Data collected from 28 video raters (males, n = 10; females, n = 18, age: 24.8 ± 5.5) was analyzed to determine the interrater reliability for the 1-minute push-up test. Raters were recruited from health science courses at the university where this study was conducted. Raters were shown 10 different video recordings of individuals performing the 1-minute push-up tests as a group in a classroom. Raters were instructed to score the performance of each video participants based on the testing procedures and criteria that were provided. **RESULTS:** A Cronbach's alpha reliability analysis of the entire sample revealed a high degree of interrater reliability for the push-up test. ($\alpha = .987$). **CONCLUSION:** Based on the results of this investigation, it appears that the push-up test can be assessed by different raters with a high degree of reliability. These findings are significant for populations, such as military, fire and police, that frequently perform these assessments as part of their yearly evaluations.

Can Lateral Weight Shift Be Reliably Observed During The Functional Movement Screen Deep Squat?

Matthew F. Moran, Eric P. Scibek, Mary C. Hemmer, Louis R. Castro, Jonathan R. Hudak, Jason K. Grimes. Sacred Heart University, Fairfield, CT.
 Email: moranm@sacredheart.edu
 (No relevant relationships reported)

Bilateral asymmetries of lower extremity strength have been reported in the literature and their existence may influence performance and increase injury risk. Although functional movement screen (FMS) deep squat (DS) scoring criteria does not include lateral weight shift, previous reports have demonstrated weight distribution asymmetry in both adolescent soccer players and active, adult participants. Lateral weight shifts are often observed in FMS DS, however, no previous report has determined the ability to validly and reliably observe this characteristic.

PURPOSE: To determine if lateral weight shift could be reliably rated when compared to bilateral vertical ground reaction forces (vGRF) during FMS DS.

METHODS: Thirty-seven active subjects (19 F, 18 M, 20.8 ± 1.4 yrs) granted informed consent and performed three FMS DS trials on two force plates (1200 Hz) while video (30 Hz) captured frontal, sagittal plane views. A Matlab script processed vGRF data with a lowpass filter and computed limb symmetry index (LSI) during the descent phase and full squat position. Two sports medicine professionals independently viewed videos and rated asymmetry using a novel, web-based sliding scale scoring rubric. Raters scored trials from 0-100 in interval increments of 1 with 50 representing a symmetric DS. Scores were averaged across trials and intraclass correlations (ICCs) were performed to determine inter-rater reliability. Receiver operator characteristics (ROC) curves determined cut-off scores that maximized sensitivity and specificity of determining substantial weight shifts (>10%, >15%).

RESULTS: Subjects demonstrated average LSI of 9.8 ± 6.9% with eighteen subjects demonstrating LSI > 10%. Raters were able to determine correct shift direction (L, R) in 57.7% of all subjects and 68.1% for those with average LSI > 10%. Inter-rater reliability was poor (ICC=0.41, 95% CI=-0.07, 0.69). All ROC curve areas were < 0.61 indicating the scoring rubric failed to accurately diagnose LSI > 10% or >15%.

CONCLUSIONS: Although active, adult subjects demonstrated lateral weight shift during FMS DS, raters weren't able to reliably observe this shift even in severe cases. Clinicians should demonstrate caution when prescribing interventions based on visual observance of lateral weight shift during the FMS DS.

Body Mass Scaling Of Metabolic Rate During Submaximal Steady-state Motorized Treadmill Climbing

Daniel P. Heil, FACSM. Montana State University, Bozeman, MT.
 Email: dheil@montana.edu
 (No relevant relationships reported)

Avid rock climbers and the research literature commonly agree that body mass (M_B , kg) is the primary determinant of the energy cost of climbing. Given that gravitational resistance is the primary external force being worked against when climbing, it is presumed that the energy cost, as measured by steady-state oxygen uptake ($\dot{V}O_2$, l/min), should be proportional to both *body mass* (M_B , kg) and the *total mass* of a climber and their gear (M_T , kg) - i.e., $\dot{V}O_2 \propto M_B^b \alpha M_T^c$, where b is the theoretical mass exponent value of +1.0. The research literature, however, has never formally addressed the issue of mass exponents for climbing energy expenditure. **PURPOSE:** To begin understanding the relationship between mass and steady-state climbing $\dot{V}O_2$, this study determined M_B and M_T scaling exponents for energy cost during motorized treadmill climbing. It was hypothesized that both mass exponents would scale to the +1.0 power. **METHODS:** Data for 16 men and 4 women (Mean±SD: 25±4 yrs age; 22.7±1.5 kg/m² BMI) from a previously published study (Heil IJPEFS 2019) were used for these analyses. Each climber performed five mins of steady-state climbing at six combinations of "slow" and "fast" climbing speeds (4.6-9.1 m/min) across three treadmill grades: vertical (0°), overhang or negative incline (-5 to -10°), positive inclines (+5 to +10°). Steady-state $\dot{V}O_2$ data collected with a portable indirect calorimetry system were analyzed using standard log-linear multiple regression analyses using treadmill speed and grade, a dummy-coded gender term, and either M_B or M_T as independent variables ($\alpha=0.05$). Derived mass exponents were then compared to the theoretical value of +1.0 using 95% CIs. **RESULTS:** Without the gender term in the regression model, mass exponents for both M_B (b ; 95%CI: 1.28; 1.11-1.45) and M_T (+1.32; 1.14-1.49) were significantly higher than +1.0 (model $P<0.001$; $R^2 = 0.79$). With the gender term, however, mass exponents for neither M_B (1.05; 0.85-1.25) nor M_T (1.09; 0.89-1.29) differed from +1.0 (model $P<0.001$; $R^2 = 0.82$). **CONCLUSIONS:** The mass exponents for both M_B and M_T did not differ from the theoretical +1.0 value attributed to gravitational resistance when accounting for gender. The reason for the need to include the gender term, however, is not clear and may be an artifact of the imbalance between men (n=16) and women (n=4) in this study.

Evaluation Of Longitudinal Combine Performance Assessments In Ncaa Division Two Football Athletes

Haley L. McVannell, Christopher C. Winter, Jeremy L. Knous. Saginaw Valley State University, Saginaw, MI.
 Email: hlmcvann@svsu.edu
 (No relevant relationships reported)

INTRODUCTION: Combine style assessments provide information regarding athlete's strengths, weaknesses and ability. Values allow strength and conditioning professionals to assess training objectives and method of operation. **PURPOSE:** To evaluate longitudinal combine performance assessments in NCAA Division II football athletes. **METHODS:** One hundred fifty-four football athletes participated in combine style assessments over three years using six time points (16WI, 16SU, 17WI, 18WI, 18SU, 19SU). Tests included vertical jump via Vertec, broad jump via meter tape, electronically timed 40-yard dash, stopwatch or electronically timed pro-agility run, and maximal power clean, back squats, and bench press. For data analysis, positions were condensed into categories of Bigs (offensive and defensive lineman) Skill (wide receivers, running backs, defensive backs) and Big Skill (quarterbacks, tight ends, linebackers). Descriptive statistics and comparative analysis, mixed methods regressions, were performed using SPSS (version 24.0) with significance set at $p \leq 0.05$. **RESULTS:** Athletes displayed significant increases in back squat ($F=4.965$, $p<0.0005$), power clean ($F=3.164$, $p=0.008$), and bench press ($F=4.329$, $p=0.001$) as they participated in subsequent assessments. Athletes displayed significant decreases related to subsequent assessment in broad jump ($F=3.889$, $p=0.002$), vertical jump ($F=3.146$, $p=0.009$), pro-agility right ($F=2.555$, $p=0.028$) and left ($F=2.797$, $p=0.017$). Squat ($F=4.931$, $p<0.0005$), power clean ($F=2.806$, $p=0.017$), 40-yard dash ($F=4.369$, $p=0.001$), pro-agility left ($F=4.509$, $p=0.001$), and right ($F=4.329$, $p=0.001$) performance improved with subsequent assessments and was significantly related to position category (Skill<Big Skill<Bigs). Bench press ($F=4.827$, $p<0.0005$) performance was significantly related to subsequent assessments and position category (Skill<Big Skill<Bigs). Broad jump ($F=4.415$, $p=0.001$) and vertical jump ($F=3.707$, $p=0.003$) performance were significantly related to subsequent assessments and position category (Skill>Big Skill>Bigs). **CONCLUSION:** Subsequent assessment had an impact on combine performance results. Further, position categories have differing attributes that will impact combine performance values.

Stressful Exercise Reveals Hidden Correlations Between Anthropometric Measurements And Cardiovascular Parameters

Sawsan M. Muthana, Anila K. Maskeen, Emily A. Freund, Jennae M. Fenton, Nick J. Rein, J. Mark VanNess, Courtney D. Jensen. *University of the Pacific, Stockton, CA.*
Email: s_muthana@u.pacific.edu

(No relevant relationships reported)

Camera-based girth measures paired with multi-spectrum bioelectrical impedance spectroscopy can aid in bodily measurements helpful for assessing composition. Fit3D is a relatively new technology for the determination of anthropometric circumferences. There are known relationships between abdominal obesity and blood pressure, but there are fewer investigations exploring the relationship between peripheral circumferences and cardiovascular parameters. **PURPOSE:** To evaluate relationships between anthropometric measurements calculated by the Fit3D to pre- and post-exercise blood pressure values. **METHODS:** 17 subjects (7 female, 10 male) underwent laboratory testing beginning with a body composition assessment by the Fit3D (Fit3D, Inc., USA). Subjects then had resting heart rate and blood pressure recorded, followed by a treadmill $\dot{V}O_2$ max assessment during which ventilatory threshold was identified using the V-slope method. This value was used to determine work rate in a subsequent 60-minute exercise session. Immediately after exercise, subjects were retested on the Fit3D and had post-exercise values of heart rate and blood pressure collected. Descriptive statistics characterized the study sample; simple linear regressions tested the relationships between anthropometric assessments and cardiovascular parameters. **RESULTS:** Subjects were 20.5 ± 1.7 years old, weighed 73.8 ± 15.4 kg, had a body fat of $24.2 \pm 6.6\%$, resting heart rate (HR) of 78.1 ± 14.9 bpm, systolic blood pressure (SBP) of 122.8 ± 4.6 mmHg, and diastolic pressure of 74.6 ± 4.9 mmHg. Fit3D-calculated "Body Shape Rating" was unrelated to HR at baseline ($p=0.297$) but a higher value predicted a lower post-exercise HR ($\beta=-0.691$, $p=0.033$). Resting forearm circumference was unrelated to SBP ($p=0.978$) and DBP ($p=0.539$), but post-exercise forearm circumference predicted both SBP ($\beta=1.336$, $p=0.031$) and DBP ($\beta=1.823$, $p=0.038$). Calf circumference was unrelated to SBP, but demonstrated trends with DBP at rest ($\beta=0.942$, $p=0.033$) and post-exercise ($\beta=1.403$, $p=0.080$). Upper arm and upper leg circumferences were unrelated. **CONCLUSION:** In a condensed age group, stressful exercise seemed to reveal otherwise-hidden correlations between peripheral anthropometric measurements and cardiovascular assessments.

A Simulated Climbing Test Is Correlated With Total Work From The Wingate Anaerobic Test

Dustin D. Dunnick, Kayla Wright, James W. Navalta, FACSM, Brian K. Schilling. *University of Nevada, Las Vegas, Las Vegas, NV.*

(No relevant relationships reported)

INTRODUCTION: The Wingate Anaerobic Test (WANt) is a popular test for measuring lower-body anaerobic capacity and related variables. However, it may be beneficial for athletes in activities where the whole body is utilized to perform an anaerobic test that includes both the upper and lower body. Simulated climbing machines may provide comparable anaerobic capacity test results to that of the WANt. **PURPOSE:** To determine if a distance climbed 30-s maximal-effort test on a simulated climbing machine correlates with WANt variables, specifically total work (anaerobic capacity). **METHODS:** 32 participants were recruited from the local university population and reported to the lab five times. Day 1 included reading and signing the IRB approved informed consent, recording of anthropometric data, and practicing the protocol on both the cycle ergometer (Monark 598E) and simulated climbing machine (Versaclimber SM Sport). On days 2-5, participants performed the anaerobic test protocol on each machine twice using a random order. The WANt protocol used a 7.5% body mass resistance with a 3-5-minute warm-up followed by 30-sec of maximal effort cycling. The climbing protocol included a 3-5-minute warm-up with no resistance followed by a 30-sec maximal effort climb with the lowest resistance possible on the machine. Each protocol was performed twice on two separate days. Intraclass correlation coefficient (ICC_{3,1}) were calculated between two trials of the WANt total work (J), between the two trials of the climber for distance climbed. Bivariate correlations were calculated for total work on the WANt and distance on the climber. **RESULTS:** Fifteen males (24.8 ± 6.5 yrs; 176.2 ± 5.4 cm; 77.0 ± 13.5 kg) and fifteen females (23.1 ± 4.1 yrs; 159.4 ± 6.4 cm; 69.2 ± 13.8 kg) completed the study. A high degree of test-retest reliability was found for WANt total work (ICC = .99 [98-.99], $p < 0.001$) and climbing distance (ICC = .94 [93-.99], $p < 0.001$). WANt total work and climbing distance were significantly correlated, $r = .81$, $p < .001$.

CONCLUSIONS: Simulated climbing machines may be a reliable method for performing anaerobic capacity testing. Athletes involved in activities involving both the upper and lower body may have a greater benefit using a simulated climbing machine over the traditional cycle ergometer.

Methods For Estimating Anaerobic Glycolytic Capacity (vLa_{Max}) In Trained Cyclists

Chris R. Harnish¹, Tasi Ann Ada¹, Emma Murphy². ¹Mary Baldwin University, Fishersville, VA. ²Shenandoah University, Winchester, VA.

Email: crharnish@marybaldwin.edu

(No relevant relationships reported)

PURPOSE: The maximum rate of lactate production (vLa_{Max}) can be used to estimate the maximum anaerobic energy contribution, which can be used to optimize endurance training. The aim of this study was to examine the reliability of a 20-sec vLa_{Max} estimate using either a variable or standardized alactic time interval (t_{alac}). **METHODS:** 16 trained male cyclists and triathletes (35.3 ± 8.9 yo, 1.80 ± 0.05 m, and 73.3 ± 11.2 kg, average 30-sec Wingate power of 9.0 ± 1.6 Wkg⁻¹) were recruited. Subjects completed two familiarization trials on their own before completing two 20-sec maximal sprints on their own bikes which were attached to a Wahoo Kickr trainer. Each session began with a 10-min warm-up at 100 W before each sprint and were then followed by 12-min passive rest. A lactate (HLA) sample was taken from the finger at the end of the sprint and then every 2-min after that until HLA dropped ≥ 1 mM. vLa_{Max} was then calculated using (HLA post - pre)/(20-sec - alactic time), where t_{alac} was either time 0-sec to time where power drops 3.5%, or was set at 5-sec. **RESULTS:** Individual sprint sessions data were analyzed and no significant differences ($p > 0.05$) nor were noted between session 1 and 2 data; all data were pooled and then vLa_{Max} calculated using methods described above. Mean 20-sec sprint power was 9.8 ± 1.0 Wkg⁻¹ (~109% of Wingate) and a total work of 14.5 ± 2.7 . The t_{alac} was calculated to be 4.0 ± 2.3 -sec. There was no significant difference ($p > 0.05$) between the calculated vLa_{Max} 0.51 ± 0.18 mL·L⁻¹·sec⁻¹ and vLa_{Max} using the a standard 5-sec value, 0.54 ± 0.15 mL·L⁻¹·sec⁻¹. Neither vLa_{Max} value appears to be associated ($r^2 < 0.10$, $p > 0.05$) with absolute sprint performance. **CONCLUSIONS:** These results indicate that using a standard t_{alac} of 5-sec produced similar results as calculating it using a 3.5% drop in power. While vLa_{Max} may ultimately influence HLA testing curves (i.e., lactate threshold) and endurance performance, it does not appear to be associated with actual sprint power output.

Comparisons Of Functional Movement Screen Values In Different Weight Populations

Dao Wang, Dong Zhou, Jingjing Wang. *Shanghai Research Institute of Sports Science, Shanghai, China.*

Email: bluebird_2003@126.com

(No relevant relationships reported)

PURPOSE: In this study, we explored the mechanism of overweight and obesity on functional exercise ability through correlating functional movement screen (FMS) with BMI, and comparing FMS values among different weight groups. **METHODS:** FMS was performed in 481 adults (male 209, female 272) aged 20 to 69. The FMS consists of 7 modes of action: deep squat, hurdle step, in-line lunge, shoulder mobility, active straight leg raise, trunk stability push up and rotary stability. The total score of FMS is 21 points. The BMI grading criteria of Chinese people was used. **RESULTS:** (1) BMI was negatively correlated with the total score of FMS, and the correlation coefficient was -0.309 ($P < 0.01$). The correlation coefficients of BMI with shoulder mobility and rotary stability were -0.404 and -0.311 ($P < 0.01$), respectively. (2) If BMI exceeded 26 kg/m², the total score showed a downward trend. The decline was most obvious when exceeded 31 kg/m². (3) The total FMS score of obese group was significantly lower than that of normal weight and overweight group ($P < 0.01$), and that of overweight group was significantly lower than that of normal weight group ($P < 0.01$). (4) The scores of shoulder mobility and rotary stability of obese people were significantly lower than those of normal weight and overweight people ($P < 0.01$). The scores of active straight leg raise in obese group were significantly lower than normal weight group ($P < 0.01$). (5) There was significant difference in the score distribution of in-line lunge ($\chi^2 = 13.097$, $P = 0.011$), the proportion of 1 point is the highest in obese people, and the proportion of 3 points from high to low is normal weight, overweight and obese people. The scores of shoulder mobility and active straight leg raise were significantly different among the three groups ($\chi^2 = 61.661$, $P = 0.000$; $\chi^2 = 14.852$, $P = 0.005$), the proportion of 3 points from high to low was normal weight, overweight and obese people. There was also a significant difference in the distribution of rotary stability scores ($\chi^2 = 34.388$, $P = 0.000$). **CONCLUSION:** BMI was negatively correlated with FMS performance, and the order of FMS performance from good to bad was normal weight, overweight and obese people. Among the three groups, the most obvious differences were shoulder mobility, rotary stability and active straight leg raise.

Examining A Method For The Comprehensive Assessment Of Instantaneous Force Using Directional Continuous Jump Motion Test

Tamotsu Kitabayashi¹, Kosho Kasuga², Syunsuke Yamaji³.
¹Tokyo University of Science, Tokyo, Japan. ²Gifu University, Gifu, Japan. ³Fukui University, Fukui, Japan. (Sponsor: Kiyoji Tanaka, FACSM)

(No relevant relationships reported)

PURPOSE: To develop a directional continuous jump motion test and conduct a comprehensive assessment and comparison of basketball players under the conventional measurement method (vertical jump, standing long jumps [forward, back]) and the directional continuous jump measurement method (vertical, forward, backward). **METHODS:** Subjects included the following two groups; general students (10 male students) and basketball students (10 male students). The conventional single jump (vertical jump, standing long jumps [forward, back]) and the directional continuous jump (vertical, forward, backward) were measured using Kinect2. For the directional continuous jumps, subjects were instructed to perform the first vertical jump to the best of their ability and then to move to the next motion as quickly as possible after landing. Overall scores were calculated for jump height/distance using the conventional measurement method and the directional continuous jump measurement method. Then, the standard score (T-score) for the basketball group was calculated on the basis of the mean for the general male student group. The difference between the means of the standard score (T-score) on the conventional single measurements and on the directional continuous jumping measurement were tested. The level of significance was set at 5%. **RESULTS:** Significant differences was not found in the means of the overall standard scores (T-Scores) for conventional single measurements and directional continuous jump measurements. The individual results indicated that six subjects had an overall standard score (T-score) that was higher than the average (50) under the conventional measurement method, and eight subjects had higher than average scores under the directional continuous jump measurement method. It show that even a player who scored below the mean for general students on the conventional measurement (single jumps) scored higher than the mean for all directions in the directional continuous jump measurement. **CONCLUSION:** When studying athletes, overall instantaneous force can be assessed and gauged efficiently using the directional continuous jump measurement method.

The Accuracy Of Prediction Equations For Estimating 1rm In The Press And The Deadlift

William Varner¹, Jonathan Boring², Lindsay LeVault Beck¹, Madison Beck¹, Christopher A. Fahs³. ¹Lindenwood University Belleville, Belleville, IL. ²Lindenwood University, St. Charles, MO. ³Logan University, Chesterfield, MO. (Sponsor: Michael Bembem, FACSM)

(No relevant relationships reported)

Many of the equations used to predict the one-repetition maximum (1RM) from the number of repetitions performed to fatigue with a submaximal load have been derived from the squat and bench press exercises in which the eccentric portion precedes the concentric portion of the repetition. In the press and deadlift, the concentric phase precedes the eccentric phase which may affect performance in the number of repetitions performed to fatigue and, thus, the accuracy of existing 1RM prediction equations for these exercises.

PURPOSE: To compare the actual 1RM to the predicted 1RM from seven existing prediction equations for the press and deadlift. **METHODS:** 30 resistance trained individuals (23±3 yrs) completed a 1RM protocol for the press and deadlift. Participants then returned to the lab on two separate occasions and completed one set of each exercise to fatigue at either 70% or 90% of their 1RM in a randomized order. The actual 1RM was compared to the predicted 1RM from seven 1RM prediction equations for each exercise at each load. A one-way repeated measures (1x8) ANOVA was used followed by Bonferroni post-hoc tests to determine pairwise differences between the actual and predicted 1RM values. **RESULTS:** For the press, the predicted 1RM from 70% 1RM lifted to fatigue was significantly ($p<0.002$) lower than the actual 1RM from three of the seven equations (mean differences of 3.1±0.7, 5.7±0.7, and 6.2±0.7 kgs) and the predicted 1RM from 90% 1RM lifted to fatigue was significantly ($p<0.012$) greater than the actual 1RM from four of the seven equations (mean differences of 3.0±0.7, 3.2±0.7, 3.5±0.6, and 4.7±0.7 kgs). For the deadlift, the predicted 1RM from 70% 1RM lifted to fatigue was significantly ($p<0.001$) lower than the actual 1RM from three of the seven equations (mean differences of 13.7±2.7, 20.1±2.3, and 20.3±3.2 kgs) whereas the predicted 1RM from 90% 1RM lifted to fatigue was significantly ($p<0.012$) greater than the actual 1RM from one of the seven equations (mean differences of 7.1±1.0 kg). **CONCLUSIONS:** Lower loads (70% 1RM) used to predict the 1RM may underestimate the actual 1RM whereas higher loads (90% 1RM) may overestimate the

1RM for the press and deadlift. The use of higher loads for 1RM prediction increases the accuracy of the 1RM prediction for the deadlift in most equations but still may lead to an overestimation of the 1RM.

Use Of Hr_{index} To Predict Oxygen Uptake: A Validation Study

Jie Kang, FACSM, Christopher Roser, Devyn Montemarano, Hannah Mercado, Morgan Choma, Christian Mendez, Matthew Pollock, Nicholas A. Ratamess, Avery D. Faigenbaum, FACSM, Jill A. Bush, FACSM. *The College of New Jersey, Ewing, NJ.*
 Email: kang@tcnj.edu

(No relevant relationships reported)

Heart rate index (HR_{index}), expressed as an activity HR divided by resting HR (HR_{rest}), has been proposed to estimate oxygen uptake (VO₂) of physical activity and aerobic capacity (VO₂max). Recently, a prediction equation (e.g., METs=6×HR_{index}-5) that used HR_{index} to predict VO₂ in MET was developed retrospectively from aggregate data of 60 published studies. However, it is unclear whether this predictive model is accurate when applied among individuals. **Purpose:** To examine the predictive validity of the HR_{index} equation by comparing submaximal and maximal VO₂ predicted by the HR_{index} equation (VO₂-Pred) with that measured by indirect calorimetry (VO₂-Meas). **Methods:** 60 healthy adults (21±2 yrs.; 28 males and 32 females) participated in this study. Each subject underwent a VO₂max test and an experimental session on two separate days. The experimental session consisted of a 15-min resting period and three successive 10-min treadmill exercise bouts performed at 40%, 60% and 80% of VO₂max. VO₂ and HR were recorded continuously during both the VO₂max test and the experimental session and these data were used to obtain VO₂-Pred and VO₂-Meas for each level of intensity and for VO₂max. Validation was carried out by Pearson product-moment correlation analysis, paired t-test, Bland-Altman plots, and by assessment of mean absolute errors. **Results:** A significant ($p<0.05$) correlation coefficient was found between VO₂-Pred and VO₂-Meas at 40% ($r=0.56$), 60% ($r=0.60$), and 80% of VO₂max ($r=0.55$) and at VO₂max ($r=0.51$). VO₂-Pred differed significantly ($p<0.05$) from VO₂-Meas at 40% (5.7±1.4 vs. 4.9±1.0 METs), 60% (8.5±2.0 vs. 7.5±1.4 METs), and 80% of VO₂max (10.5±2.4 vs. 9.6±1.8 METs) and at VO₂max (11.8±2.7 vs. 12.6±2.3 METs). Prediction biases were +0.74, +1.06, +0.82, and -0.83 METs, while mean absolute errors of prediction were 22.1%, 21.6%, 19.1% and 16.1% at 40%, 60%, and 80% of VO₂max and at VO₂max, respectively. **Conclusion:** It appears that the prediction equation involving HR_{index} overestimates VO₂ at submaximal intensities and underestimates VO₂max in healthy adults. These results suggest that further investigation aimed to establish the accuracy of using HR_{index} to predict VO₂ is warranted.

A Novel Device To Assess Eccentric Grip Strength

Naoki Kikuchi¹, Takuya Hashimoto², Mika Saito¹, Yuki Udagawa², Yukina Mochizuki¹, Hiroki Honma¹, Madoka Ogawa¹, Takanobu Okamoto¹. ¹Nippon Sport Science University, Tokyo, Japan. ²Tokyo University of Science, Tokyo, Japan.
 Email: n.kikuchi@nittai.ac.jp

(No relevant relationships reported)

PURPOSE: To determine normative values for eccentric grip strength derived from an original device in general Japanese populations and to investigate the relationship between isometric grip strength and eccentric grip strength. **METHODS:** In the present study, 102 subjects (32 men: age 61.5±11.0 years, height 170.6±6.7 cm, weight 68.2±9.8 kg; 70 women: age 60.7±14.9 years, height 156.0±7.4 cm, weight 52.4±7.2 kg) participated. Isometric grip strength was assessed using a dynamometer (Takei, Co., Ltd, Tokyo, Japan). The peak force of eccentric grip strength was assessed using an original device. The device utilized an AC servo motor (60 W class) to generate eccentric force to unclench the subject's hand at a constant speed of 32.67 mm/s. Intra-class correlation coefficients (ICCs) and coefficients of variation (CVs) were calculated for the variables of interest.

RESULTS: The isometric grip strength was 39.2±7.8 kg and 25.6±4.7 kg in men and women, respectively. The peak eccentric grip strength was 50.0±12.1 kg and 30.9±7.2 kg in men and women, respectively. The CV tended to be higher in the eccentric grip strength (26-26.6%) than in the isometric grip strength group (18.7-20.0%). The ICC of eccentric grip strength was 0.944-0.953 for both groups.

CONCLUSIONS: Based on these findings, it is suggested that the eccentric grip strength device shows good test-retest reliability. In addition, the eccentric grip strength is 20.7-27.5% higher than the isometric grip strength in the general population.

Does Heart Rate Response Confirm The Attainment Of Maximal Oxygen Uptake In Adults 45 Years And Older?

Jeremy Ducharme, Ann Gibson, FACSM, Jonathan Houck, Lydia Hallam, Zachary Mckenna, Christine Mermier. *University of New Mexico, Albuquerque, NM.* (Sponsor: Ann Gibson, FACSM)
 Email: jducharme@unm.edu
 (No relevant relationships reported)

Heart rate plateau (HR_{plat}) is an effective indicator for confirming $\dot{V}O_{2max}$ attainment. However, it is unknown if this criterion holds for older populations. **PURPOSE:** Test the efficacy of HR_{plat} for confirming $\dot{V}O_{2max}$ in older individuals. **METHODS:** Twelve males and twelve females (60±8 years, N=24) completed individualized ramp and staged protocols to volitional fatigue on the cycle ergometer (CE) and treadmill (TM), respectively. Participants then performed verification protocols at 105% of their peak workload from each $\dot{V}O_{2max}$ test. $\dot{V}O_{2max}$ was confirmed using a plateau in $\dot{V}O_2$ ($\dot{V}O_{2plat}$ = largest $\dot{V}O_2$ value - closest neighboring point ≤150 ml/min), a $\dot{V}O_{2max}$ verification criterion of a $\dot{V}O_2$ not greater than 2% higher than the incremental phase, and two different criteria for HR_{plat} (≤2 bpm or ≤4 bpm). Secondary criteria for establishing maximal effort were $RER_{max} \geq 1.10$, $HR_{max} \pm 10$ bpm of $APHR_{max}$, $RPE \geq 17$, and $[BLa] \geq 8$ mM. **RESULTS:** Data are presented (Table 1) as sex-specific percentages. All attained $\dot{V}O_{2plat}$ on both modalities. The verification criterion was met by ≥ 67% of females and ≥ 92% of males in our sample regardless of modality. HR_{plat} (≤2 bpm) was met by ≤ 67% of females and ≤ 44% of males in our sample regardless of modality. Males more frequently attained HR_{plat} (≤4 bpm) than did females; females attained HR_{plat} (≤4 bpm) more frequently on TM as compared to CE. **CONCLUSION:** A verification bout is reliable for confirming $\dot{V}O_{2max}$ in older males on both modalities and for females on the TM. HR_{plat} (≤4 bpm) may serve as a standalone criterion for TM $\dot{V}O_{2max}$ attainment for males and females. $\dot{V}O_{2plat}$ was the most robust method for confirming $\dot{V}O_{2max}$ attainment in older adults. Due to wide variability in the literature regarding $\dot{V}O_{2plat}$ criteria and indirect calorimetry processing methods, agreement on a standardized definition for $\dot{V}O_{2plat}$ and clear data processing procedures are needed. Table 1. $\dot{V}O_{2max}$ attainment criteria for all tests across sex and modality (N=24)

Criterion	Treadmill (%)		Cycle Ergometer (%)	
	Males	Females	Males	Females
$\dot{V}O_{2plat}$ (≤150ml/min)	100	100	100	100
HR_{plat} (≤2 bpm)	44	67	25	18
HR_{plat} (≤4 bpm)	100	83	75	64
$[BLa]$ (≥8mM)	25	8	50	25
HR_{max} (± 10 bpm $APHR_{max}$)	90	92	92	75
RER_{max} (≥ 1.10)	83	75	92	100
RPE (≥17)	92	100	100	100
$\dot{V}O_{2verif}$ (≤2% higher than $\dot{V}O_{2max}$)	92	83	92	67

$\dot{V}O_{2plat}$ = plateau in oxygen consumption. HR_{plat} = plateau in heart rate. $[BLa]$ = maximal blood lactate concentration. $APHR_{max}$ = age-predicted heart rate max (220-age). RER_{max} = maximal respiratory exchange ratio, RPE = maximal rating of perceived exertion. $\dot{V}O_{2verif}$ = $\dot{V}O_{2max}$ of the verification trial.

242 Board #58 May 27 9:30 AM - 11:00 AM
SEX DIFFERENCES IN MAXIMAL OXYGEN UPTAKE: WHAT ARE THE BIGGEST CONTRIBUTORS?

Nicholas D. Tocci, Madeline G. Miller, Marco Meucci. *Appalachian State University, Boone, NC.* (Sponsor: Scott Collier, FACSM)
 (No relevant relationships reported)

Previous investigations in maximal aerobic capacity ($\dot{V}O_{2max}$) have attributed sex differences to anatomical and physiological parameters. **PURPOSE:** To determine the main factor affecting $\dot{V}O_{2max}$ in a sample of physically active young adults. **METHODS:** Sixteen college-aged students (18-25 years, 8 males and 8 females) participated in one laboratory visit including body composition, hematocrit (HCT), and $\dot{V}O_{2max}$ assessment. Lean body mass (LBM) and fat mass (FM) were obtained from a whole-body DEXA scan. Hematocrit (HCT) was determined using a finger prick blood sample and validated by measures of urine specific gravity (USG) to control for hydration status. A graded exercise test was performed on the cycle ergometer using 25 watt (W) per minute and 20 W per minute incremental protocols for men and women respectively. $\dot{V}O_{2max}$, cardiac output max (Qmax) and stroke volume max (SVmax) were recorded using the COSMED Quark CPET metabolic cart. Cardiac output was

determined using the Fick principle. Test measure means were grouped by sex and analyzed for significance using a one-way ANOVA. A Pearson's R correlation was performed to determine the association between variables of HCT, LBM, SVmax, Qmax, absolute $\dot{V}O_{2max}$.

RESULTS: Males showed significantly greater measures of height (177.94 cm ± 5.74 cm vs. 166.6 cm ± 3.1 cm; p<0.01), LBM (63.70 kg ± 7.51 kg vs. 43.85 kg ± 1.90 kg; p<0.01), HCT (46.9% ± 3.5% vs. 42.2% ± 3.0%; p<0.05), absolute $\dot{V}O_{2max}$ (3.377 L/min ± 0.464L/min vs. 2.439 L/min ± 0.300 L/min; p<0.05), Qmax (20.4 L/min ± 2.3 L/min vs. 14.84 L/min ± 1.80 L/min; p<0.01) and SVmax (110.1 mL ± 13.5 mL vs. 78.24 mL ± 7.47 mL; p<0.01) compared to females. Pearson's R correlation analysis showed that absolute $\dot{V}O_{2max}$ (L/min) was positively correlated with Qmax (R= 0.989), SVmax (R= 0.958) and LBM (R= 0.777).

CONCLUSIONS: Sex differences in maximal aerobic capacity should be understood predominantly as a consequence of maximal cardiac output and sex-related differences in body size and lean mass.

Accuracy Of Age-predicted Maximal Heart Rate In The General Population

Daniel Shookster, Bryndan Lindsey, Joel Martin, Nelson Cortes. *George Mason University, Manassas, VA.*
 Email: ncortes@gmu.edu
 (No relevant relationships reported)

Age-predicted maximal heart rate (APMHR) is an essential measure for health care professionals in determining cardiovascular response to exercise testing, exertion during exercise, and exercise prescription. Although multiple prediction equations have been validated for specific populations, the criterion validity of each for use in a general population requires testing. **PURPOSE:** To evaluate the agreement between measured max heart rate (HR_{max}) with APMHR equations in the general population. **METHODS:** HR_{max} from 99 graded treadmill exercise tests (GXT) at a sports performance clinic were attained (age: 38.2±12.4, BMI: 25.6±3.9, $\dot{V}O_{2max}$: 46.5±10.3). GXTs was terminated once volitional fatigue was achieved and were only included for analysis if RER exceeded 1.10. Five previously established equations were used to predict HR_{max} : Fox (220-age), Tanaka (208 - 0.7*age), Gellish (207-0.7*age), Gulati (206-0.88*age), and Arena (209.3-0.72*age). Bland-Altman plots were used to establish the level of agreement. Univariate ANOVA with pairwise comparisons was performed to assess if differences existed between measured and predicted HR_{max} . **RESULTS:** Figure 1 depicts agreement between measured and predicted HR_{max} . A significant main effect was found for HR_{max} between measures ($F_{5,588} = 12.094$, p<0.001). The Gulati equation was significantly different from GXT HR_{max} (p<.001). Analysis of Bland-Altman plots revealed minimal bias with similar levels of agreement in all prediction equations with the exception of Gulati (mean difference: 9.3). Slope of the plots show that prediction equations underestimate HR_{max} in individuals with lower measured HR_{max} and vice versa, with the exception of the Fox equation. **CONCLUSION:** All prediction equations aside from Gulati may be suitable to predict HR_{max} in a general population. The Fox equation may be superior as it is less likely to under or overestimate based on individual HR_{max} .

Figure 1. Bland-Altman plots showing levels of agreement between HR_{max} during GXT and the Fox (A) and Gulati (B) prediction equations

A Validation Study Of A Treadmill Speed Incline Conversion Chart

Nicholas A. Foreman, Christopher J. Lundstrom, Emma J. Lee. *University of Minnesota, Minneapolis, MN.*
 Email: forem056@umn.edu
 (No relevant relationships reported)

PURPOSE: To investigate the accuracy of the Hillrunner.com treadmill speed/incline conversion chart using ventilatory data, heart rate, subjective perceived effort, and blood lactate. **METHODS:** Two groups of experienced runners, divided based on their self-reported easy run pace, ran at 6 different speed/incline combinations for 5 minutes each. All stages were equivalent according to the HillRunner.com chart, and 1 minute standing rest was given between stages. Group 1 (n=11) ran at inclines up to 4%, while Group 2 (n=22) ran at inclines up to 10%. Oxygen consumption ($\dot{V}O_2$),

respiratory exchange ratio (RER), heart rate (HR), blood lactate (BL), overall rate of perceived exertion (RPE), and leg RPE (LRPE) were measured for each stage. $\dot{V}O_2$ was compared against the $\dot{V}O_2$ predicted by the ACSM equation (ACSM. $\dot{V}O_2$). Stage order was randomized, and repeated-measures ANOVA was used to detect differences between stages and inclines. **RESULTS:** Measures of exercise intensity did not change as incline rose from 0% to 4% in Group 1 ($p > .05$). Increases in $\dot{V}O_2$ (42.2 ± 3.6 to 45.9 ± 4.0 mL.kg⁻¹.min⁻¹; $p < .05$), HR (146 ± 12 to 151 ± 12 bpm; $p < .05$), BL (1.4 ± 0.9 to 1.9 ± 1.2 mM; $p < .05$) and LRPE (10 ± 2 to 12 ± 2 ; $p < .05$) were found as incline increased from 0% to 10% in Group 2. When compared with $\dot{V}O_2$, ACSM. $\dot{V}O_2$ underestimated oxygen consumption at all inclines up to 8% ($p < .05$). ACSM. $\dot{V}O_2$ was similar to $\dot{V}O_2$ at an incline of 10% in Group 2 (45.9 ± 4.0 vs. 46.7 ± 2.4 mL.kg⁻¹.min⁻¹; $p > .05$). Within subjects, pooled results show moderate correlations between HR and BL at 0% and 2% ($R = 0.478$, $R = 0.587$; $p < .01$) but not at 4% ($R = 0.309$; $p > .05$). Statistically significant correlations were also found between HR and BL at 6%, 8%, and 10% ($R = 0.601$, $R = 0.560$, $R = 0.600$; $p < .01$) in the Group 2 participants. **CONCLUSIONS:** The HillRunner.com chart appears valid at relatively low inclines. However, at higher inclines, the decreases in speed may not prevent increases in exercise intensity as measured with $\dot{V}O_2$, HR, BL, and LRPE. The ACSM $\dot{V}O_2$ prediction equation underestimates oxygen consumption in a trained population at inclines up to 8%.

245 Board #61 May 27 9:30 AM - 11:00 AM
Development And Reliability Of A Comprehensive Test Battery For Performance Diagnostic In Team Sports
 Valerie Dieter, Katharina Riegert, Inga Krauss. *Medical Clinic, University Hospital, Tuebingen, Germany.*
 (No relevant relationships reported)

Team sports are characterized by complex coordinative and conditional abilities that are prerequisites for optimal performance and injury prevention of the athletes. To assess these abilities, comprehensive and reliable tests are needed. **Purpose:** The aim of this study was to determine the test-retest reliability of team-sports specific performance tests and to optimize test execution with respect to test quality. **Methods:** Single-limb standing balance (SB_left, SB_right), straight-line sprint over 10 m (SLS_10), foot tapping test over 3 and 15 s (FTT_3 and FTT_15), Countermovement Jump (CMJ) and Drop Jump (DJ) were evaluated. 16 healthy students (8 males, 8 females) participated in the study, which was conducted in two waves with $n = 8$ each. From the findings of study 1 (s1), test execution modifications for 3 of 6 tests were defined in study 2 (s2). Therefore SLS_10, FTT_3 and FTT_15 were analyzed with $n = 16$. Results of SB, CMJ and DJ refer separately to s1 and s2. Test-retest was assessed on two occasions within 1 week. Reliability was analyzed by use of intraclass correlation coefficient (ICC) and 95%-limits of agreement (LoA). Classification of reliability was based on the following ICC values: < 0.5 : poor, $0.5 < 0.75$: moderate, $0.75 < 0.90$: good, > 0.90 excellent. **Results:** The overall ICC indicate an excellent reliability for SLS_10 (ICC 0.93; LoA -0.1 to 0.1 s). FTT_15 and FTT_3 show moderate to good reliability (FTT_15: ICC 0.74; LoA -1.4 to 0.8 Hz; FTT_3: ICC 0.77; LoA -1.4 to 0.9 Hz). CMJ demonstrate an excellent reliability for both studies with ICC 0.92 (s1) vs. 0.93 (s2) and LoA -2.5 to 6.2 cm (s1) vs. -1.2 to 4.5 cm (s2). SB_left (s1: ICC 0.66; LoA -139.2 to 199.1 mm; s2: ICC 0.68; LoA -97.6 to 83.8 mm) and SB_right (s1: ICC 0.61; LoA -70.8 to 200.7 mm; s2: ICC 0.67; LoA -81.9 to 111.4 mm) indicate a moderate reliability and DJ a good reliability (s1: ICC 0.77; LoA -5.6 to 7.4 cm; s2: ICC 0.81; LoA -5.2 to 5.4 cm) in both study groups. **Conclusion:** Except for tests of standing balance, all other tests revealed a good to excellent test-retest reliability by use of ICC with SLS_10 and CMJ as the outstanding tests. Test modifications towards s2 led to slight improvements in reliability. However LoA reveal remarkable intra-individual variations between s1 and s2 which should be kept in mind when testing and rating an athlete's performance.

Comparison Of Portable Metabolic Analyzers During Walking, Running, And Jogging
 Alex Toulouse¹, Patrick Davis¹, Dustin Joubert², Gary Oden¹.
¹Sam Houston State University, Huntsville, TX. ²Stephen F. Austin University, Nacogdoches, TX.
 (No relevant relationships reported)

Portable devices that accurately detect the composition of expired gases open new possibilities in research and accessibility of energy expenditure and aerobic capacity measurements.

PURPOSE: The purpose of this study was to compare the O_2 uptake measurements of the $\dot{V}O_2$ Master Pro (VM) to the Cosmed K5 (K5) during walking, jogging, and running in field and lab conditions.

METHODS: Twelve proficient runners, with a current 10k pace of 5:19 min/km, performed 3 matched intervals at 3 different speeds (4.82, 8.05, 11.27 kph) on a treadmill and on an outdoor track, while expired gasses were measured. During walking intervals, the VM did not report data for the majority of participants, and were, therefore, excluded from analysis. Jogging and running measurements were analyzed

using a repeated measures ANOVA. In addition to the human subject measures, a device airflow test was performed using a 3L calibration syringe timed to a metronome at 15, 25, and 35 bpm to simulate different respiratory frequencies (RF).

RESULTS: The indoor analysis revealed significant differences in $\dot{V}O_2$ (2284 vs. 1320 ml/min at jogging pace; 3,016 vs. 1,880 ml/min at running pace), $\dot{V}e$ (51.1 vs. 40.7 ml/min at jogging pace; 71.02 vs. 57.11 ml/min at running pace), and HR (130 vs. 128 bpm at jogging pace; 157 vs. 155 bpm at running pace) between the K5 and VM respectively ($p < .05$). Outdoor running analysis revealed a significant difference in $\dot{V}O_2$ (2359 vs. 1354 ml/min at jogging pace; 3295 vs. 1969 ml/min at running pace) and $\dot{V}e$ (53.4 vs. 40 ml/min at jogging pace; 81.77 vs. 63.01 ml/min at running pace) between the K5 and VM respectively ($p < .05$). Notably, the outdoor analysis did not show a significant difference in HR or speed ($p > .05$). For the airflow test, a 2-tailed, paired t-test revealed a significant difference in $\dot{V}e$ (46.0 vs. 42.7 ml/min at 15 bpm; 77.2 vs. 69.3 ml/min at 25 bpm; 107.9 vs. 96.2 ml/min at 35 bpm) and TV (3.05 vs. 2.85 L/breath at 15 bpm; 3.07 vs. 2.77 L/breath at 25 bpm; 3.08 vs. 2.75 L/breath at 35 bpm) at all Rf ($p < .001$).

CONCLUSIONS: These findings indicate that there are significant discrepancies between the VM and the K5.

247 Board #63 May 27 9:30 AM - 11:00 AM
Evaluation Of Maximal Oxygen Uptake Using Verification Phases Of Different Intensities Across Fitness Levels
 Seth F. McCarthy, Jarryd MP Leung, Tom J. Hazell. *Wilfrid Laurier University, Waterloo, ON, Canada.*
 (No relevant relationships reported)

Confirmation of maximal oxygen consumption ($\dot{V}O_{2max}$) has relevance in both clinical and exercise settings. Though there are criteria in place to confirm $\dot{V}O_{2max}$ has been attained, they are inconsistently achieved. For example, a plateau in $\dot{V}O_2$ with a corresponding increase in workload is often absent, and other criteria such as a respiratory exchange ratio (RER) ≥ 1.15 or heart rate (HR) within 10 beats per min (bpm) of age predicted maximum can result in an inaccurate estimate of $\dot{V}O_{2max}$. Due to these shortcomings, some researchers have suggested the use of a verification phase (VP) to confirm the attainment of $\dot{V}O_{2max}$. **PURPOSE:** Therefore, this study aimed to provide further evidence for the need to use a VP with $\dot{V}O_{2max}$ testing protocols in populations of different fitness levels. **METHODS:** 49 participants (M: 27, F: 22; 21.9 ± 2.6 y, 24.3 ± 2.8 kg·m²) had their $\dot{V}O_2$ and HR measured during three maximal graded treadmill tests with each test followed by a VP of differing intensity (85%, 95%, 105% final workload). Participants were divided into groups based on their $\dot{V}O_{2max}$ using norms adapted from American College of Sports Medicine (ACSM) $\dot{V}O_{2max}$ guidelines (poor, fair, good, excellent) resulting in 7, 19, 18, and 5 participants respectively. $\dot{V}O_{2max}$ from the graded treadmill test was confirmed with the VP and/or an additional test if the highest $\dot{V}O_2$ value achieved was no more than 2 x typical error (TE: 1.9 to 3.7 mL·kg⁻¹·min⁻¹ across groups). **RESULTS:** Plateau was achieved on 43/147 tests (29%), RER ≥ 1.15 was achieved on 104/147 tests (71%), HR within 10 bpm of age-predicted max was achieved on 83/147 tests (56%), and volitional fatigue was reached on 147/147 tests (100%). The highest $\dot{V}O_2$ value attained on the initial $\dot{V}O_{2max}$ test was not different than either value attained following the VP at 95 or 105% of final $\dot{V}O_{2max}$ test workload or a second repeat test on a separate day ($P > 0.211$). The 85% VP $\dot{V}O_2$ value was lower than the initial $\dot{V}O_{2max}$ test value ($P < 0.001$). **CONCLUSION:** While traditional criteria to confirm the attainment of $\dot{V}O_{2max}$ were inconsistently achieved, the use of a VP (at 95 or 105%) or a subsequent repeat test on a separate day were able to confirm the $\dot{V}O_{2max}$ value attained. Our data also suggests exercise studies employing only a single $\dot{V}O_{2max}$ test should consider these inconsistencies across a range of fitness levels.

DOES LOWER EXTREMITY FMS PERFORMANCE PREDICT VERTICAL JUMP HEIGHT IN FEMALE NCAA DIVISION III FOOTBALLERS
 Kevin R. Alicea-Kuilan. *Norfolk State University, Norfolk, VA.*
 (No relevant relationships reported)

BACKGROUND: Functional Movement Screening (FMS) is typically used as a pre- and post-sports participation tool that examines the athlete's ability to maintain balance, core strength, range of motion, flexibility and stability, which are all components of optimal sports performance. In FMS, higher scores indicate a greater ability to perform one of seven movement patterns. This study aimed to identify which lower extremity FMS movement patterns (deep squat, hurdle step, in-line lunge, and active straight leg raise) would predict vertical jump height. **METHODS:** Twenty-four members of a NCAA Division III women's soccer team (mean \pm SD): (age=19 \pm 1 yrs.; height=1.7 \pm 0.1 m; BMI=23.6 \pm 2.5 kg·m²; body fat=29.1 \pm 4.3%) volunteered for FMS screening in addition to performance testing including vertical jump. All testing was conducted pre-season. **RESULTS:** This study suggests a relationship between deep squat FMS scores and vertical jump height. Stepwise multiple regressions ($p \leq 0.05$) indicated that there is a direct relationship between vertical jump

height and the deep squat ($r = 0.416$, $F = (1, 22) = 4.611$, $p = .043$) but not amongst the other lower extremity FMS tests (in-line lunge, hurdle step, active straight leg raise, p 's = 0.82, 0.78, 0.27 respectively). **CONCLUSIONS:** While there is no one perfect screening tool to assess optimal performance, individual tests within the FMS battery can be useful in identifying performance in NCAA Division III female athletes. The use of individual FMS testing can be an additional predictor for performance variables, particularly those involved with power motion such as the vertical jump.

ESTIMATION OF THE VENTILATORY THRESHOLD USING WIRELESS NEAR-INFRARED SPECTROSCOPY AND DISTANCE MAXIMUM ANALYSIS

David Lawson, Ericka Pursley, Noah Smith, Kendra Voth, Trent E. Cayot. *University of Indianapolis, Indianapolis, IN.*
(No relevant relationships reported)

The ventilatory threshold (VT) separates moderate intensity (<VT) and heavy intensity (>VT) domains and can be determined using a pulmonary gas exchange system in a laboratory setting. Knowledge of an exercise workload (i.e., velocity during running) in which the VT occurs is useful when prescribing individualized cardiorespiratory exercise. If wireless near-infrared spectroscopy (NIRS) systems could estimate the VT, more environment specific testing results could be obtained. **PURPOSE:** To investigate if the VT can be estimated via wireless NIRS responses from the medial gastrocnemius (G) or vastus lateralis (VL) during a running graded exercise test (GXT). **METHODS:** 17 healthy, recreationally active adults (age = 21 ± 4 years, height = 1.68 ± 0.11 m, weight = 66.3 ± 16.8 kg) completed a GXT on a treadmill to volitional fatigue. Every three minutes the velocity was increased by +1 km/hr (starting velocity = 5 km/hr) while the incline remained at 1%. Pulmonary gas exchange and NIRS (G, VL) data were continuously collected. The pulmonary gas exchange data was visually inspected (V-Slope, end-tidal pressures, and ventilatory equivalents) to identify the velocity at which the VT occurred (vVT). The last 15 seconds of NIRS data (G, VL) for each stage were averaged and the velocity at each NIRS threshold (vNIRS-G, vNIRS-VL) were determined by the distance maximum (Dmax) analysis. Concurrent validity of the NIRS thresholds (vNIRS-G, vNIRS-VL) were assessed against the VT (vVT) using Pearson correlation coefficients (r) and standard error of estimate (SEE). Statistical significance was established *a priori* at $p < 0.05$. **RESULTS:** vNIRS-G was not significantly related to vVT (vNIRS-G = 8.6 ± 1.2 km/hr, vVT = 8.1 ± 1.1 km/hr, $r = -0.08$, $p = 0.769$) and had an SEE of 1.2 km/hr. vNIRS-VL also was not significantly related to vVT (vNIRS-VL = 9.1 ± 1.6 km/hr, $r = 0.313$, $p = 0.221$) and had an SEE of 1.1 km/hr. **CONCLUSION:** The present results demonstrate poor concurrent validity between the NIRS thresholds and the VT during running exercise. Based upon the present results, it is suggested that the NIRS threshold not be determined by Dmax analysis during running GXT.

Maximal Oxygen Consumption Differences Between A Treadmill And A Combined Arm And Leg Ergometer Protocol

Jeremy M. Frost, Jacob Kostuck, Corey A. Selland. *Minnesota State University, Mankato, Mankato, MN.* (Sponsor: Donna J. Terbizan, FACSMS)
 Email: jeremy.frost@mnsu.edu
(No relevant relationships reported)

There are different modes of exercise and equipment to measure maximal oxygen consumption (VO_{2max}). The equipment used may elicit different values depending on the amount of muscle mass recruited, the participant's activity history, and if the participant is sitting (bike) or weight-bearing (treadmill). Using a simultaneous arm and leg protocol may serve as an additional testing mode for accurate assessment of cardiorespiratory capacity. **Purpose:** The purpose of this study is to compare the relative VO_{2max} elicited from a common treadmill protocol (TM) to a simultaneous arm and leg ergometer protocol (AL). **Methods:** Participants completed two VO_{2max} trials, separated by 7-14 days, with the order of the trials randomized. The TM trial assessed VO_{2max} using the Bruce protocol. For the AL trial, participants used an arm and leg ergometer at the same time throughout the duration of the test. Resistance started at 50 watts on the electromagnetically-braked bike ergometer and increased by 30 watts for each two minute stage. The arm ergometer resistance started at 24.5 watts and increased 4.9 watts for each two minute stage. Cadence on the arm ergometer was set at 50 rpm while the leg rpm was self-selected. **Results:** Thirteen apparently healthy college-aged participants completed both TM and AL assessment trials (21 ± 1.68, female n = 9). There was a difference ($p < .05$) between TM and AL in VO_{2max} (ml/kg/min) (45.0 ± 7.3 vs. 42.1 ± 6.7, respectively), RER (1.18 ± .08 vs. 1.13 ± .06 min, respectively), and completion time (10.9 ± 1.3 vs. 7.5 ± 2.2 min, respectively), with AL values at 93.6 ± 5.7% (range = 78.8-100.7%) of TM. Peak heart rate was not different between TM and AL (185.7 ± 8.3 vs. 188.3 ± 10.5 min, respectively). **Conclusion:** A standard treadmill protocol elicited a higher VO_{2max} , RER, and completion time than

a novel simultaneous arm and leg ergometer protocol. However, AL values were a high percentage of the TM values. Therefore, a simultaneous arm and leg protocol may serve as an additional option in the assessment of cardiorespiratory capacity.

Temporal Trends In Handgrip Strength For Adults

Trevor Dufner¹, John S. Fitzgerald¹, Justin J. Lang², Grant Tomkinson¹. ¹*University of North Dakota, Grand Forks, ND.* ²*Public Health Agency of Canada, Ottawa, ON, Canada.*
 Email: trevor.j.dufner@und.edu
(No relevant relationships reported)

PURPOSE: To estimate national and international temporal trends in handgrip strength for adults.

METHODS: Data were obtained from a systematic search of studies reporting temporal trends in handgrip strength for adults aged 20-89 years, and by examining national fitness datasets. Sample-weighted temporal trends were estimated using best-fitting regression models relating the year of testing to mean handgrip strength. International and national trends were estimated by a post-stratified population-weighting procedure. **RESULTS:** Trend data from nine studies/datasets representing 2,550,360 adults from five high- and two upper-middle-income countries between 1967 and 2017, collectively showed a negligible decline in mean handgrip strength of -2.6% (95%CI: -2.8 to -2.4) or -0.08 standard deviations (95%CI: -0.09 to -0.07). Internationally, trends were curvilinear over time, with the rate of change (per decade) in handgrip strength steady from 1967 to 2000 at 0.3% (95%CI: 0.0 to 0.6), before declining at -3.5% (95%CI: -3.3 to -3.7) from 2000 onwards. National trends ranged from a decline of -6.3% (95%CI: -7.2 to -5.4) per decade in England (50-89-year-olds between 2004 and 2013) to an improvement of 3.3% (95%CI: 2.8 to 3.8) per decade in Mexico (20-69-year-olds between 1978 and 2000). **CONCLUSIONS:** Despite a negligible improvement from 1967 to 2000, handgrip strength has declined among adults over the past two decades, which is suggestive of a modern decline in overall strength capacity. Temporal handgrip strength data from low- and lower-middle-income countries are needed to better track trends in population health and fitness and to guide healthy public policy.

Metabolic Equations To Estimate VO_{2max} Of Healthy Active Canadian Men Aged 18-34 Years-old: Preliminary Results

Laurie Simard, Marc-Olivier Dugas, Frédérique Lehouillier, Patricia Blackburn, Fernanda Ribeiro, Martin Lavallière, Tommy Chevette. *UQAC, Chicoutimi, QC, Canada.*
 Email: Laurie_Simard@uqac.ca
(No relevant relationships reported)

VO_{2max} is simply defined by the body's ability to use oxygen during physical exercise and is widely used as an indicator of cardiorespiratory fitness. Lower VO_{2max} is associated with higher risk of morbidity and mortality as well as low physical performance while higher VO_{2max} levels predict good performance in aerobic sports. Direct measurement of VO_{2max} is still considered as the gold standard. However, it is costly, required sophisticated equipment, and less accessible. Therefore, several metabolic equations have been developed to estimate VO_{2max} using indirect calculation in sub maximal tests. The most commonly used equations are those developed by the American College of Sport Medicine (ACSM) and the research group of Fitness Registry and the Importance of Exercise National Database (FRIEND). **PURPOSE:** This study aims to evaluate the accuracy of these two equations to estimate VO_{2max} comparatively to direct O_2 consumption measurement. **METHODS:** 30 healthy active men aged between 18-34 years old (BMI: 23.9±2.9 kg/m²) who are avid runners performed a maximal treadmill test with direct VO_2 measures (mlO₂/kg/min) using a metabolic cart (Vyntus CPX). VO_{2max} estimation was calculated using ACSM and FRIEND running metabolic equations. Direct and indirect results were compared with repeated measures T-test. These preliminary results are part of a larger study which includes 180 men and women of all age group (18-34, 35-54, and ≥ 55y.o.). **RESULTS:** Indirect VO_{2max} obtained from ACSM and FRIEND equations showed very large ($d = 2.01$) and moderate ($d = 0.6$) effect size, and were significantly different when compared to direct measures (ACSM: 66.4±7.0; FRIEND: 56.5±5.9; Vyntus: 53.0±6.3; $p < 0.001$). The mean ACSM overestimation was 13.4 mlO₂/kg/min while FRIEND equation was only 3.5 mlO₂/kg/min. **CONCLUSION:** The VO_{2max} calculated with ACSM and FRIEND equations for running showed overestimate values in our male sample. However, the average difference between direct and indirect measurement is smaller when using the FRIEND equation suggesting better accuracy. More research is needed to evaluate the accuracy in different populations and different fitness levels to optimize the VO_{2max} estimation formula.

Self-selected Music Effects Perceived Exertion But Not Metabolic Indices During VO₂Max Testing In Women

Edward H. Robinson, IV. *Meredith College, Raleigh, NC.*
 Email: ehrobinson@meredith.edu
 (No relevant relationships reported)

VO₂max testing for research is often conducted in a highly controlled environment with only "encouragement" from testers to help ensure maximal effort is given. It has been hypothesized that music can have an ergogenic effect by either increasing the state of readiness to perform the exercise or create a state of disassociation from the task being performed to increase performance. For this reason, music is often discouraged during athletic testing. While there is a myriad of hypotheses and research on exercise with music, little research exists on the effect of music on optimal VO₂max testing conditions.

Purpose: This study seeks to determine the effects of self-selected music during a VO₂max test on measures of metabolic indices and perceived exertion.

Methods: Twenty-two women (19.95±0.79y and 65.41±9.96kg) volunteered to participate in this study. Individuals were asked to perform a modified Bruce protocol incremental treadmill test to exhaustion on two occasions separated by at least 24 hours, once with no music, and once listening to self-selected music. Time at volitional fatigue (TTE) was also recorded. During the test, expired gases were recorded to analyze maximal VO₂ and VO₂ at VT. RPE during each stage using the Borg scale and then averaged for each individual throughout the test. Following each test, participants were asked to rate their overall feeling of exertion on a visual analog scale (VAS). Paired samples t-tests were conducted to determine any differences between each condition.

Results: Paired samples t-tests showed no significant difference for TTE (\bar{x} music = 684.18±86.07s; \bar{x} no music = 668.1±81.25s; $p=0.12$), VO₂max (\bar{x} music = 44.45±5.82ml/kg/min; \bar{x} no music = 43.9±7.27ml/kg/min; $p=0.36$), or VT (\bar{x} music = 27.29±6.52ml/kg/min; \bar{x} no music = 26.93±7.03ml/kg/min; $p=0.32$). However, paired samples t-tests revealed significant difference for RPE (\bar{x} music = 13.1±1.58; \bar{x} no music = 14.13±1.48; $p<0.05$) and VAS (\bar{x} music = 10.85±2.29cm; \bar{x} no music = 9.37±2.72cm; $p<0.05$).

Conclusions: The findings of this study supports previous research demonstrating a connection between music and a decrease in perceived exertion during exercise. However, the addition of self-selected music during a testing session did not have a significant effect on all physiological variables measured.

Comparison Of Novel Hop Testing Method To Identify Decreased Performance And Asymmetries

Andrew J. Hermann¹, Garrett Bullock², Bethany Huebner³, Kyle Matsel³, Kyle Kiesel³, Jenna Gourlay¹, Nathan Denning⁴, Phillip J. Plisky³. ¹*ProRehab-PC, Evansville, IN.* ²*University of Oxford, Oxford, United Kingdom.* ³*University of Evansville, Evansville, IN.* ⁴*EXOS, Gulf Breeze, FL.*
 Email: ajhermann21@gmail.com
 (No relevant relationships reported)

Hop testing is used to evaluate athletes that are returning to sport. Evaluating alternative tools that use less repetitive impact could put these vulnerable populations at lower risk for injury during testing. Limited research examines various plyometric tests and traditional hop testing at identifying decreased performance and asymmetries.

Purpose: To examine the association between alternative and traditional hop tests in physically active adults.

Methods: Participants performed a series of seven hop tests in a randomized order including both single and double leg takeoffs for a single, double, and triple jump, and 2-1-2 bound. Three successful trials were performed for each jump. Left and right limbs were combined for all analyses. Spearman's Rho correlations were performed to investigate the relationship between jump tests.

Results: Twenty physically active individuals (age 18 - 32; 11 female, 9 male) participated. There were large associations between single leg single, double, and triple jumps ($r = 0.854-0.960$, $p<0.001$). There were large association between double leg single, double, and triple jumps ($r = 0.908-0.923$, $p<0.001$). There were large associations between single leg single jump and double leg single jump ($r = 0.939$, $p<0.0001$), single leg double jump and double leg double jump ($r = 0.886$, $p<0.0001$), and single leg triple jump and double leg triple jump ($r = 0.851$, $p<0.001$). There were large associations between single leg single jump and 2-1-2 jump ($r = 0.853$, $p<0.001$), single leg double jump and 2-1-2 jump ($r = 0.900$, $p<0.0001$) and single leg triple jump and 2-1-2 jump ($r = 0.904$, $p<0.001$). There were large associations between double leg single jump and 2-1-2 jump ($r = 0.929$, $p<0.001$), double leg double jump and 2-1-2 jump ($r = 0.905$, $p<0.0001$), and double leg triple jump and 2-1-2 jump ($r = 0.832$, $p<0.001$). **Conclusion:** There was a high positive correlation between all single leg jumps tested and the 2-1-2 jump as well as all double leg jumps and the 2-1-2 jump. These results indicate that utilization of double leg 2-1-2 jump may be a safer precursor to examining performance before initiating single leg jumps. These results

demonstrate that the 2-1-2 jump and double leg jumps may be utilized without the increased load of repetitive landing impact on a unilateral limb as seen in traditional hop testing.

ACSM And FRIEND Running Equations, Are They Valid For Healthy Active Women?: Preliminary Results

Marc-Olivier Dugas, Laurie Simard, Frédérique Lehouillier, Patricia Blackburn, Fernanda Ribeiro, Tommy Chevrette, Martin Lavallière. *UQAC, Chicoutimi, QC, Canada.*
 Email: marc-olivier.dugas1@uqac.ca
 (No relevant relationships reported)

VO₂max is simply defined by the body's ability to use oxygen during physical exercise and is widely used as an indicator of cardiorespiratory fitness. Lower VO₂max is associated with higher risk of morbidity and mortality as well as low performance while higher VO₂max predict good performance in aerobic sports. Direct measurement of VO₂max is still the gold standard, however this method presents high cost and required sophisticated equipment. Therefore, several metabolic equations have been developed to estimate VO₂max using indirect calculation. The most commonly used equations are those developed by the American College of Sport Medicine (ACSM) and the research group of Fitness Registry and the Importance of Exercise National Database (FRIEND).

Purpose: The aim of this study is to evaluate the accuracy of these two equations to estimate VO₂max comparatively to direct O₂ consumption measurement.

Methods: 21 healthy active women aged between 22-50y.o. (mean: 37,1±7,4) (BMI: 23,0±2,5kg/m²) performed a maximal treadmill test using a metabolic cart (Vyntus CPX) to measure direct VO₂max (mlO₂/kg/min). VO₂max estimation was then calculated using ACSM and FRIEND running metabolic equations. Results were compared using repeated measures T-test. These preliminary results are part of a larger study which includes 180 men and women of all age group and fitness level (18-34, 35-54 and ≥ 55y.o.).

Results: When compared to the direct measurement (Vyntus: 44,9±4,9), only the ACSM equation showed significantly higher results 53,0±6,6(mean difference: 8,1; $p<0,01$). The FRIEND equation did not significantly differ from the metabolic cart result (45,5±4,7)(mean difference: 0,56; $p=0,5$). In the same direction, ACSM showed a large effect size (Hedge's $g = 1,29$) while Friend only showed a small effect size ($g = 0,11$).

Conclusion: The VO₂max calculated with the ACSM equation for running showed overestimated values in our female sample. The average difference between direct and indirect measurement when using the FRIEND equation suggests a better accuracy. More research is needed to evaluate the accuracy in different populations and different fitness level to optimize the VO₂ estimation formula.

Comparison Of Peak Lactate Levels Between A Wingate Test And Dune Climb

Jennifer A. Ostrowski, Thompson C. Paige, Marlene Wenta. *Alma College, Alma, MI.*
 (No relevant relationships reported)

The Wingate cycle test has been a widely accepted and utilized laboratory test to assess anaerobic power. Blood lactate levels measured during tests of maximal exertion, such as the Wingate, provide useful information regarding energy production pathways that are beneficial to training. Research has indicated that blood lactate levels measured during a cycling test may be lower than those measured during a treadmill test.

However, we were unable to find research that compared peak blood lactate during a laboratory based Wingate cycle test to peak values immediately following a dune climb sprint. **Purpose:** The purpose of this study was to compare maximum blood lactate levels measured directly following a laboratory based Wingate test v. a sprint dune climb in healthy college subjects. **Methods:** 11 participants (5 male, 6 female, mean age 201 years) that were enrolled in a cycling spring term course at Alma College voluntarily completed a sprint dune climb (approximately 70 feet uphill at 5% incline) and a Wingate test. Tests were performed 7 days apart to minimize effects of muscle fatigue. Blood lactate levels were measured immediately following cessation of exercise. **Results:** There was no significant difference in maximum blood lactate level achieved between the two tests (w: 7.4±2.13 mg/dL v. dc: 6.35±4.19, $p = .235$). **Conclusion:** Peak blood lactate levels achieved following maximal anaerobic exercise does not appear to be altered by mode or environment (laboratory v. field based) in this study.

A Comparison Of Female Only Predictive Equations Versus Measured Resting Metabolic Rate

Grace O'Connor¹, Ben Pike¹, Brian Miller², Justin P. Guilkey¹, Jakob D. Lauver¹, Kelly E. Johnson¹. ¹Coastal Carolina University, Conway, SC. ²Mary Baldwin University, Staunton, VA. (Sponsor: William G. Lyerly, FACSM)
Email: mgoconno@coastal.edu
(No relevant relationships reported)

Established prediction equations, such as Dore, Garrow and Weber (GW), and Cunningham (CH) were developed to predict resting metabolic rate (RMR) in females. However, these female prediction equations should be reexamined to determine if an update is required. **PURPOSE:** To examine several well-known female only RMR prediction equations (RMR_{predict}) against measured (RMR_{meas}) values in healthy females. **METHODS:** Fourteen female participants (36.5 ± 16.2 yrs, 166.8 ± 3.6 cm, and 62.7 ± 33.2 kg) participated in this study. Each participant followed standard pre-test guidelines and underwent a single RMR assessment using a metabolic cart calibrated before each test. Each participant laid motionless in a supine position under a ventilated canopy for 25-30 minutes. The most stable 5 minutes of resting data within $\leq 5\%$ of coefficient of variation was defined as the measured resting metabolic rate. A one-way repeated measures ANOVA was used to compare the RMR_{meas} against RMR_{predict} (Dore, GW, and CH). Additionally, Bland Altman Limits of Agreement (LA) were reported as frequency of subjects outside of agreement compared to RMR_{meas} . For significant differences, Cohen's *d* effects sizes were reported. All results are expressed as $M \pm SD$ with significance set at $p \leq 0.05$. **RESULTS:** The GW (1408.3 ± 149.3 kcal/day) and CH (1497 ± 135.8 kcal/day) prediction equations did not differ from the RMR_{meas} (1485.4 ± 247.2 kcal/day) ($p > 0.05$). However, significant differences were observed for Dore (1104.5 ± 89.3 kcal/day; $d = 2.71$) prediction equation when compared to RMR_{meas} . Dore under-predicted 100% of cases under the LA and the Garrow had the highest variability over-predicting and under-predicting 50% and 21.4%, respectively. The Dore equation significantly underestimated RMR when compared to RMR_{meas} by $23.8 \pm 9.3\%$. **CONCLUSION:** Our preliminary data shows that the use of the Dore prediction equation underestimated RMR by 380.9 ± 157.9 kcal/day. Therefore, using this equation to estimate calories in females should be interpreted with caution. Although not statistically different from the RMRmeas, the GW equation had the largest variability of RMR estimates. Our data supports the continued use of the CH prediction equation, as no significant differences were observed compared to RMRmeas in a healthy population of females.

Validation Of A Novel $VO_{2\text{max}}$ Protocol

Griffin Keith Green, Thomas S. Lyons, Whitley J. Stone, Danilo V. Tolusso. Western Kentucky University, Bowling Green, KY.
Email: griffin.green463@topper.wku.edu
(No relevant relationships reported)

The Bruce treadmill protocol is commonly utilized when assessing maximal oxygen consumption ($VO_{2\text{max}}$). As the Bruce was developed originally for cardiac patients, and its initial stages are very slow coupled with a steep grade, it may not be an appropriate protocol for young or trained individuals with higher levels of cardiorespiratory fitness. Additionally, the steep grade used in the Bruce protocol elicits significant local muscular fatigue, which may cause participants to end the test prior to reaching their true $VO_{2\text{max}}$. Secondly, the Astrand protocol also utilizes a steep grade and the speed of the first two stages is relatively slow, which may not elicit a significant cardiovascular response in healthy individuals. The apparent flaws of these two validated tests may present limitations that can induce measurement error and underestimation of $VO_{2\text{max}}$ in healthy or well-trained populations.

PURPOSE: The purpose of this study is to validate a novel $VO_{2\text{max}}$ protocol that may be better suited for healthy or well-trained populations. **METHODS:** Ten participants performed the Bruce, Astrand, and Novel protocols in a randomized and counterbalanced order with the following maximal values being recorded from each protocol: $VO_{2\text{max}}$, minute ventilation (V_e), respiratory exchange ratio (RER), heart rate (HR), rating of perceived exertion (RPE), and time to exhaustion (TTE). **RESULTS:** Paired samples t-tests revealed no differences in $VO_{2\text{max}}$ when comparing the Novel versus both the Bruce ($p = .151$) and Astrand protocols ($p = .503$). Results from the Bland-Altman Analysis revealed that the Novel protocol exhibited a low degree of bias with tight limits of agreement when compared to the Bruce (mean bias $\pm 95\%$ LOA = 1.102 ± 4.357) and Astrand protocols (mean bias $\pm 95\%$ LOA = -0.440 ± 3.920). Additionally, the Novel protocol resulted in significantly lower TTE when compared to the Bruce ($p < .001$) and Astrand protocols ($p = .001$). **CONCLUSION:** The Novel protocol produces similar $VO_{2\text{max}}$ values to that of the Bruce and Astrand protocols with lower TTE, or test duration, making it a quicker and more effective protocol for this population.

Swim Or Run? Comparison Of Flume And Treadmill Maximal Aerobic Capacities In Trained Swimmers

Daniel J. Monarrez, Leonardo D. Dominguez, Merry A. Bestard, Veronica L. Pinedo, Cheryl A. Simmons, George H. Crocker. Cal State LA, Los Angeles, CA.
(No relevant relationships reported)

PURPOSE: Treadmill testing and cycle ergometry are the most common modes of exercise testing for assessing maximal aerobic capacity ($VO_{2\text{max}}$). Most sedentary subjects and trained runners have higher $VO_{2\text{max}}$ measurements during treadmill testing compared to cycle testing, suggesting mode of exercise affects $VO_{2\text{max}}$. However, trained cyclists attain higher $VO_{2\text{max}}$ values on cycle ergometry than treadmill testing due to the specific adaptations of cycle training. Front-crawl swimming is a dynamic exercise involving both upper and lower limbs. The purpose of this study was to determine if trained swimmers have higher $VO_{2\text{max}}$ values when swimming compared to running. **METHODS:** Eight trained swimmers (3 M, 5 F; 21.6 ± 2.9 years) performed $VO_{2\text{max}}$ testing on a treadmill and in a swim flume. For the flume test, subjects breathed through a 2-way non-rebreathing snorkel that collected their expired breath for analysis. For the treadmill test, subjects used a mouthpiece, nose clip, and 2-way non-rebreathing valve. For both modes of exercise, the subjects' expired air was collected into a mixing chamber and analyzed by a metabolic cart. The subjects exercised at increasing intensities until volitional fatigue on both tests. Blood lactate was assessed before and after each test. Metabolic measurements and heart rates (HR) were measured continuously and reported as 10-s averages. **RESULTS:** The subjects had higher $VO_{2\text{max}}$ values on the treadmill than in the swim flume (56.2 ± 7.8 vs. 50.6 ± 11.5 ml $\text{kg}^{-1} \text{min}^{-1}$, $p = 0.034$). At $VO_{2\text{max}}$, minute ventilation, tidal volume, and respiratory frequency were all higher on the treadmill than in the flume. Respiratory exchange ratio and HR were significantly higher following the treadmill test and post-run lactate tended to be higher on the treadmill test ($p = 0.055$). However, oxygen pulse (VO_2/HR), an index of cardiac stroke volume, did not differ between tests, as both VO_2 and HR were lower while swimming. **CONCLUSIONS:** Results from the study suggest that running elicits a greater cardiovascular demand than swimming even in trained swimmers. This may be due to greater involvement of the larger leg muscles in running than in swimming. Future studies should examine the other three competitive swimming strokes, as they are less efficient than the front crawl and more reliant on the lower body for propulsion.

 $VO_{2\text{max}}$ And Ventilatory Threshold Comparison Between Boxing And Arm-crank Exercise Tests

Enrique A. Sosa, Francisco Morales-Acuna, Manuel Gomez, Lisa Rodriguez, Paulina Caraveo, Janet Juarez, Alvaro N. Gurovich, FACSM. University of Texas at El Paso, El Paso, TX.
(Sponsor: Alvaro N. Gurovich, FACSM)
Email: easosa@miners.utep.edu
(No relevant relationships reported)

PURPOSE: Maximum oxygen uptake ($VO_{2\text{max}}$) and ventilatory thresholds (VT) obtained from an exercise test are indicators of functional capacity. Additionally, they can be employed to prescribe exercise and to evaluate the evolution of an exercise program. For upper-body exercise, the arm-crank exercise test is considered the gold standard to estimate $VO_{2\text{max}}$. Recently, boxing training has been employed as an upper-body physical activity modality in cardiovascular disease populations to improve health outcomes, such as cardiorespiratory fitness. However, according to the specificity principle of exercise training, changes on physical fitness are better reflected if the same modality of exercise is being used during its assessment. Therefore, the purpose of this study was to compare $VO_{2\text{max}}$ and VT estimations between boxing and arm-crank exercise test.

METHODS: Twelve subjects (8 males, 4 females) performed a boxing exercise test by repeatedly executing the boxing combination of right hook and left hook. A metronome set a tempo for participants to follow throughout the exercise protocol; for males, the metronome started at 140 Beats Per Minute (BPM) and increased by 30 BPM after every stage until exhaustion; for females, the tempo was set to 125 BPM and increased 30 BPM after every 2-minute stage until exhaustion. When performing the arm-crank exercise test, participants pedaled at a range of 50 to 60 revolutions per minute. Male subjects start pedaling at 50 Watts (W) resistance and would increase 15 W at the end of each 2-min stage until exhaustion. Female subjects pedaled at 40 W resistance and would increase by 10 W at the end of each stage until exhaustion. Throughout both exercise tests, VO_2 was constantly recorded. Statistical analysis included Bland-Altman analysis for agreement and Pearson correlation for strength of association. **RESULTS:** Although $VO_{2\text{max}}$ and ventilatory threshold showed statistical agreement between both exercise modalities ($VO_{2\text{max}}$ 95% CI [-7.6 to 6.7], VT 95% CI [-29.1 to 21.4]), clinical agreement was not obtained. Additionally, there was a strong association for $VO_{2\text{max}}$ ($r: 0.7$, $p < 0.05$) and a weak correlation for VT ($r: 0.2$, $p < 0.05$). **CONCLUSIONS:** Exercise tests should be specific for the exercise modality that is being used for training.

Contrasting Product Claims With Actual Physiological Measurements Of Popular "Exercise" Equipment

Johnny A. Montoya-Arroyo, Jimena Ramírez-Cambronero, Luis F. Aragon-Vargas, FACSM. *Universidad de Costa Rica, Sabanilla, Montes de Oca, Costa Rica.* (Sponsor: Luis F. Aragón-Vargas, FACSM)
 Email: jjmontoyacr@gmail.com
 (No relevant relationships reported)

People around the world are increasingly aware of their need to exercise regularly. Many of them are turning to simple, attractive solutions they see on television, but not all countries have equally strict regulations for assessment of product claims, and the criteria for scientific support appear to be lax for exercise equipment. It would be unfortunate for people to purchase useless equipment and give up exercise because of a lack of positive results. **PURPOSE:** to measure the acute physiological response to using a popular piece of equipment, commercially available in Costa Rica. **METHODS:** 1) VO_2 was tested at rest and using the equipment with a Jeager MasterScreen CPX metabolic cart (CareFusion Corporation, San Diego, CA). Energy expenditure was calculated simultaneously from heart rate (Polar FT7, Kempele, Finland) (HRM), accelerometry (Actigraph wGT 3x-BT, Pensacola, FL) (ACC), and a pedometer (3DActive PDA-100, London, UK) (PED). 27 young, apparently healthy students (15F, 12M) rested in a supine position for 10 min while measuring oxygen consumption. They proceeded to use the exercise machine according to manufacturer's instructions, in the highest setting, for 10 min (EXER). **RESULTS:** All data are Mean \pm SD. Subjects were 19.1 \pm 1.0 y.o., 1.647 \pm 0.073 m tall, and weighed 63.09 \pm 10.13 kg; resting $\text{VO}_2 = 3.2 \pm 0.7 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$. During EXER, calculated energy expenditure was highest with PED (63.3 \pm 7.6 kcal, gross), registering 2099.1 \pm 250.5 "steps"; HRM recorded 24.7 \pm 7.9 kcal (gross), while ACC recorded 0.8 \pm 1.2 kcal (net) during those 10 min. Exercise intensity was measured from VO_2 at 1.54 \pm 0.23 METs, corresponding to 5.6 \pm 2.2 kcal of net (16.8 \pm 2.8 kcal gross) 10-min energy expenditure. **CONCLUSION:** Not even the least accurate, most generous measurement using PED was close to the infomercial claim of 277 kcal in 10 min for a lean, small female runner. The actual net energy expenditure while using this equipment, as carefully measured in this study with indirect calorimetry, will result in an insignificant amount of body fat loss, even if used for a full hour every day. Users are advised to save their money and buy two or three good pairs of walking shoes instead. Funded by the University of Costa Rica, project VI-838-B6-766.

Constructing A Tool To Assess Orienteer'S Competence

Kuan Yu Lin¹, Kheng Win Khor², Chia Chih Lin³, Bing Zhang¹.
¹Tsinghua University, Beijing City, China. ²National Taiwan Sport University, Taoyuan City, Taiwan. ³National Dong Hwa University, Hualien City, Taiwan.
 (No relevant relationships reported)

Components to determine orienteering performance consists of orienteering map reading ability and physical conditioning. Orienteers are typically trained in a well-designed course with pre-determined locations of start, controls and finish. The winner expends the least time. In addition, athletes always train themselves in varied outdoor settings or even on a treadmill. However, there had been no a tool to assess orienteering map reading ability and physical conditioning respectively. **PURPOSE:** To develop a systematic approach to assess individual map-reading ability and physical conditioning with considering physiological characteristics. **METHODS:** Twelve orienteers (9 males and 4 females, training experience: 3.6 \pm 1.7 yrs., BMI: 21.8 \pm 1.8 kg/m²) were recruited to participate the study. Participants were asked to have 2 runs in the same test course wearing device of Garmin Forerunner® 935/HRM-Tri. The first run mimicked the real competition, which was followed by a second run after enough rest and reviewing the map in detail. Anaerobic threshold (AT: 10.0 \pm 2.0 km/hr) and critical velocity (CV: 11.4 \pm 2.0 km/hr) were measured in lab using a standardized protocol on treadmill. The map-reading ability is defined by the difference between the first run velocity and the second run velocity. Repeated measures of one-way ANOVA was used to exam the mean difference among the first run velocity, the second run velocity, AT and CV. Statistical significant difference is set at $p < .05$. **RESULTS:** The first run velocity was significantly lower than the second run velocity, AT and CV (8.5 \pm 1.2 km/hr vs. 9.5 \pm 1.5 km/hr, 10.0 \pm 2.0 km/hr, 11.4 \pm 2.0 km/hr). However, the second run velocity did not differ from AT. The %HR_{max} of the first run was also significantly lower than that of the second run (85.7 \pm 4.3% vs. 89.8 \pm 2.6%). To further assess individual map-reading ability and physical conditioning, we constructed a four-quadrant analysis tool to interpret the current state and future training direction. Two of participants showed excellent map-reading ability and good physical conditioning, which matched their achievements in formal competition. **CONCLUSION:** A tool for assessing orienteer's competence was developed. It may be helpful for a coach to prescribe individual training plan or select some talent athletes.

Physical Performance Testing For Entry-level Undergraduate Turkish Physical Education Students

CENGİZ AKALAN¹, ROBERT SCALES². ¹ANKARA UNIVERSITY, ANKARA, Turkey. ²MAYO CLINIC, PHOENIX, AZ.
 Email: cengizakalan@gmail.com
 (No relevant relationships reported)

Background: Physical performance testing is required in Turkey on entry to undergraduate study in physical education (PE). However, there is no standard test battery across academic institutions. **Purpose:** This investigation compared a laboratory cardiorespiratory (CR) fitness evaluation with field testing in a convenient group of first year students at an accredited undergraduate PE program. **Methods:** Twelve apparently healthy athletic male undergraduate PE students (mean age=19.5, SD=1.5) individually performed laboratory cardiopulmonary exercise testing (CPET), the Cooper 12-minute Run (C12RT) and the Shuttle Run (SRT) field tests one week apart. Body composition including detailed segmental analysis was also assessed with a Full Body BIA Analyzer. **Results:** The mean CPET VO_2 max was 64.21 ml/kg/min (SD=7.3) with a superior age-gender fitness classification (>55 ml/kg/min; >95th percentile). Both the C12RT (Mean=59.54 ml/kg/min, SD=7.1) and SRT (Mean=60.67 ml/kg/min, SD=3.8) correlated with CPET ($p < 0.05$). The mean Mass of Body Fat and Body Fat% was 10.9, SD=2.4, and 16%, SD= 2.8 respectively. The mean Lean Body Mass was 56.76 kg, SD=6.8. **Conclusions:** The field tests were valid and practical methods of measuring CR fitness in this sample group. **Future Directions:** PE teachers can positively influence students by modeling an active lifestyle to promote physical fitness. The identification of an approved comprehensive physical performance test battery for PE programs in Turkey may provide an opportunity for benchmarking across academic institutions.

Effects Of A Race Timer On The 3 Minute All-out Test For Critical Power

Paul Mandell¹, Boe Burrus², Taylor Bloedon¹. ¹Humboldt State University, Arcata, CA. ²Gonzaga University, Spokane, WA.
 Email: pkm80@humboldt.edu
 (No relevant relationships reported)

The Critical Power (CP) model provides a valuable insight into the physiological capacities of an individual to perform work by profiling both aerobic and anaerobic capacities. The 3 Minute All-Out Test for Critical Power (3MT) was developed as a time conscious method for obtaining CP as well as providing insights into the amount of work done above CP (WEP). Concerns about pacing during the test lead researchers to develop a protocol which blinds participants to time during the 3MT. Due to the role that knowledge of time plays in anticipation, pacing, and decision-making during exercise, this protocol may lead to inaccurate results obtained from the 3MT. **PURPOSE:** To investigate the effects of incorporating a race timer in the 3MT. **METHODS:** Twelve healthy active males (Age: 24.9 \pm 2.2 yrs; Height: 180.4 \pm 7.5 cm; Weight 78.1 \pm 6.6 kg; VO_2 peak 53.9 \pm 6.1 ml.kg.min) completed one VO_2 peak test and one 3MT familiarization trial before completing one standard 3MT and one 3MT with the presence of a countdown race timer in a randomized and counterbalanced order. Paired T-tests were used to compare CP, WEP, PPO, Mean Power, Total Work, VO_2 peak, & HRmax. **RESULTS:** CP was significantly higher in the timer condition (Timer: 276.7 \pm 49.6 Watts vs. Standard: 267.51 \pm 44.54 Watts, $p = 0.02$) while WEP was significantly lower in the timer condition (Timer: 12.47 \pm 4.01 kJ vs. Standard: 13.71 \pm 4.34 kJ, $p = 0.004$). No significant differences were observed in PPO, Mean Power, Total Work, VO_2 peak, & HRmax between trials. **CONCLUSION:** These results suggest that the knowledge of time (elapsed or remaining) may have a significant impact on CP and WEP in the 3MT. This impact may be due in part to the role that knowledge of time plays in pacing and decision making, and fits within the framework of the Affordances Competition Hypothesis. These findings warrant further investigation in more experienced cyclists in order to better understand what role knowledge of time plays in the 3MT.

Shuttle Run And Performance In Aerobic And Anaerobic Capacities.

Nathaniel J. Holmgren, Gianna D. Maragliano, Lena Perry, Karlijn B. Roijackers, Courtney D. Jensen. *University of the Pacific, Stockton, CA.*
 (No relevant relationships reported)

Field hockey is a physiologically demanding sport with intermittent bouts of aerobic and anaerobic performance. The ability to assess player condition is vital to coaching success. In place of VO_2 , the 20-meter shuttle run test (SRT) is a common alternative for on field determination of a player's aerobic fitness. Limited data supports the

relationship between shuttle run and anaerobic fitness in this population. **PURPOSE:** To determine the accuracy of a shuttle run test (SRT) as a predictor of field hockey performance. **METHODS:** We enrolled 19 D1 field hockey players (18-22 years old) in an 11-week prospective study. Goalies and injured players were excluded from the study. A 6-week program prior to the study consisted of a 20m shuttle run during practice. Speed was gradually increased by 0.5 km/h at a time, each increase in running speed was coded as a change in level. A Polar Pro GPS/heart rate recorder (Polar Electro Inc. Bethpage, NY) recorded effort parameters during 43 practices. Data included time in heart rate (HR) zone 4 (80-89%) (sec), time in HR zone 5 (90-100%) (sec), percentage of HR max (%) total distance covered (m), distance/min (m/min), maximum speed (km/h), number of sprints (acceleration >1.9 m/s²), and distance in speed zone 5 (>19.00 km/h) (m). Bivariate correlations and linear regressions tested relationships between SRT and on-field performance. **RESULTS:** SRT was significantly related to total distance covered ($r=0.090, p=0.022$), distance per minute ($r=0.112, p=0.004$), maximum speed ($r=0.097, p=0.013$), distance in speed zone 5 ($r=0.119, p=0.002$), and number of sprints ($r=0.188, p<0.001$). No other relationships were detected. Better performance on the SRT corresponded to more (and more frequent) in-practice sprinting. **CONCLUSION:** Although the SRT may not provide a valid estimate of VO₂ max, it is a valid predictor for many components of on-field performance. It associates with total distance, distance per minute, maximum speed, distance in speed zone 5, and number of sprints in collegiate field hockey players.

Stroboscopic Vision-induced Sensory Reweighting During Postural Control
 Hwigeum Jeong, J. Ty Hopkins, FACSM, Seunguk Han, Hyunwook Lee. *Brigham Young University, Provo, UT.*
 (Sponsor: Ty Hopkins, FACSM)
 Email: hwiguem@gmail.com
 (No relevant relationships reported)

Human postural control is achieved by dynamic reweighting of sensory inputs among visual, vestibular, and somatosensory systems in accordance with an external environment. However, due to experimental limits, little is known how partially disrupted visual inputs affect postural control. **PURPOSE:** The purpose of this study was to explore the effects of stroboscopic glasses on postural control. **METHOD:** 24 healthy people (M: 12, F:12, Height: 172.1±7.8, weight: 67.5±10.4) performed balance tests (jump landing balance and single leg balance) with 3 sets of 10 second, respectively. While the jump landing test has three conditions (eyes-open (EO), and high and low strobe vision (HSV, and LSV) respectively), the single-leg balance has four conditions (EO, HSV, LSV, and eyes-closed (EC)). These two balance tests will be implemented on a firm surface and a foam surface. Main outcome measure were dynamic postural stability index (DPSI) and the center of pressure (COP) excursion with 2 directions (anterior-posterior (A/P) and medial-lateral (M/L)). For the surface conditions, student-t test was used. For DPSI and COP excursion, an analysis of variance with repeated measures was performed to determine difference in balance performance between these visual conditions. **RESULT:** In the jump landing balance, DPSI was greater on the foam than the firm ($p = .0474$). Likewise, in the single leg balance, CoP excursion was greater in both A/P and M/L on the foam than the firm ($p < .0001$). For the vision conditions, in the jump landing balance, DPSI was greater in HSV and LSV than EO ($p = .0100$ and $p = .0013$, respectively). In the single leg balance, CoP excursion was greater in EC, HSV, and LSV than EO ($p < .0001$). Additionally, CoP excursion in EC was greater than HSV and LSV ($p = .0012$ and $p = .0093$, respectively). In the single leg balance, both HSV and LSV showed greater interaction with foam in both A/P and M/L than the firm (6% up to 22%). **CONCLUSION:** The effects of stroboscopic glasses on postural control were less than the effects of eye-close. The subjects seemed to rely more on visual inputs to stabilize posture in an unstable condition. The stroboscopic glasses, that can adjust visual inputs, may be used to measure the reliance of visual inputs in those who have reduced or altered somatosensory function.

Anaerobic Power Measurement Tests In Athletes
 Rodrigo D. Pandelo¹, Braulio H M Branco², Emilson Colantonio³, Romeu Candido, Jr¹, Domingos R. Pandelo, Jr¹.
¹Centro de Alta Performance, Santos, Brazil. ²UNICESUMAR, Santos, Brazil. ³UNIFESP, Santos, Brazil.
 Email: rodrigo.pandelo@hotmail.com
 (No relevant relationships reported)

PURPOSE: The aim of the present study is to verify if Countermovement Jump (CMJ) and Countermovement Jump with arm swing (CMJA) can be used as an alternative for anaerobic power measurement in athletes, due to the higher physical and psychological demand demands required by the Wingate test (WAnT). **METHODS:** Thirteen individuals were selected, all males and physically active. All participants had reported any known cardiovascular, orthopedic or neuromuscular problems. A protocol familiarization session was held before each test in order to

participants had the opportunity to learn about each protocol. WAnT was performed with 7.5% of the participants' body mass. For all tests data were collected for analysis of Peak Power (PP), Average Power (AP) and Fatigue Index (FI). **RESULTS:** The results were as expected as the PP and AP indicators were higher in CMJA compared to CMJ. This was to be expected due to the increased power transfer rate through the use of the arms. The highest power measurements were found in the WAnT test, which was also expected. However, when analyzing FI, WAnT also has the highest index (6.33% in CMJ, 4.89% in CMJA, and 17.08% in WAnT). Comparing the AP (in watts) of the 3 tests, based on measurement of effect size (Hedge's g), the following values were reached: 1.67 for WAnTxCMJ, 1.17 for WAnTxCMJA, and 0.42 for CMJxCMJA. So, can be said that there is large difference, in practical terms, in the first 2 cases, and moderate in the third case **CONCLUSIONS:** This study showed that there are significant differences between the 3 anaerobic lower limb power assessments tested (WAnT, CMJ and CMJA). Therefore the WAnT test should not be replaced by the CMJ and CMJA tests when we are evaluating anaerobic power of the lower limbs, since the existence of significant differences between them, as showed in the effect size analysis (Hedge's g). Remarks can be done in sports that have specific characteristics that recommend the adoption of one or another test, depending on the motor skill and other specific demands

Establishing Prediction Equations For "the Big 3": Bench Press, Squat, And Deadlift
 Amanda Aileen Wheeler Gryffin, Brian Church, Lance Bryant, Greg Allen. *Arkansas State University, State University, AR.*
 Email: awheeler@astate.edu
 (No relevant relationships reported)

The bench press (BP), squat (SQ), and deadlift (DL), often referred to as "the big 3", are three exercises implemented into programs to improve muscular strength, power, and hypertrophy. Many times athletes are limited by injury to perform only one or two of these lifts. Identifying a relationship that would allow prediction of the 1RM for one of these lifts based on the other two would help clinicians, coaches, and other fitness professionals in these situations. **PURPOSE:** The purpose of this study was to use the 1RM bench press, squat, and deadlift for top ranked power lifters and Division I football athletes to establish prediction equations for "the big 3". **METHODS:** Upon University IRB approval, one hundred seventy-four (88 power lifters; 86 Division I football athletes) experienced participants' bench press, squat, and deadlift 1RM scores were collected via the International Powerlifting Federation website and the local university strength and conditioning coaches. Multiple regression was used to determine variability within each set of scores as well as to determine strong predictors. **RESULTS:** Multiple regression analysis demonstrated 86% of variance in 1RM DL is explained by BP and SQ [$F(2, 169)=511.861; p<.001$] with SQ ($\beta=.670$) being the stronger predictor. Eighty-three percent of variance in 1RM SQ is explained by DL and BP [$F(2, 169)=415.904; p<.001$] with DL ($\beta=.798$) being the stronger predictor. And 71% of variance in 1RM BP is explained by DL and SQ [$F(2, 169)=201.718; p<.001$] with DL ($\beta=.624$) showing as the stronger predictor. **CONCLUSION:** When taken together, scores from two of the three lifts may predict the score of the third lift. This allows regression equations to be developed for each of the lifts. The following equations were developed to predict scores for DL, SQ, and BP, respectively, and where DL = 1RM for DL, SQ = 1RM for SQ, and BP = 1RM for BP.
 $DL = 40.511 + (.632)SQ + (.382)BP$
 $SQ = -18.829 + (.847)DL + (.179)BP$
 $BP = 7.855 + (.489)DL + (.171)SQ$
 Clinicians, coaches, and other fitness professionals may use these equations to estimate 1RM scores of power lifters and football athletes in instances where a new 1RM is being established, a return to play decision is being made, or any lift may not be completed for other reasons.

Relationship Between Academic Ability And Physical Fitness In Elementary And Middle School Students
Kosho KASUGA¹, Takahiro NAKANO², Syunsuke YAMAJI³, Kazuo OGURI⁴, Tamotsu KITABAYASHI⁵, Tomoaki SAKAI⁶.
¹Gifu University, gifu, Japan. ²Nagoya Gakuin University, seto, Japan. ³Fukui University, fukui, Japan. ⁴Gifu Shotoku Gakuen University, gifu, Japan. ⁵Tokyo University of Science, Noda, Japan. (Sponsor: Kiyoji Tanaka, FACSM)
(No relevant relationships reported)

PURPOSE: The purpose of this study was to clarify the relationship between physical fitness and academic ability of Japanese children. **METHODS:** The participants were 2,417 elementary school 6th graders and middle school 2nd graders. The overall physical fitness assessment determined from eight physical fitness tests was used as the evaluation value (A: Excellent, B: Slightly excellent, C: Standard, D: Slightly inferior, E: Very inferior). For evaluation of academic ability we used the number of correct answers for basic and applied questions in national language and mathematics, national language (basic and applied), mathematics (basic and applied), basic academic ability (national language and math), applied academic ability (national language and math), and the total number of correct answers for all tests were calculated and analyzed. An independence test was applied to verify the relationship between academic ability and physical fitness. **RESULTS:** As a result of the analysis, significant ($p < 0.01$) associations were found between all items of academic ability and the overall physical fitness assessments for elementary and middle school students. Significant χ^2 values were also found for all academic ability items in total number of correct answers by physical fitness evaluations. Residual analysis indicated that the rate of low correct answers was significantly lower, and the rate of high correct answers was significantly higher in children with higher levels of physical fitness. In other words, important evidence has emerged showing that children who have increased physical fitness owing to outdoor play and sports tend to have higher levels of academic ability. **CONCLUSIONS:** Elementary school students tended to have higher academic ability as their overall physical strength was higher. This tendency appears as a remarkable difference in applied academic ability. On the other hand, in middle school students, the academic ability levels of groups A, B, and C were similar. However, the level of academic ability in groups D and E was remarkably low, and it seems that students in the low physical fitness group lacked a positive approach to study.

Relationship Between Parental Granting Mobility License And After-school Physical Activity In Children
Jie Feng, Wendy Y. Huang, Ruirui Xing. *Hong Kong Baptist University, Hong Kong, China.* (Sponsor: Stephen H.S. Wong, FACSM)
Email: 19481233@life.hkbu.edu.hk
(No relevant relationships reported)

Independent mobility refers to the freedom of children to play or travel without adult supervision. Parents play an important role in influencing their children's physical activity (PA). However, how parental granting mobility license may influence children's after-school PA has seldom been investigated. **PURPOSE:** To investigate the relationship between parental granting mobility license and objectively measured after-school PA among children in Hong Kong. **METHODS:** One hundred twenty-seven children aged 8-12 years were recruited from 3 primary schools. Their parents responded to an 11-item scale to measure parental granting mobility license in four domains: travel to/from school, travel to sport-related destinations, travel to other destinations, and active play. Children wore an ActiGraph accelerometer for 8 consecutive days to assess PA accumulated in after-school period during school days. Univariate and stepwise multiple regression analyses were performed to examine the associations between parental granting mobility license (in both overall score and the four domains) and after-school PA. **RESULTS:** Ninety-five children (9.1 ± 0.7 years, 53.7% boys) provided valid ActiGraph data for at least 3 days and their parents completed the questionnaire. On average, the after-school period lasted for 292.3 ± 100.7 minutes, of which 31.3% was accumulated in light-intensity PA (LPA) and 7.3% in moderate-to-vigorous PA (MVPA). After adjusting for gender, age and body mass index, the overall score of parental granting mobility license was positively associated with after-school MVPA ($B = 0.211$, 95% confidence interval [CI]: 0.033 to 0.389). Two domains of the parental license, i.e., travel to sport-related destinations ($B = 1.112$, 95% CI: 0.322 to 1.901) and active play ($B = 1.633$, 95% CI: 0.473 to 2.792), showed significant associations

with after-school MVPA. However, only active play remained significant in the stepwise multiple regression models. Neither the overall score nor the 4 domains of parental granting mobility license was related with after-school LPA. **CONCLUSIONS:** Higher level of parental granting mobility license, especially the freedom of children to play without adult's supervision, was associated with more after-school MVPA in children.

Exercise Capacity Vs. Mobile And Screen Time In Healthy Pediatric Population
Ronen Bar-Yoseph¹, Lydia Shehadeh¹, Monnera Hanna¹, Merav Zucker-Toledano¹, Gur Mainzer², Mor Mizrachi-Elizarov³, Lea Bentur¹. ¹Ruth Children's Hospital, Rambam Health Care Campus, Haifa, Israel. ²The Baruch Padeh Medical Center, Poriya, Israel. ³Technion-Israel Institute of Technology, Haifa, Israel.
Email: rbaryose@uci.edu
(No relevant relationships reported)

Background: Exercise capacity is related to morbidity and mortality in the general population. Screen time is related to sedentary behavior and physical inactivity in children and adults. There is a paucity of data on screen time vs. exercise capacity using cardiopulmonary exercise test (CPET) in children and adolescents. Our aim was to evaluate and compare exercise capacity using CPET and screen time in healthy pediatric population. **Methods:** Cross-sectional retrospective study assessing daily screen time (questionnaire) and CPET (cycle ergometer). Screen time was analyzed as "total screen time", "mobile devices" (smartphones and tablets) and "sedentary devices" (computer and television). **Results:** Seventy-two healthy non-obese children (mean age 13.6 ± 3.4 y/o, 47% Female, BMI₅₀ 50 ± 30.3) were evaluated. Peak oxygen uptake (peak $\dot{V}O_2$, %predicted) was preserved (mean peak $\dot{V}O_2$, %pred $98.8 \pm 19.2\%$). A negative correlation was found between peak $\dot{V}O_2$ and "total screen time" ($r = -0.32$, $p < 0.007$) and peak $\dot{V}O_2$ and "mobile devices" ($r = -0.33$, $p < 0.004$) while no correlation was found for "sedentary devices". **Conclusions:** "Mobile devices" and "total screen time" were negatively correlated with exercise capacity in pediatric healthy population. Children and adolescents should be encouraged to decrease daily screen time and highlight mobile technology. Larger longitudinal studies are needed to better study the impact of screen time on morbidity in children.

Comparing $\dot{V}O_{2max}$ Assessed By The 20-m Shuttle-run And Maximal Treadmill Test In Adolescents With Obesity
Bryan L. Haddock, FACSM¹, Raphael Mendes Ritti-Dias², Jason Ng¹, Joao Paulo Botero³, Breno Quintella Farah⁴, Wagner Luiz do Prado¹. ¹California State University, San Bernardino, San Bernardino, CA. ²Universidade 9 de Julho, Sao Paulo, Brazil. ³Universidade Federal de Sao Paulo, Santos, Brazil. ⁴Universidade Federal Rural de Pernambuco, Recife, Brazil.
Email: bhaddock@csusb.edu
(No relevant relationships reported)

Cardiorespiratory fitness (CrF) is a strong predictor of health. The 20-m shuttle-run test is widely used to estimate CrF in children. However, it is not clear if it provides reliable data in adolescents with obesity. **PURPOSE:** To compare CrF assessed by the 20-m shuttle-run test and a maximal graded exercise test (GXT) in adolescents with obesity. **METHODS:** Thirty-seven adolescents (16 boys: 15 ± 2 y, 32.5 ± 2.9 kg·m⁻² and 41.9 ± 6.6 % fat and 21 girls: 15 ± 2 y, 34.6 ± 3.3 kg·m⁻² and 48.5 ± 8.5 % fat) underwent two CrF assessments on different days (7-days wash-out between). For the 20-m shuttle-run test, adolescents were instructed to run between two points separated by 20 meters at a predetermined pace that started at 8.5 km·h⁻¹ and increased by 0.5 km·h⁻¹ until the participant failed twice to keep up with an auditory signal or reached exhaustion. Maximum oxygen uptake ($\dot{V}O_{2max}$) was estimated using Barnett and colleague's equation. For the GXT, participants exercised on a treadmill with a speed that started at 3.0 km·h⁻¹ and increased by 1.0 km·h⁻¹ each minute until failure. During the GXT, $\dot{V}O_2$ was measured using open circuit spirometry. **RESULTS:** Estimated $\dot{V}O_{2max}$ was higher in the shuttle-run test (33.4 ± 4.6 ml·kg⁻¹·min⁻¹) compared to the GXT (24.6 ± 6.7 ml·kg⁻¹·min⁻¹, $p < 0.01$). Estimated $\dot{V}O_{2max}$ obtained in the shuttle-run test was not related to $\dot{V}O_{2max}$ obtained in the GXT ($\rho = -0.03$; $p = 0.85$). However, the $\dot{V}O_{2max}$ obtained in GXT was associated with final speed ($\rho = 0.58$; $p < 0.01$) and number of completed stages ($\rho = 0.59$; $p < 0.01$) on the shuttle-run test. **CONCLUSIONS:** Performance indicators from the 20-m shuttle-run test are significantly associated with directly measured $\dot{V}O_{2max}$. However, the predictive equation to estimate $\dot{V}O_{2max}$ based on 20-m shuttle run test is not adequate for adolescents with obesity.

Pilot Study Of A 12 Week Intervention (AERIAL©) To Teach Youth To Head The Ball Safely

Sara PD Chrisman¹, Rachel Hays², Roger Levesque³, Christine MacDonald¹, Stanley A. Herring, FACSM¹, Samuel R. Browd¹.
¹The Sports Institute at UW Medicine, Seattle, WA. ²Seattle Children's Research Institute, Seattle, WA. ³VICIS, Seattle, WA.
 (Sponsor: Stanley Herring MD, FACSM)
 Email: sara.chrisman@seattlechildrens.org

Reported Relationships: S.P. Chrisman: Receipt of Intellectual Property Rights/Patent Holder; The AERIAL program was co-developed by The Sports Institute at UW Medicine and VICIS and both hold ownership. No fees are associated with this program.

PURPOSE: To assess feasibility and acceptability of AERIAL©, a 12-week heading training program developed by VICIS© in collaboration with the University of Washington (UW). **METHODS:** We conducted a longitudinal cohort study with n=21 youth (9 male, 12 female) from 2 premier level U12 soccer teams in the Seattle area. Coaches were trained regarding the AERIAL© program, instructing youth to perform the drills each week while correcting form. Drills focused on active core strength, spatial awareness, and heading progression and took approximately 20 minutes per week. Data were collected at three time points (baseline, 6 weeks and 12 weeks) with a primary outcome of feasibility and acceptability, secondary outcome of heading confidence, and an exploratory outcome of heading safety behaviors (assessed via standardized video at the same three time points). **RESULTS:** Feasibility and acceptability were high for all stakeholders (mean/total, standard deviation): youth (4.60/5, SD 0.28), parents (4.52/5, SD 0.86), and coaches (3.83/5, SD 0.55). Heading confidence significantly improved in females in both games and practice from baseline to 6 weeks (Wilcoxon matched-pairs signed rank, p=0.0033 games and p=0.032 practice), and remained stable at 12 weeks. Males reported a high level of heading confidence at baseline and had no significant increases during the study. Video coding indicated a number of safety behaviors were present at baseline in nearly all athletes (eyes open, core and neck as one, contact with front of head, squared shoulders), while other safety behaviors increased during the training period, though not significant with this small sample size: 1) legs staggered 2) knees bent 3) arms up and 4) palms open. **CONCLUSION:** The AERIAL© program appears to be a feasible and acceptable means for introducing youth to heading and aerial maneuvers, and preliminary data suggests potential efficacy for improving safety and performance.

Effects Of Athletic Performance Training On Injury Prevention And Psychosocial Health In Female Adolescent Athletes

Calvin L. Cole, Kostantinos Vasalos, Gregg Nicandri, Michael D. Maloney, Edward M. Schwarz. *University of Rochester, Rochester, NY.* (Sponsor: Leslie Brandon, FACSM)
 Email: calvin_cole@urmc.rochester.edu
 (No relevant relationships reported)

Two major health concerns with female adolescent athletes are psychosocial wellness and sports-related injuries. It is also known that these health concerns are much greater for minority students who attend high school in economically depressed cities.

PURPOSE: To complete a pilot study on urban underrepresented minority and suburban female high school athletes, to determine the feasibility and utility of using Functional movement screening (FMS) to assess injury risk and Patient-Reported Outcomes Measurement Information System (PROMIS) to assess psychosocial health in this population during 10-weeks of athletic training.

METHODS: In this feasibility pilot study, female student-athletes from an urban minority high school (n=10) and suburban high schools (n=10) were recruited into a 10-week athletic training study. The primary goals of this study were to: 1) recruit and retain the human subjects throughout the study period, 2) evaluate global health (depression, anxiety, pain, peer relationships and physical function) and physical performance, and 3) assess injury risk. Self-reported data from the subjects were collected at each session, and FMS and performance data were collected at pre- and post-intervention. Statistical analyses to assess changes after the 10-weeks of athletic training were performed using paired t-test.

RESULTS: Fifteen students completed the 10-week training, and no adverse events of the training or study were reported. Anxiety (45.8±7.4 vs. 41.4±7.0, p=0.006), peer relationships (51.5±6.8 vs. 54.1±6.5, p=0.02), pain interference (47.0±6.4 vs. 44.1±7.8, p=0.02), were significantly improved, while depression (47.0±7.9 vs. 44.1±6.8, p=0.08) trended towards significance. Bench Press (70.2±10.7 vs. 82.0±13.9, p=0.0009), Pro Agility (5.8±0.5 vs. 5.4±0.4, p=0.005), and Total FMS (20.3±4.6 vs. 30.4±4.5, p<0.0001) were all significantly improved. Surprisingly, 10 students (67%) were in peril of sports-related injury (FMS<14) at the start of the program, and all but 1 (90%) eliminated this serious risk factor.

CONCLUSION: PROMIS and FMS are effective outcome measures to quantify changes in psychosocial wellness and sport-related injury risk in high school female athletes. In addition, exercise improves mood and overall health. Supported by William & Sheila Konar Foundation

An Investigation Of Factors Predicting Injury Among Adolescent Softball Players

Chelsea Martin¹, Kaylee Pobocik¹, Mallory Faherty², Srikant Vallabhajosula¹, Mary Kay Hannah¹. ¹Elon University, Elon, NC. ²Duke University, Durham, NC. (Sponsor: Dr. Stephen Bailey, FACSM)
 Email: cleonard12@elon.edu

(No relevant relationships reported)

Upper extremity (UE) injury risk is a concern among adolescent softball players. Previous studies have found injury rates among adolescent softball players to be between 0.95 to 5.6/1000 athlete exposures. Few studies exist that investigate that seek to predict injury in adolescent softball players via musculoskeletal characteristics (MSC) or outcome measures. Understanding factors that can predict injury is important to clinicians for mitigating injury risk. **PURPOSE:** To investigate which MSC and outcome measures can predict injury in adolescent softball athletes. **METHODS:** 67 adolescent softball athletes participated (Age: 15.8±3.3 years). MSC and outcome measures were assessed prior to the start of the high school season, and each athlete was interviewed at the mid-season (8 weeks) and end of season (16 weeks) time points to update injury status. For MSC, the dominant side throwing UE and ipsilateral hip were established. ROM assessments included internal (IR), external rotation (ER), and total range of motion (TROM) of glenohumeral and hip joints. Strength included IR and ER of glenohumeral and hip joint, and hip abduction. Flexibility assessments included pectoralis minor length, and posterior shoulder tightness. Postural measurements included forward head posture and forward shoulder posture. Outcome measures included the QuickDASH with Sport Module, the Kerlan-Jobe Orthopaedic Clinic Shoulder and Elbow questionnaire (KJOC), and the Functional Arm Scale for Throwers. A ROC curve analysis was performed to assess all aforementioned variables and outcome measures ability to predict injury. **RESULTS:** 27 participants experienced an injury from the mid-season to end-season. The QuickDASH Sport Module displayed fair accuracy to predict injury (Area under curve = 0.721). All other measurements had either poor accuracy or failed to predict injury altogether (Area under curve < 0.7). **CONCLUSION:** The QuickDash Sport Module may be used prior to the start of the season as a tool to identify those at a greater risk of injury with caution. Further research is needed to investigate predictors of injury among the softball adolescent population with increased sample size and considering differences among those who play year around, specialize in softball, or amongst different positions.

Does The Mixed Relay Triathlon Affect Respiratory Function In Healthy Junior Triathletes?

Michael D. Kennedy¹, Scott C. Forbes², Joao Henrique Falk Neto¹. ¹University of Alberta, Edmonton, AB, Canada. ²Brandon University, Brandon, MB, Canada. (Sponsor: Darren DeLorey, FACSM)

Email: kennedy@ualberta.ca

(No relevant relationships reported)

Exercise-induced bronchoconstriction (EIB) is a transient narrowing of the airway that can be attributed to heavy ventilation associated with sustained high intensity exercise greater than 8 min. High aerobic and ventilatory training demands can exacerbate the EIB response and lead to prevalence of EIB in endurance athletes like triathletes. The mixed relay triathlon, due to its high intensity and short duration format, will induce heavy ventilation that could lead to EIB. However, no research at present has determined the influence of a mixed relay on respiratory function and baseline spirometry measures which influence EIB.

PURPOSE: To determine severity and prevalence of EIB in healthy triathletes competing in a mixed relay and understand if baseline spirometry is predictive of the EIB response and race performance. **METHODS:** Seven males (17.7 ± 0.4 years, 183.7 ± 3.0 cm) and 5 females (17.6 ± 0.6 years, 171.1 ± 2.7 cm) competed in the Canadian Championships (300m swim, 6km bike, 1.6km run). Spirometry measures of Forced Expiratory Volume in 1 sec (FEV1), Forced Vital Capacity (FVC), FEV1/FVC (%), Forced Expiratory Flow at 50% FVC (FEF50), FEF 25-75% and Peak Expiratory Flow (PEF) was performed before warm up and 5 min post-race. Measures were calculated as % delta change (for EIB determination) and in raw units to determine pre-post differences in measures via paired sample t-tests. **RESULTS:** Mean race time was 22.4 ± 1.5 min including transitions (swim 4.5 ± 0.5 min, bike 10.4 ± 0.7 min, run 6.1 ± 0.6 min). No spirometry measure was significantly decreased post-race. One athlete had mild EIB (% decrease in FEV1 between 10 and 25%) and 2 athletes had a baseline FEV1/FVC ratio <0.7. Percent delta change in PEF and FEF 25-75% were

correlated to finish time ($r=-0.78, r=-0.83, p<0.05$ respectively). **CONCLUSION:** An all-out 20 min ultra-short triathlon does not negatively affect respiratory function in young healthy junior triathletes. It maybe that the decrease in PEF and FEF 25-75 affected finish time due to reduced airway function affecting exercise intensity. The low prevalence of EIB compared to older endurance athletes supports the late onset of EIB in endurance athletes (> 25 years) although the 2 athletes with <0.7 resting FEV1/ FVC ratios show signs of underlying airway obstruction.

Dynamic Warm-up Effects On Maximal Treadmill Exercise Performance In Children: A Pilot Study

Avery D. Faigenbaum, FACSM, Jie Kang, FACSM, Nicholas A. Ratamess, Anne Farrell, Morgan Choma, Hanna Mercado, Devyn Montemarano, Jill Bush, FACSM. *The College of New Jersey, Ewing, NJ.*
Email: faigenba@tcnj.edu
(No relevant relationships reported)

Dynamic warm-up protocols (DWP) consisting of moderate- and high-intensity exercise movements have been found to enhance strength and power performance in youth; however, the effects of DWP on maximal treadmill exercise performance in children are unclear. Prior to pediatric exercise testing participants typically perform low-intensity treadmill walking (TW). **PURPOSE:** To compare the effects of a DWP with a TW warm-up protocol on maximal exercise performance in children. **METHODS:** 11 healthy children (10.8 ± 1.5 yrs) were tested for peak oxygen uptake (VO₂ peak) on 2 nonconsecutive days following different 6 min warm-up protocols performed in random order. DWP consisted of 9 progressive body weight movements including dynamic stretches, lunges, hip bridges, and jumps whereas the TW protocol consisted of walking on a motor-driven treadmill at 2.2 mph and 0% grade. Comparisons between trials were made with a paired t-test. **RESULTS:** VO₂ peak was significantly higher ($p=0.04$) following DWP than TW (56.9 ± 9.1 vs 52.7 ± 9.4 ml/kg/min) and a trend ($p=0.08$) towards greater maximal heart rate was noted following DWP vs TW (192.5 ± 7.5 vs 190.9 ± 7.1 bpm, respectively). No significant differences between DWP and TW trials were observed for maximal minute ventilation (70.7 ± 17.5 vs 64.0 ± 10.4 L/min, respectively), maximal respiratory exchange ratio (1.08 ± 0.05 vs 1.08 ± 0.07, respectively) and total exercise test time (640.9 ± 77.8 vs 638.0 ± 97.4 sec, respectively). No order effects between test day 1 and test day 2 were observed for any variable. **CONCLUSIONS:** These findings indicate that the design of the warm-up protocol can influence the cardiopulmonary responses to maximal treadmill exercise and that a DWP can result in a higher VO₂ peak than a low intensity TW protocol in healthy children.

Differences Of Children's Physical Fitness Between Villages And Cities In Middle China

Jianping Li. *Hubei Minzu University, Enshi, China.*
Email: 383131822@qq.com
(No relevant relationships reported)

PURPOSE: Physical fitness during childhood is an important indicator of current and future health. School-based physical activity (PA) outcomes may be mediated by physical self-concept. Low physical self-concept may negatively impact PA engagement, compromising childhood and adolescent physical fitness, which may translate into adulthood. To establish the physical fitness of children in middle China, and examine differences between boys and girls for physical self-concept, and engagement in school-based and extra-curricular PA. **METHODS:** 456 (girls =223) healthy primary school participants were chosen, and the average age is 7.1±0.3y. Demographics questionnaires and fitness assessment were performed to identify the differences of physical fitness between the villages and city children in the middle of China. Physical self-description questionnaire were asked to answer 'yes' or 'no' to whether they participated in school-based and extra-curricular PA. **RESULTS:** The results showed in table 1 Table 1 The physical fitness differences between villages

Variables	Girls		Boys	
	Villages	Cities	Villages	Cities
Standing long jump (cm)	95.1±18.2	91.2±21.3	104.6±13.8	106.1±17.0
Tennis ball throwing (m)	6.2±2.2	6.4±2.4	9.4±2.7*	7.3±2.4
Sit-and-reach (cm)	8.7±4.4	8.2±4.6	8.1±3.8*	6.3±4.4
Turn back to run (s)	7.1±0.7	6.9±1.1	6.7±0.9	6.6±1.1
Walking on the balance beam (s)	7.7±5.6	8±4.4	5.8±4.5	5.9±2.1
Continuous foot jump (s)	6.9±2	6.6±1.4	5.9±1.8	6.1±1.2

CONCLUSIONS: The data suggests that there was no significant difficulty between villages and cities girls, but the country boys' physical fitness was better than cities boys'. All the students must improve physical fitness through increased PA, especial the girls.

Sprint Speed And Musculoskeletal Fitness Test Performance In Youth

Brittany N. Walleck. *Illinois State University, Normal, IL.*
(Sponsor: Dr. Dale Brown, FACSM)
(No relevant relationships reported)

Sprint speed is a common focus of adult strength and conditioning programming and research. However, the links between sprint speed and other tests of musculoskeletal fitness (MSF) have not been extensively studied in youth. **PURPOSE:** To investigate the relationship between sprint speed and tests of jumping performance, muscular strength/endurance, agility, and anaerobic capacity in children and adolescents. **METHODS:** The analysis included 402 boys and 148 girls (ages 7 to 18 years) participating in a baseline MSF evaluation. Sprint speed was assessed via a 10-yard and 20-yard sprint. Agility and anaerobic capacity were assessed via the pro-agility and 200-yard shuttle run, respectively. Muscular strength and endurance were assessed by maximal number of chin-ups and jumping performance was assessed via the vertical jump, broad jump, and 5-hop jump tests. Pearson correlations were used to determine the associations between each fitness test relative to the 10- and 20-yard sprints, controlling for age and sex. **RESULTS:** Correlations were generally larger between 20-yard dash and other MSF tests than for the 10-yard dash. For example, the strongest correlation with both sprints was the pro-agility test, with $r = 0.755 (p < 0.001)$ for the 20-yard sprint and $r = 0.655 (p < 0.001)$ for the 10-yard sprint. Similar associations were found between the sprints and the 200-yard shuttle run, with correlations of $r = 0.758 (p < 0.001)$ and $r = 0.640 (p < 0.001)$ for the 20-yard and 10-yard dashes, respectively. While similar, the broad jump ($r = -0.657 [p < 0.001]$) had a slightly better correlation with the 20-yard sprint than either the vertical jump ($r = -0.633 [p < 0.001]$) or 5-hop test ($r = -0.629 [p < 0.001]$). The chin-up test had the smallest correlation with 20-yard sprint speed out of the MSF battery ($r = -0.414 [p < 0.001]$). **CONCLUSIONS:** Stronger relationships to the 10- and 20-yard sprints were found for the agility and anaerobic capacity tests compared to all MSF tests; however, all the MSF tests had greater associations to the 20-yard sprint overall. All three jumping tests were similarly associated with sprint speed. Future research is needed to determine if interventions targeting these MSF tests would lead to proportional alterations in the sprinting speed of youth.

Measurement Properties Of Agility And Movement Skill Assessment In Children: A Rasch Analysis

Jindong Chang¹, Naiqing Song². ¹College of Physical Education Southwest University, Chongqing, China. ²The Branch of the Collaborative Innovation Center of Assessment toward Basic Education Quality at Southwest University, Chongqing, China.
Email: changlai@163.com
(No relevant relationships reported)

PURPOSE: To investigate the measurement properties (including rating scale performance, unidimensionality, and differential item functioning) of the motor quotient scale of Chinese version of Agility and Movement Skill Assessment (AMSA) in children, by using the Rasch analysis. **METHODS:** A total of 1116 children (aged 7 to 9 years, 51.3% boys) were recruited in China for this prospective study. Each child was evaluated with the AMSA that consists of 28-item motor scale. Construct validity of the Chinese version of AMSA was investigated using Rasch analysis, whereas inter-rater and test-retest reliabilities were evaluated using Kappa coefficients (n=12). **RESULTS:** The result indicated that the Kappa coefficients for the interrater and test-retest reliabilities were 0.81 (ranging from 0.76 to 0.99) and 0.87 (ranging from 0.80 to 0.99), respectively. No ceiling or floor effects were observed and only one item exhibited misfit to the Rasch model expectations. Item 24 "Dribbling2" exhibited marginal misfit (outfit =1.38), but it did not affect the unidimensionality of the scale. **CONCLUSIONS:** The Chinese version of the AMSA demonstrated satisfactory measurement properties. It showed good indicators of validity and reliability to be used for the assessment of motor quotient of children for 7-9 years old. (This study was supported by NPOPSS Grant 15CTY011)

The Influencing Factor Of Chinese Adolescents' Scientific Fitness Literacy

Lei Yao¹, Yan Li¹, Xiaolei Liu², Jindong Chang³. ¹Southwest University, Chongqing, China. ²High School Affiliated to Southwest University, Chongqing, China. ³Institute of Motor Quotient of Southwest University, Chongqing, China. Email: yaoleisouthwest@163.com
(No relevant relationships reported)

Scientific fitness literacy (SFL) is based on scientific theories and methods to guide the body's ability to exercise. It includes five main contents: knowledge, skills, behavior, attitude, and cognition of scientific fitness. **PURPOSE:** To investigate the main factors affecting Chinese adolescents' scientific fitness and provide countermeasures for Chinese adolescents' health promotion. **METHODS:** A total of 4663 healthy adolescents (age: 22.56 ± 5.81yrs, female: 54.5%) were investigated from 33 provinces. Divided into three groups according to age: juvenile (12-17yrs), pre-youth (18-28yrs), and late youth (29-40yrs); divided into three regions based on the administrative districts: Eastern Region (ER, 13 provinces), Central Region (CR, 8 provinces) and Western Region (WR, 12 provinces). **RESULTS:** We used the "China Adolescents' Fitness Literacy Questionnaire (CAFLQ)". The CAFLQ consists of two parts: (1) Knowledge and Skills (RRC 0.91), and (2) Cognitive, Attitude and Behavior (ICC 0.97, RRC 0.93). The content validity of the questionnaire was assessed by 11 experts. The structural validity was evaluated by the factor analyses. The results indicate that there are differences in the scientific and fitness literacy of adolescents in the following aspects. (1) Gender differences ($F_{(1,4661)}=80.224, P=0.000<0.05$), females (28.60±3.69) were higher than males (27.58±4.07); (2) Age differences ($F_{(2,4660)}=30.332, P=0.000<0.05$), pre-youth (28.32±3.81)>late youth (28.21±3.77)>juvenile (26.94±4.40); (3) Differences of education ($F_{(2,4660)}=63.10, P=0.000<0.05$), Postgraduate (28.54±3.50)>University (28.41±3.76)>Middle school students (26.75±4.43); (4) Region differences ($F_{(2,4660)}=11.165, P=0.000<0.05$), CR (28.63±3.84)>WR (28.15±3.76)>ER(27.85±4.13); (5) Differences of exercise patterns ($F_{(3,4659)}=205.194, P=0.000<0.05$), regular exercise (30.09±3.96)>less regular exercise (28.70±3.51)>occasional exercise (27.92±3.42)>no exercise (25.94±4.00). **CONCLUSIONS:** Age, gender, education, region and exercise patterns are the main factors affecting the Chinese adolescents SFL. Female's SFL is higher than males, pre-youth than juveniles, and CR and WR are higher than ER. The higher education levels, SFL can; the more regular the exercise, SFL can. (#3 is corresponding author)

Exercise Type, Physical Activity Level And Bmi: Association With Cardiorespiratory Fitness In Adolescents

Ana Beatriz Pacifico, Thiago Silva Piola, Michael Pereira da Silva, Edina Maria de Camargo, Jhonatan Gritten Campos, Eliane Denise Araújo Bacil, Wagner de Campos. *Universidade Federal do Paraná, Curitiba, Brazil.* (Sponsor: Carlo Baldari, FACSM)
Email: ana_pacifico@hotmail.com
(No relevant relationships reported)

PURPOSE: To verify the association between type of exercise, physical activity level and body mass index (BMI) with cardiorespiratory fitness in Brazilian adolescents. **METHODS:** Descriptive correlational study, conducted with 350 adolescents (16.26 ± 0.66 years old), from Curitiba, Brazil. Gender, age, type of exercise (sport practice, other type of exercise practice, or not engaged in any type of physical exercise) and physical activity level (at least 420 minutes a week) were evaluated through self-reported questionnaires. The BMI was calculated using kg/m² equation. The pacer physical test was applied to evaluate the cardiorespiratory fitness (VO_{2max}). Poisson regressions, with robust variance, adjusted for gender and age, were calculated to verify the variables associated with VO_{2max} adopting p<0.05. **RESULTS:** Adolescents who practiced sports had a 2.04 times higher prevalence of having VO_{2max} in the healthy zone (PR: 2.04; 95% CI: 1.21-3.44) than those who did not exercise. The VO_{2max} of adolescents that practice another type of physical exercise did not differ from those not engaged in any type of physical exercise. Adolescents classified as sufficiently active had a 1.56 times higher prevalence of being in the healthy zone for VO_{2max} (PR: 1.56; 95% CI: 1.02-2.41) than those who were classified as insufficiently active. BMI showed no significant associations with VO_{2max}. **CONCLUSION:** Adolescents practicing sports had better levels of cardiorespiratory fitness than those who practiced other types of physical exercise and those who did not exercise at all. Additionally, adolescents who achieved adequate levels of physical activity had better levels of cardiorespiratory fitness.

Lower Limb Force And Power Production And Its Relation To Body Composition In 14- To 15-year-old Adolescents

Faton Tishukaj¹, Ismet Shalaj², Masar Gjaka³, Harald Tschan², Barbara Wessner². ¹University of Prishtina, Prishtina, Kosovo, Republic of. ²University of Vienna, Vienna, Austria. ³University of Rome "Foro Italico", Rome, Italy. Email: faton.tishukaj@uni-pr.edu
(No relevant relationships reported)

PURPOSE: To determine the influence of under- or overweight and obesity on force and power production as well as on lower limb asymmetry. **METHODS:** A cross-sectional study including 14- to 15-year-old adolescents was performed. Anthropometric measures and 20-m sprint time were measured and countermovement jump (CMJ) was measured. Force and power production were determined using a portable force plate. **RESULTS:** CMJ and 20-m sprint performances were significantly influenced by BMI categories (both, p<0.001), with obese subjects performing worse than their normal weight counterparts. Peak force and peak power were significantly higher (p < 0.001), especially in obese adolescents, whereas relative peak power was worse in overweight and obese adolescents (p<0.001). Multiple regression analysis revealed that 66.3% of the variance in CMJ and 70.0% of the variance in 20-m sprint may be predicted by gender, body fat percentage, peak force and power. In 13.6% of the participants, limb asymmetries above 15% were detected when limb symmetry index (LSI) was calculated using peak force as underlying factor, whereas only 4.5% had asymmetries in power production between left and right leg. LSI_{power} was higher in obese when compared to underweight children (p = 0.040). **CONCLUSIONS:** Findings of variations in peak force and power between body composition categories, with obese subjects having lowest performance scores, particularly when results are expressed in relation to body mass. Most importantly, a slightly higher LSI was detected among obese adolescents adding to the deleterious effects of childhood obesity on health.

Physical Fitness In Relation With Attention Capacity In Latin-american Youth With Overweight And Obesity
 Antonio García Hermoso¹, Ignacio Hormazábal-Aguayo², Omar Fernández-Vergara², Nicole González-Calderón², Javier Russell-Guzmán³, Francisca Vicencio-Rojas², César Chacana-Cañas², Kely Johana Bonilla-Vargas⁴, Katherine González-Ruiz⁵, Alicia Alonso-Martínez⁶, Mikel Izquierdo⁶, Robinson Ramírez-Vélez⁶. ¹*fundación Miguel Servet - Navarrabiomed, Pamplona, Spain.* ²*Universidad de Santiago de Chile, Santiago de Chile, Chile.* ³*Universidad Autónoma de Chile, Santiago de Chile, Chile.* ⁴*Universidad Nacional de Colombia, Bogotá, Colombia.* ⁵*Universidad Manuela Beltrán, Bogotá, Colombia.* ⁶*Public University of Navarra, Pamplona, Spain.*
 (No relevant relationships reported)

Purpose: There is an increased interest in exploring the association between fitness components with cognitive development in youth in recent years. However, most of the studies so far have focused on healthy weight young people with little evidence with excessive fat accumulation population. To examine the association of health-related physical fitness with attention capacity in Latin-American children and adolescents and to examine whether body fat is moderator of the association between them.
Study design: A cross-sectional study involving 201 children and adolescents with overweight and obesity (12.1 ± 2.1 years old; 34.3% girls) from Chile (The Active-Start study) and Colombia (HEPAFIT study). We assessed physical fitness components (i.e., muscular strength, speed-agility, and cardiorespiratory fitness) using the ALPHA and FUPRECOL batteries. Attention capacity was measured by the d2 test. Lineal regression and moderation analyses were conducted.
Results: Linear regression analysis adjusted for potential confounders (age, sex, body fat, peak height velocity, mother education and study [i.e., Active-Start or HEPFIT]) revealed association between speed agility ($\beta = -7.7$; $p = 0.030$) and cardiorespiratory fitness ($\beta = 4.5$; $p < 0.001$) with attention capacity. The Johnson-Neyman technique revealed a significant relationship between cardiorespiratory fitness and muscular strength and attention capacity when body fat was below, but not above, 34.8% (20% of sample) and 29.5% (48% of sample), respectively.
Conclusions: Cardiorespiratory fitness and speed-agility are associated with higher attention capacity in youth with overweight and obesity, but body fat seems to moderate these relationships. Randomized controlled trials in this population would help to better understand whether improvements in different components of physical fitness leads to better attention capacity by a reduction in their body fat.

Impact Of School Fitness Environment On Children's Fitness: A Mixed Method Study
 Zhiyun Ma. *UIUC, Urbana, IL.* (Sponsor: Weimo Zhu, FACSM)
 Email: zym61801@gmail.com
 (No relevant relationships reported)

OBJECTIVE: While school fitness environment is known to have a significant impact on children's physical activity and fitness, no quick, easy, yet accurate tool is available to assess school fitness environment. The purpose of this study was to develop such a tool and validate it using a contracting-group method.

METHOD: After a comprehensive search on the literature, a check list of school fitness environment, including items in sports facilities, role of PE teachers, training methods by PE teachers, perceived values by principals and teachers and students' reported PE participation etc., was developed. An evaluation team consisting of one researcher and two graduate students was formed and trained. The team then went to two schools, A and B, in Jiujiang city, China, to interview the principals, PE teachers, students in each school, went over the school sport facility, as well as tested a group of Grade 9 students' aerobic fitness (1000-M run for boys and 800-M run for girls).

RESULTS: A total 219 students (106 boys, 113 girls) in School A and 235 students (125 boys, 110 girls) in School B were tested and their aerobic fitness level were evaluated using the 2018 high school entrance exam (HSEE) criterion. After comparing with their rating and some discussions, School A was rated having a better school fitness environment and students' fitness performance (running time in seconds) and corresponding t-test comparison further supported the observation:

	School A	School B	P
Boys (1000-M in s)			
Total	234.0 ± 28.4	242.5 ± 30.8	< .05
HSEE Good & Above	221.4 ± 14.5	227.1 ± 11.8	< .05
Girls (800-M in s)			
Total	216.1 ± 22.6	231.0 ± 27.8	< .05
HSEE Good & Above	211.3 ± 14.4	215.6 ± 13.1	< .05

CONCLUSIONS: With a combination of qualitative and quantitative methods, a simple school fitness environment tool was developed, and by comparing students' aerobic fitness from two schools, its initial validity evidence was collected and confirmed.

Physical Activity, Physical Fitness And Body Mass Index Among Elementary School Children In The Arctic Area
 Karin H. Danielsen, Thilde K. Vårnes, Gunnar E. Mathisen, Kim A. Heitmann, Edvard H. Sagelv, Bente Morseth. *UIT The arctic University of Norway, Tromsø, Norway.*
 Email: karin.danielsen@uit.no
 (No relevant relationships reported)

The World Health Organization recommends that children accumulate at least 60 minutes of moderate-to-vigorous-intensity physical activity (MVPA) daily. However, knowledge about the association between physical activity (PA), physical fitness and body mass index (BMI) among elementary school children in the Arctic is limited.

PURPOSE

To examine the association between PA levels, physical fitness and BMI in elementary school children in Northern Norway.

METHODS

Elementary school children in 1st, 3rd, 5th and 7th grade were recruited to wear an accelerometer (wGT3X-BT, ActiGraph, LLC, Pensacola, United States) for seven consecutive days ($n = 216$). PA was categorized according to intensity, and dichotomized into reaching the PA recommendations or not. Physical fitness was measured by using Test of Physical Fitness (Fjørtoft et al. 2011) consisting of a nine-item compound motor activity score that includes various combinations of endurance, strength, agility, balance, and motor coordination, which is calculated as total physical fitness based on z-scores. BMI (kilogram/height²) was used as body composition measure.

RESULTS

In total, 94 (43%) of 216 the children reached the recommendation of 60 min MVPA per day. There was a significant difference ($p < 0.001$) in total physical fitness score between boys (3.01) and girls (-2.35). A positive association between physical fitness score and reaching the PA recommendations was observed in 3rd, 5th and 7th grade ($p < .05$). BMI was inversely associated with physical fitness in 5th and 7th grade ($p < 0.05$) but not in 1st and 3rd grade. There was no significant association between those who achieved the PA recommendations and BMI.

CONCLUSION

Children in elementary school who reach the recommendations for PA seem to have a higher score on the physical fitness test, except for the first graders. BMI was not related to physical fitness or reaching PA recommendations except an inverse association between BMI and physical fitness in higher grades.

Talk Test As A Measure Of Exercise Intensity In Children
 John P. Porcari, FACSM¹, Makayla Heim¹, Brandon van Galen¹, Deb Sazma¹, Cordial Gillette¹, Cristina Cortis², Andrea Fusco², Carl Foster, FACSM¹. ¹*University of Wisconsin-La Crosse, La Crosse, WI.* ²*University of Cassino e Lazio Meridionale, Cassino, Italy.*
 Email: jporcari@uwlax.edu
 (No relevant relationships reported)

INTRODUCTION: The Talk Test (TT) is a well-accepted measure of exercise intensity and is a useful surrogate of ventilatory (VT) and respiratory compensation (RCT) thresholds in sedentary, fit, athletic, and cardiac populations. Recently, the TT has also been shown to reflect these same markers in children. **PURPOSE:** The present study was designed 1) to replicate TT results during incremental exercise in children, and 2) to evaluate the ability of the TT to predict when the subjects would be above (-TT) or below (+TT) VT intensity during interval exercise. **METHODS:** Healthy pre-pubertal children (5m, 5f) were studied using the TT and gas exchange during incremental exercise to determine the match between TT stages and VT. Another group of healthy pre-pubertal children (7m, 6f) were studied both during incremental and stochastic exercise, in order to determine how well TT responses during stochastic exercise predicted whether the children were above or below VT. **RESULTS:** During incremental exercise, there was good correspondence between the $\dot{V}O_2@VT$ and the $\dot{V}O_2@$ the last positive (LP) ($r = 0.79$) and the equivocal (EQ) ($r = 0.75$) stages of the TT, which match earlier findings from our laboratory (Giddings et al., 2018; LP TT, $r = 0.62$ & EQ TT, $r = 0.75$). During stochastic exercise, correct matching of predicted vs. observed +TT and predicted vs. observed -TT were present 73% of the time. Discordant results were present 27% of the time. These findings

match earlier findings from our laboratory in adults relative to the matching of observed vs. predicted results. **CONCLUSION:** The TT behaves as a similar surrogate of VT in children, as it does in adults, during both incremental and stochastic exercise.

Effect Of Exercise Intervention On Physical Fitness Factors In Elementary School Children
Junjiro Kubo, Saburo Nishimura, Takayuki Ogiwara. *heisei international university, kazo, Japan.*
Email: kubo@hiu.ac.jp
(No relevant relationships reported)

Sports have been very popular after-school activities for children. It is quite likely that sports have a positive effect on child growth in many ways. The Ministry of Education, Culture, Sports, and Technology of Japan has reported that the total scores of physical fitness tests differ greatly between those who exercise regularly and those who do not. However, it is not clear how exercise habits affect physical fitness factors during childhood. Such detailed knowledge would be useful in promoting long-term athlete development and improving physical fitness throughout life. **PURPOSE:** To explore the effect of exercise intervention on physical fitness factors in elementary school children. **METHODS:** The subjects of this study were 1,079 1st- to 6th-grade male elementary school students. A questionnaire survey was conducted to investigate the exercise and lifestyle habits and the results of physical fitness tests conducted at Japanese elementary schools. The existence or not of exercise habits after-school activities and the results of physical fitness tests were used for the analysis. The physical fitness test includes measurements of grip strength, sit-ups, sitting front stretches, side steps, twenty-meter shuttle run, fifty-meter run, standing long jump, softball throw, height, and weight. **RESULTS:** There were no significant differences between grades in the existence or not of exercise habits about height and weight. After the 3rd grade, children with exercise habits showed higher performance on sit-ups, side steps, the twenty-meter shuttle run, the fifty-meter run, and softball throw than children with no exercise habits. There was little difference in grip strength, sitting front stretches, and long jump between children with exercise habits and those without. **CONCLUSION:** Endurance, speed, and agility develop greatly in elementary school children who exercise regularly. However, exercise habits have little effect on single strength and power. In addition, differences between children with and without exercise habits are observed after the 3rd grade.

Changes In Cardiorespiratory Fitness Among Children In The Hearts And Parks Healthy Lifestyle Intervention
Jonathan D. Kenyon, Alyssa M. Zidek, Josi R. Gabaldon, Alexandra R. Zizzi, Julie D. Counts, Leanna M. Ross, Cameron S. Catherine, Ashley C. Skinner, Jennifer S. Li, William E. Kraus, FACSM, Sarah C. Armstrong. *Duke University, Durham, NC.*
(No relevant relationships reported)

In children, resting heart rate (RHR) and heart rate recovery (HRR) serve as markers of cardiorespiratory fitness (CRF), predicting future cardiovascular morbidity and mortality risk. The 2018 Physical Activity Guidelines for Americans recommends children should engage in at least 60 minutes of daily, moderate-to-vigorous exercise. However, less than one-quarter of children in the U.S. meet this recommendation. The Hearts and Parks randomized controlled trial utilizes a novel clinic-community intervention consisting of clinic-based behavioral support and nutrition education, as well as physical activity through the Bull City Fit program for children 5-17 with a body mass index (BMI) $\geq 95^{\text{th}}$ percentile. One aim of the trial is to assess the efficacy of the intervention for improving CRF. **PURPOSE** To examine the effect of the Hearts and Parks intervention program on RHR and 1-min HRR. **METHODS** To date, 49 participants (age: 9.9 ± 3.3 y; non-Hispanic: 61%; males: 45%) completed ≥ 6 months of the Hearts and Parks intervention program and were included in this preliminary analysis. Pre- and post-intervention anthropometric and physical fitness assessments occurred at Duke Children's Primary Care Clinic. CRF was assessed via the 3-min YMCA Bench Stepping Test, adapted for children 5-18. Heart rate was measured via pulse-oximetry prior to the test (RHR), immediately upon test completion, and 1-min after the test. HRR was calculated as the difference between the 1-min post-test and immediate post-test values. Gender-specific paired t-tests were used to determine whether post- minus pre-intervention values were significantly different ($\alpha = 0.05$). **RESULTS** In females only, there was a significant decrease of 5.3 ± 13.0 BPM in RHR following the intervention ($p=0.02$). There was no significant change in HRR following the intervention for males or females.

CONCLUSION Our results showed a beneficial change in RHR for females completing at least 6 months of the Hearts and Parks intervention program. However, we did not observe any significant changes in HRR after the intervention. These preliminary results suggest the potential for this novel clinic-community intervention framework to have beneficial changes in some markers of CRF in children who have obesity.

(No relevant relationships reported)

This Asia-Fit study focused on the physical index of adolescents from Singapore (SGP), providing an overall indication of living habits that may affect obesity levels. **PURPOSE:** To compare physical activity (PA) levels and obesity rates among SGP adolescents. **METHODS:** A total of 1648 adolescents from SGP (age: 13.49 ± 1.21 years, height: 159.76 ± 8.94 cm, weight (WT): 51.98 ± 13.41 kg, body mass index: 20.21 ± 4.22 $\text{k}\cdot\text{g}\cdot\text{m}^{-2}$, body fat percentage (BF%): 21.54 ± 10.21 %) participated in this study. A series of physical tests (15m youth Progressive Aerobic Cardiovascular Endurance Run (PACER) test, one-legged sit-and-reach (SRT), handgrip strength (HS) test, and 1-minute sit-up test (SUT)), a PA questionnaire and anthropometric measurements were collected from schools all over Singapore. **RESULTS:** There were significant correlations between WT and BMI (WT: 51.98 ± 13.41 kg; BMI: 20.21 ± 4.22 $\text{k}\cdot\text{g}\cdot\text{m}^{-2}$; $r = 0.90$, $p = 0.00$), BMI and BF% (BMI: 20.21 ± 4.22 $\text{k}\cdot\text{g}\cdot\text{m}^{-2}$; BF%: 21.54 ± 10.21 %; $r = 0.78$, $p = 0.00$), vigorous exercise (VE) and moderate exercise (ME) (VE: 3.19 ± 2.07 days; ME: 3.06 ± 2.06 days; $r = 0.46$, $p = 0.00$). Negative significant correlation was found between VE and WT (3.19 ± 2.07 days; WT: 51.98 ± 13.41 kg; $r = -0.06$, $p = 0.03$). No significant correlation was observed between ME and BMI (3.06 ± 2.06 days; 20.21 ± 4.22 $\text{k}\cdot\text{g}\cdot\text{m}^{-2}$; $r = -0.04$, $p = 0.13$), VE and BF% (VE: 3.19 ± 2.07 days; BF%: 21.54 ± 10.21 %; $r = -0.04$, $p = 0.09$). 89.5% adolescents participated in ME (3.06 ± 2.06 days), 10.5% did not indicate participation. 70.7% adolescents participated in VE (3.19 ± 2.07 days), 12.1% did not indicate participation. 2.8% adolescents adhered to the American College of Sports Medicine (ACSM)'s recommendation of 60 minutes of PA daily. A slightly higher percentage of adolescents sat for more than 8 hours daily (48.9%) than adolescents who sat for 1 to 8 hours daily (43.0%). 9.1% of adolescents did not report their sedentary duration. **CONCLUSIONS:** Results indicate that Singapore adolescents are active and should continue regular PA as it effects BMI. Lifestyle changes of active behavior as opposed to prolong sitting is important as pre-pubertal obesity may predict adult obesity. Singapore adolescents need to adopt a healthy lifestyle that includes a well-balanced diet, with less sitting time and regular PA to reduce the risk of cardiovascular diseases in adulthood.

Relationship Between Muscle Strength And Body Composition In Young Athletes
Diana Marcela Zapata Torres, Johan E. Ortiz, Danny W. Sanjuanelo, Isabel C. Paz, Maria A. Contreras. *University of applied and environmental sciences (U.D.C.A), Bogota, Colombia.*
Email: diazapata@udca.edu.co
(No relevant relationships reported)

Introduction: A lower cardiometabolic risk in adulthood has been suggested when a better development of the cardiopulmonary and strength condition is reached at an early age. It is important to be able to assess the cardiometabolic risk against variables such as strength in the upper and lower limbs. **Purpose:** To explore the correlation between anthropometric and strength condition variables in upper and lower limbs in boys and girls assigned to sports training schools (soccer, volleyball, skating) in the municipality of Madrid (Colombia). **Method:** A total of 110 children and adolescents were evaluated using long jump test and handgrip strength (HS). The anthropometrics characteristics are, for boys and girls, respectively: weight (kg): 50.5 ± 12.9 and 49.2 ± 11.9 ; height (m): 158.3 ± 11.8 and 152.6 ± 9.2 ; age (years): 13.7 ± 13.8 and 12.9 ± 2.2 . The Pearson's correlation coefficient (r) was used to calculate the correlations regardless of gender and divided by boys and girls. The correlations studied were between the anthropometric variables (weight, height, body mass index (BMI), waist circumference and fat%), compared to long jump test (LJT), right HS (RHS) and left

HS (LHS). The results of r are indicated with a statistical level of significance of $p < 0.001$. **Results:** In the general analysis, $r = 0.81$ was obtained for height versus RHS and LHS and, for weight, $r = 0.68$ and 0.67 was found in RHS and LHS, respectively. When correcting by gender, the height in girls shows $r = 0.7$ and 0.65 in RHS and LHS; while, in children, it was 0.61 , 0.85 and 0.89 for SL, RHS and LHS, respectively. The weight in girls showed $r = 0.6$ for RHS and, in boys, 0.8 and 0.84 for RHS and LHS, in whom $r = 0.6$ and 0.63 for RHS and LHS were also found when compared were made in front of BMI. No associations were found with LJT. **Conclusions:** The results indicated that the strength in the upper limbs (measured through the determination of handgrip strength) is a strong and moderate association in relation to height and weight respectively and regardless of gender. When comparing by gender, this relation is maintained in boys but the association in height went to a moderate level in girls. Thus, the results suggest that the development of strength measured through HS is closely related to the anthropometric characteristics of young athletes, especially height and weight.

Accuracy Of Multi-frequency BIA In %Fat Change During Weight Loss Among Competitive Girl Runners

Eriko Uchiyama¹, Norimitsu Kinoshita¹, Kenta Okuyama².
¹Hosei University, Tokyo, Japan. ²Lund University, Malmö, Sweden.

(No relevant relationships reported)

Periodical measurement of %fat with accuracy is crucial for optimizing the health and performance in competitive runners who need strict weight control. Multi-frequency bioelectrical impedance analysis (MFBI) is feasible for routine use but the evidence of the accuracy is limited to cross-sectional evaluation and no data is available for tracking of %fat change in competitive runners.

PURPOSE: To determine the accuracy of MFBI for evaluating the decrease in %fat by weight loss among competitive girl runners.

METHODS: The data of %fat were obtained from consecutive 25 freshmen long distance runners over 5 years in the same girl's high school team and were retrospectively analyzed. The team regularly participated in the All-Japan high school Ekiden championship. MFBI was performed at the preparatory season (PRE) and repeated after 5.6 ± 0.5 months at the competitive season (CMP) with dual energy X-ray absorptiometry (DXA) as reference. Weight loss period was defined as that between PRE and CMP and changes in %fat ($\Delta\%$ fat) was calculated by subtracting %fat in PRE from those in CMP. Bland-Altman analysis was used to evaluate the validity of MFBI compared to DXA for $\Delta\%$ fat. Statistical significance of the mean difference between MFBI and DXA was assessed by paired t -test. $P < 0.05$ was considered as statistically significant. Written informed consent was obtained from the runners and their parents.

RESULTS: %Fat by DXA vs. MFBI at PRE and CMP were 19.7 ± 5.6 vs. 17.9 ± 5.4% and 12.7 ± 3.1 vs. 12.2 ± 2.6%, respectively. Thus, systemic error (the mean difference) of $\Delta\%$ fat between the 2 methods was 1.2 percentage points [pp] (DXA, -6.9 vs. MFBI, -5.7pp, $p = 0.008$). Random error (the limits of agreement) was -3.0 to 5.5pp and no proportional error was observed between MFBI and DXA.

CONCLUSIONS: The small size of systemic error (mean difference) allow the use of MBIA to evaluate a group mean of $\Delta\%$ fat. However, due to the large random error size relative to the low level of %fat of the competitive runners, caution should be taken to use MFBI for individual monitoring of %fat change during weight loss period.

Physical Qualities Discriminate Playing Level In Elite Youth Hockey Players

David Doan, Sebastien Lagrange, Pierre-Marc Ferland, Alain Steve Comtois. Université du Québec à Montréal, Montreal, QC, Canada.

(No relevant relationships reported)

PURPOSE: The purpose of this study was to compare physical test results between playing levels and positions in youth elite hockey players. **METHODS:** Subjects ($n = 49$) came from 3 distinct levels: *Bantam AAA Relève* (the lowest, $n = 16$), *Bantam AAA Major* (the second highest, $n = 17$), and *Midget Espoir* (the highest, $n = 16$). Physical characteristics and qualities were measured. The stationary broad jump was utilized to measure lower-body power. Jump distance was measured from toes to the closest landed heel. The best of two attempts was marked as the final score. The seated medicine ball throw was utilized to measure upper-body power. Throw distance was measured from the back of the wall to where the ball first made contact with the ground. The 20-meter shuttle run test was utilized to measure aerobic capacity. VO_{2max} was estimated from the last level completed with the Leger-Lambert formula. Results are presented as mean and standard deviation. A single factor (level or position) ANOVA and when significant a post-hoc analysis was also performed by using the least significant difference (LSD) for pairwise comparisons between groups tests results. Statistical significance was set at $p < 0.05$. Analysis was conducted with IBM SPSS Statistics for Windows version 25. **RESULTS:** Hockey

players of the two higher levels were significantly ($p < 0.05$) taller ($1.73 \pm 0.08m$ and $1.74 \pm 0.08m$, respectively, vs $1.63 \pm 0.09m$), heavier ($66.68 \pm 8.09m$ and $68.60 \pm 10.96m$ respectively vs $53.52 \pm 8.73m$), jumped further ($2.25 \pm 0.13m$ and $2.26 \pm 0.12m$ respectively vs $2.01 \pm 0.20m$), and had greater aerobic capacity (3.87 ± 0.52 L/min and 3.84 ± 0.57 L/min respectively vs 2.96 ± 0.49 L/min) than the hockey players from the lower level. However, the higher level players, scored lower than the middle level at the seated medicine ball throw ($3.74 \pm 0.49m$ vs $4.60 \pm 0.48m$), even though the middle level scored higher than the lower level ($4.60 \pm 0.48m$ vs $3.49 \pm 0.53m$). Results also show that the goaltenders were significantly taller than the other hockey players ($1.77 \pm 0.10m$ vs $1.72 \pm 0.08m$ for defensemen and $1.67 \pm 0.10m$ for forwards). **CONCLUSION:** The stationary broad jump, the seated medicine ball throw and the 20 meters shuttle run are field tests that could be used in order to discriminate playing levels in youth elite hockey players.

Comparison Of Adolescents Fitness Status Between Shanghai And Taipei

Peggy Boey¹, Govindasamy Balasekaran, FACSM¹, Stanley Sai-Chuen Hui, FACSM², Ying Mei Liou³, Dajiang Lu⁴, Visvasuresh Victor Govindaswamy⁵, Yew Cheo Ng¹, Jolene Lim¹. ¹National Institute of Education, Singapore, Singapore. ²The Chinese University of Hong Kong, Shatin, Hong Kong. ³National Yang-Ming University, Taipei, China. ⁴Shanghai University of Sport, Shanghai, China. ⁵Concordia University Chicago, Chicago, IL. Email: peggy_boey@hotmail.com

(No relevant relationships reported)

INTRODUCTION: Chinese communities have a tight knit culture with similar culture practices such as lifestyle choices which have a direct impact on health and fitness level. **PURPOSE:** To investigate the health components of adolescents in Shanghai and Taipei. **METHOD:** A total of 3207 adolescents were recruited for the study from Shanghai ($N = 1588$) and Taipei ($N = 1619$). All adolescents had their percentage body fat (%BF) taken by a bio-impedance analysis machine. The health status, muscle strength and flexibility were measured with a handgrip strength test (HGST), one-minute sit-up test (SUT) and a single-leg flexibility test (SLFT) respectively. The HGST was taken three times per arm in alternate turns. The best result of each side was taken and summed for analysis. Adolescents had to complete as many repetitions of sit-ups within one minute for the SUT. The SLFT was taken thrice on each side consecutively and the best score was used for analysis. Their cardiovascular fitness was measured by a 15m Youth Progressive Aerobic Cardiovascular Endurance Run (PACER) test. Adolescents were paired up for the PACER test, with one as the runner and another as the marker. Runners had to run back and forth 15m according to the frequency of the beep. Adolescents need to reach the 15m mark before the beep. Each unsuccessful attempt is indicated on the PACER test results slip. The test ceased upon the third unsuccessful run. **RESULTS:** Significant differences were identified between both countries for %BF (Shanghai: $22.22 \pm 9.64\%$, Taipei: $23.29 \pm 10.30\%$, $p = 0.03$), SUT (Shanghai: 36.21 ± 9.25 count, Taipei: 33.03 ± 9.71 count, $p = 0.00$), flexibility [left side] (Shanghai: 54.59 ± 9.95 cm, Taipei: 51.36 ± 11.52 cm, $p = 0.00$), flexibility [right side] (Shanghai: 55.30 ± 9.91 cm, Taipei: 52.18 ± 11.51 cm, $p = 0.00$), HGST (Shanghai: 55.23 ± 14.08 kg, Taipei: 50.86 ± 14.66 kg, $p = 0.00$) and cardiovascular fitness (Shanghai: 40.12 ± 16.04 laps, Taipei: 37.75 ± 18.87 laps, $p = 0.00$). **CONCLUSION:** Shanghai's adolescents had significantly higher scores than Taipei's in all health components. Though both countries may have similar lifestyle choices, Shanghai's adolescents may have higher energy expenditure with a healthier diet than Taiwan's adolescents. Both countries' adolescents should continue with regular physical activity to maintain their health.

Association Between Body Composition And Physical Skills In Early Adolescent Athletes

Marcelo L. Cardey, Aldo F. Longo, Gustavo D. Aquilino, Enrique O. Prada. Centro Nacional de Alto Rendimiento Deportivo (CeNARD), Buenos Aires, Argentina.

(No relevant relationships reported)

PURPOSE: This study aimed at appraising the strength of association of body composition components with a set of physical skills in early adolescent athletes. **METHODS:** A sample of 505 subjects (283 boys and 222 girls) was studied (Age = 13.6 ± 0.8 years, BMI = 20.1 ± 2.4 kg·m⁻²; mean ± SD). Anthropometric assessments were carried out, and the four-compartment model of De Rose and Guimaraes (1980) was applied to estimate body fat, muscle and bone mass percentages (%FM, %MM and %BM). The model was updated using the simple regression equations for male and female athletes proposed by Withers *et al.* (1987; cited by Norton, 1996) to calculate body density, and Siri equation (1961) was then applied to compute the percentage of fat mass. The three body composition components were correlated with the following physical skill tests: Handgrip strength (HAST), Abalakov jump (ABJ), 10 m Sprint test

(10ST), Sit and reach flexibility (SARF) and Simple eye-hand reaction time (SEHRT). Pearson's *r* was used to test correlations within each gender stratum. Statistical significance was fixed at the 0.05 level.

RESULTS: HAST showed negligible to low correlations with %FM, %MM and %BM ($|r| < 0.3$); statistical significance was found in all cases except in the correlations with %FM and %MM observed in girls. On the other hand, the correlations of ABJ with %FM and %MM reached moderate magnitudes in the male stratum ($r = -0.51$ and $r = 0.51$, respectively); ABJ evidenced significant associations with the three body composition components in both genders. Despite the opposite signs of the coefficients, 10ST presented similar degrees of association to the ones of ABJ. And SARF and SEHRT also showed negligible to low correlations with the three body composition components ($|r| < 0.3$), being statistically significant the ones of SARF with %FM and %MM found in boys, the one of SARF with %MM found in girls, and the one of SEHRT with %MM found in boys.

CONCLUSIONS: The athletes, especially the male ones, with lower %FM and higher %MM tended, though not strongly, to have higher performances in the physical skill tests where the power is decisive. In general, %BM showed weak degrees of association with the physical skills.

Tethered Swimming Ineffective As Post Activation Potentiation Procedure For 50-m Swimming Performance In Adolescent Swimmers

Monoem Haddad¹, Zied Abbes², Khalid Bibi¹, Inigo Mujika³, Cyril Martin², Karim Chamari⁴. ¹Qatar University, Doha, Qatar. ²University Claude Bernard Lyon 1, Lyon, France. ³University of the Basque Country, Leioa, Spain. ⁴ASPETAR, Qatar Orthopaedic and Sports Medicine Hospital, Doha, Qatar.
 Email: mhaddad@qu.edu.qa
 (No relevant relationships reported)

PURPOSE: The aim of the study was to investigate if tethered swimming (TS) performed 8 min before a 50-m freestyle swimming sprint could be an effective post-activation potentiation (PAP) method to improve performance. **METHODS:** Regional level male adolescent swimmers (age: 13.0±2.0 y; height: 161.1±12.4 cm; body mass: 52.5±9.5 kg) performed two trial conditions (1 experimental (TS), 1 control (CTR)) on different days. The control group performed a standardized 1200-m warm-up followed by 8 min of rest and a maximal 50 m freestyle swimming sprint. The experimental group performed the same protocol with an added TS component at the end of warm-up, which consisted of 3 x 10 s maximal effort of tethered swimming with 1 min rest in-between sprints. Performance (time-trial), selected biomechanical (stroke length), physiological (blood lactate concentrations, heart rate), psychophysiological (ratings of perceived exertion (RPE)) variables and Counter movement jump (CMJ) flight-time were collected.

RESULTS: Pre-performance tethered swimming had no effect on swimming time, RPE, stroke rate or CMJ flight time. Before the 50 m race, blood lactate concentrations were significantly higher in TS than in control condition ($p=0.03$, $\eta^2 = 0.62$). One minute after the 50 m sprint, heart rate was significantly higher in the control condition compared to the TS ($P=0.046$, $\eta^2 = 0.27$).

CONCLUSIONS: The present study showed that 3 x 10 s tethered swimming performed 8 min prior to the event did not impact the 50 m sprint performance in young swimmers and may not be considered an effective PAP stimulus.

Wearable Sensors Differentiate Impacts And Intensity Between Games And Practices Among National Junior Ice-hockey Teams

Aaron Pilotti-Riley, Dakota Burke, Davor Stojanov, Stephen McGregor. Eastern Michigan University, Ypsilanti, MI.
 (Sponsor: Mark Peterson, FACSM)
 Email: apilotti@emich.edu
 (No relevant relationships reported)

Purpose: Use wearable sensors (WS) to compare player incurred impacts (PII) and absolute vs relative workload intensity between practices, games and teams to determine if developmental age affects these factors at the national team level. **Methods:** 90 total members of the U.S. National (NTDP) U17 (45 members) and U18 (45 members) teams consented to procedures approved by EMU Human Subjects Committee. Bioharness-3 (Zephyr, MD) WS recorded triaxial accelerations during practices (P) and games (G) of the two teams over two seasons. Impacts were identified using Impact Processor (Zephyr, MD). Impacts greater than 6 g (Z3, Z4, Z5 and above) were used as previously validated for PII. Triaxial accelerations were used to generate absolute intensity metrics 30 minute exponentially weighted Dynamic Accelerations (DYNAs) and session DYNAs. Relative intensity metrics Individual Hustle Score (IHS) and Intensity factor (IF) were based on session DYNAs relative to

Dynamic functional threshold (DFT). Intensities and PII of two teams were compared between sessions and teams using MANOVA with Tukey post hoc ($\alpha=0.05$; SPSS 26.0, IBM, NY)

Results: 7288 sessions (1400 G, 2802 P; U17 and 1039 G and 2047 P; U18) were compared. For all combined sessions, impacts were greater for U18 (6.4 ± 7.7) than U17 (5.4 ± 7 ; $p<0.05$). Interestingly, impacts in G were not significantly different. Therefore, differences between teams were solely the result of higher impacts in P for U18 (5.8 ± 7.3) vs U17 (4.1 ± 6.3 ; $p<0.05$). For workload intensity, overall, 30-min DYNAs and Session DYNAs were not different between teams or for P, but both were higher in G for U17 (0.372 ± 0.0439 & 0.307 ± 0.0386 , respectively) than U18 (0.360 ± 0.0579 & 0.292 ± 0.0524 , respectively; $p<0.05$). Although 30-min and Session DYNAs were not different for P, IHS and IF were higher for U17 (0.896 ± 0.1016 & 0.790 ± 0.0964 , respectively) than U18 (0.890 ± 0.1116 & 0.767 ± 0.0981 , respectively; $p<0.05$).

Conclusion: Since PII are not different in G between U17 and U18, it appears developmental age does not affect PII in G. PII were higher in P for U18 than U17, but DYNAs were not different and relative intensities IHS and IF were higher, therefore, it doesn't appear as though PII are related to developmental age in these two teams.

299 Board #115 May 27 9:30 AM - 11:00 AM
Vibration Platform Stretching Increases ROM Acutely, With No Long-term Effect In Junior Olympic Women's Gymnasts

Michael M. Lockard, Tynan F. Gable. Willamette University, Salem, OR.
 Email: mlockard@willamette.edu
 (No relevant relationships reported)

Flexibility, particularly range of motion (ROM) of the hips, is critical for gymnasts' performance. Despite consistent flexibility training, many competitive gymnasts still need greater ROM. **PURPOSE:** To investigate the acute and chronic effects of vibration platform (VP) flexibility training on ROM at the hips in the middle split position. **METHODS:** Participants included 18 female gymnasts aged 7-16 years competing in JO level 6. Gymnasts were paired according to baseline ROM then randomly assigned to either the VP treatment group or the control group. The control group continued normal team stretching at the end of every practice, four days per week. The treatment group substituted standard stretching for VP stretching twice per week. ROM was measured after a single one-minute VP treatment and after 10 weeks of VP treatment. Prior to each measurement gymnasts completed a standard team warm-up including active ROM exercises. Measurements were taken using Myomotion inertial sensors placed on the lateral aspect of the distal femur and overlaying the sacrum. **RESULTS:** After 10 weeks of training, the VP group's ROM increased by 8.4 (±5.5) degrees ($p=0.002$), while the control group's ROM increased by 5.8 (±8.0) degrees ($p=0.064$). There was no significant difference between groups ($p=0.435$). A single VP treatment increased ROM by 3.6 (±7.3) degrees ($p=0.045$). **CONCLUSIONS:** There was a significant, although temporary, improvement in ROM after a single VP treatment. However, VP stretching does not appear to be a viable training option to improve ROM beyond standard stretching over time in child and adolescent female JO gymnasts.

Functional Bilateral Asymmetries In Adolescent Competitive Skiers

Jacob E. Earp¹, Ariana Cambio¹, Domenic Angelino¹, Nick Chartier¹, Connor Duff¹, Shelby Downing², Susan D'Andrea¹, Disa Hatfield¹. ¹University of Rhode Island, Kingston, RI. ²Carrabassett Valley Academy, Carrabassett, ME.
 Email: jacob_earp@uri.edu
 (No relevant relationships reported)

When skiing both legs function independently and the stresses experienced by both legs is dependent upon the movement being performed (e.g. turning, jumping, landing, ect...). It is well established that greater stress is placed upon the outside leg when turning and initiating tricks and that the magnitude of these forces changes based on the athlete's momentum and the turn radius. Thus, ski athletes are at risk for developing bilateral asymmetries, which may put them at increased injury risk due to repetitive training on competition courses and non-symmetrical movement patterns. **PURPOSE:** To determine if a pattern of functional asymmetries are present in adolescent ski athletes from the same training mountain. **METHODS:** Competitive adolescent (aged 14-18 years) skiers from Carrabassett Valley Academy in Kingfield, ME ($n = 22$) with a minimum of 2 years competing in their sport, performed a series of bilateral tests to determine dominant and non-dominant lower body strength (5 s isometric mid-thigh pull of a force platform) and power (vertical jump), rotational power (accelerometer measured medicine ball throw) and balance (Y-balance test). Differences between legs were compared using a series of paired t-tests ($p < 0.05$). **RESULTS:** Athletes demonstrated greater rotational power moving towards their non-dominant (1115 ± 680 W) than dominant side (924 ± 605 W, $p=0.046$). However, no differences were observed between dominant and non-dominant legs in lower-

body strength (dominant: 565.5 ± 38.5 N, non-dominant: 549.9 ± 38.1 N, $p=0.063$), lower-body power ($p=0.572$), or balance in the anterior ($p=0.153$), posterior-medial ($p=0.880$), or posterior-lateral ($p=0.164$) directions. **CONCLUSIONS:** In the present study adolescent skiers demonstrated asymmetrical rotational power and non-significant trends asymmetrical lower-body strength but no other noteworthy differences in power or balance. In skiing, rotational power is necessary for rapid initiation of turns away from their dominant side. Training to correct this asymmetry may help athletes when turning towards their dominant side.

Determinants Of Head Impact Exposure In Youth Football

Jason C. Dorman, Kori J. Fink, Daniel N. Poel, Thayne A. Munce, FACSM. *Sanford Sports Science Institute, Sioux Falls, SD.*

Email: jason.dorman@sanfordhealth.org

(No relevant relationships reported)

Concussions are on the minds of many football players, parents and coaches; but attention has increased toward the potentially damaging effects of repetitive, subconcussive head impacts, particularly among youth football players. Advocates of the sport are looking for ways to improve player safety and reduce the potential risk of long-term brain abnormalities.

PURPOSE: To identify intrinsic and extrinsic characteristics of play associated with head impact exposure in youth football.

METHODS: Head impacts from one youth football team (7th & 8th grade) were measured during every practice and game during the 2018 & 2019 football seasons via a sideline head impact telemetry system and subsequently evaluated using video collected during each session. Each verified head impact was scored using a validated rubric consisting of up to 12 discrete characteristics of play (5 intrinsic, 7 extrinsic). The mean, median and 95th percentile linear acceleration (LA) was calculated for each play characteristic.

RESULTS: Over two seasons, 1202 practice (median LA: 19.90 g) and 1571 game (median LA: 21.00 g) head impacts (2773 total) were examined. The “kickoff” ($n = 95$ impacts; 6% of all game impacts) had the highest 95th percentile LA (69.89 g) among all game play types (e.g., “run”, “pass”, “punt”, etc.). Impacts that occurred “outside the hash marks” (61.75 g) and in the “redzone” (59.40 g) had the highest 95th percentile LA rankings among horizontal and vertical field positions, respectively. When players did not anticipate being hit ($n = 53$; 1.9% of all impacts), head impacts had a 95th percentile LA of 69.52 g, compared to 47.02 g when they anticipated the impact. Head impacts resulting from players’ helmets hitting the ground (95th percentile LA: 72.94 g) accounted for 11.6% of all impacts ($n = 323$).

CONCLUSIONS: These data indicate that certain, modifiable characteristics of play are associated with higher magnitude head impacts in youth football. Additional research is warranted to continue to examine practice and game situations (extrinsic characteristics) that produce higher magnitude head impacts, which could assist football-governing bodies in developing or modifying policy guidelines to help make the game safer.

Supported by a grant from The National Operating Committee on Standards for Athletic Equipment (NOCSAE).

Relationship Between Mixed Relay Performance And Physiological Measures Of Fatigue And Metabolism In Junior Triathletes.

Joao Henrique Falk Neto¹, Scott C. Forbes², Michael D. Kennedy¹. ¹University of Alberta, Edmonton, AB, Canada. ²Brandon University, Brandon, MB, Canada. (Sponsor: Dr. Darren DeLorey, FACSM)

Email: falkneto@ualberta.ca

(No relevant relationships reported)

The mixed relay triathlon is a new event in the Summer Olympics consisting of teams of 2 females and 2 males whom each complete a super-sprint triathlon (~20 min per athlete) in sequential order. Given the duration of the event, the intensity will likely be higher than longer distance triathlons. Thus, muscular power and anaerobic metabolism may be more important determinants of performance. To date, no research has investigated the physiological determinants nor the muscular fatigue associated with the event.

PURPOSE: The primary purpose was to determine the changes in leg muscle power (to assess muscular fatigue) and anaerobic metabolism during a mixed relay triathlon. A secondary purpose was to determine the relationships between leg muscle power and anaerobic metabolism with overall and leg specific (swim, bike, run) performance.

METHODS: Twelve highly-trained junior (5 female, 7 male) triathletes (age: 17.6 ± 1.3 years) competed in the Canadian Mixed Relay Championships (300 m swim, 6 km bike, 1.6 km run). Before and immediately after the race vertical jump height (VJH)

and blood lactate (BLa) were measured. Paired sample t-tests were used to compare pre- and post-race differences. Pearson correlations were used to determine the relationships between finishing time, and swim, bike, and run times with BLA and VJH. **RESULTS:** Mean race time was 22.4 ± 1.4 min, including transitions (swim 4.5 ± 0.4 min, bike 10.3 ± 0.6 min, run 6.05 ± 0.5 min). VJH increased pre- to post-race (pre: 43.8 ± 8.4 cm; post: 46.1 ± 8.0 cm, $p=0.05$) in 7 out of 12 participants. A significant correlation between VJH pre-race and bike time was determined ($r=-0.60$, $p=0.03$). BLA significantly increased from pre- to post-race (pre: 1.3 ± 0.4 mmol·L⁻¹; post: 10.7 ± 2.4 mmol·L⁻¹, $p<0.001$) and significantly correlated to bike and overall finishing time (bike: $r=-0.71$, $p=0.02$; finishing time: $r=-0.76$, $p<0.001$). **CONCLUSIONS:** Based on the high BLA after the race, the mixed relay event requires a large contribution from anaerobic metabolism and faster athletes had greater post-race BLA. Despite the high physiological demands, muscular fatigue was not found in most participants. Furthermore, the relationship between VJH and bike performance demonstrates the importance of muscular power in the mixed relay event.

Does 45 Minutes Of Daily Pe Impact Health Related Fitness Of Under-resourced Middle School Females?

Jordan Lang, Julian A. Reed, Langdon Kennedy, Heather Paget-Brown, Sarah Radziewicz. *Furman University, Greenville, SC.* (Sponsor: Anthony Caterisano, FACSM)

Email: jordan.lang@furman.edu

(No relevant relationships reported)

Girls have a greater decline in physical activity compared to boys do during adolescence. **PURPOSE:** The purpose of this study was to examine the impact of 45 minutes of daily PE on the fitness levels of African American middle school females. **METHODS:** An analysis of variance (ANOVA) mixed effect linear model was used to evaluate the effectiveness of 45 minutes of daily physical education on the Progressive Aerobic Cardiovascular Endurance Run (PACER), push-ups, curl-ups and BMI among youth in grades 6th-8th attending Legacy Early College, a Title I school in the southeastern US. Gain scores (final post-test assessment in May 2019 - original pre-test assessment in September 2018) were calculated and analyzed for significance. The interaction between school and time was estimated for each outcome. Each analysis was stratified by gender and adjusted by age to control for baseline differences by school. A Title I control school that provided physical education for only one semester was identified and utilized as a comparison. **Summary of RESULTS:** African American females at Legacy Early College ($N=374$) observed significant differences compared to control middle school females ($N=393$) who did not receive daily PE on the PACER, curl-ups and push-ups assessments at post-test ($P=.000$, $P=.004$ and $P=.003$), respectively. A decrease in aerobic capacity was observed for females at both schools, however this decrease was less at Legacy, but was not significant ($F=1.38$, $P>.05$). BMI of control school females increased significantly ($F=8.206$, $P=0.005$), compared to Legacy students. **CONCLUSIONS:** 45 minutes of daily physical education led to increases in PACER laps, push-ups and curl-ups, as well as decreases in BMI among under-resourced middle school students.

Evaluation Of Bioelectrical Impedance Analysis For Estimating Percent Body Fat In Children.

Sierra Barnhart¹, Meghan Fetterman¹, Kyle S. Beyer¹, Curt B. Dixon, FACSM², Joseph L. Andreacci, FACSM¹. ¹Bloomsburg University of Pennsylvania, Bloomsburg, PA. ²Lock Haven University of Pennsylvania, Lock Haven, PA. (Sponsor: Joseph L. Andreacci, FACSM)

(No relevant relationships reported)

PURPOSE: To compare percent body fat (%BF) measurements estimated by bioelectrical impedance analysis (BIA) with dual-energy x-ray absorptiometry (DXA) in children.

METHODS: Forty-nine children (28 girls; 21 boys) volunteered to participate in this study (age = 14.5 ± 2.9 years; body mass index = 22.4 ± 5.6 kg/m²). During the assessment, %BF was measured using hand-to-hand bioelectrical impedance analysis (HBIA; Omron HBF-306), leg-to-leg bioelectrical impedance analysis (LBIA; Tanita 300-A), segmental bioelectrical impedance analysis (SBIA; Tanita BC-418), and DXA, which served as the criterion. %BF data from the four devices was assessed using one-way repeated measures ANOVA with Bonferroni-adjusted post-hoc tests. Alpha level was set a priori to $p<0.05$.

RESULTS: LBIA ($24.2 \pm 9.7\%$, $p < 0.001$) and SBIA ($26.4 \pm 8.0\%$, $p = 0.028$) significantly underestimated mean %BF when compared to DXA ($28.7 \pm 11.5\%$) while no differences were observed between DXA and HBIA ($28.4 \pm 7.3\%$, $p = 1.0$). Linear regression revealed significant ($p < 0.001$) correlations between %BF determined by DXA and the BIA methods: LBIA ($r = 0.87$), SBIA ($r = 0.91$), and HBIA ($r = 0.65$).

For a large percentage of the children (LBIA = 37%, SBIA = 53%, HBIA = 67%), %BF values were outside the $\pm 3.5\%$ minimally acceptable standard for accurate estimation.

CONCLUSIONS: The HBIA analyzer produced mean %BF similar to DXA supporting the potential use of this technology when group assessments in this population are of interest. However, due to the large intra-individual variability observed in this study, we do not recommend using the HBIA analyzer when precision of a specific child's %BF is critical.

Mechanical Stimulation Of Osteocyte-like Cells Changes Their Secretome - Implications For Regenerative Medicine**

Livia Santos, Aslihan Ugun-Klusek, Amanda K. Miles, Clare Coveney, David Boock. *Nottingham Trent University, Nottingham, United Kingdom.*
Email: livia.santos@ntu.ac.uk
(No relevant relationships reported)

Osteocytes are secretory bone cells that regulate bone homeostasis and for this reason, are often coined as the "brain of the bone". *In vitro* studies demonstrated that mechanically stimulated osteocytes release interleukins and growth factors that help coordinating bone formation and resorption, however, their secretome remains largely unknown.

Purpose: To investigate WNT signalling and the secretome of mouse and human osteocyte-like cells. Insights from this study could help to devise informed therapeutic exercise regimen e.g. aiming to preserve bone mass across ageing or accelerate bone fracture healing.

Methods: The murine MLO-Y4 (Kerafast) cell line was cultured according to Kerafast instructions. Human adipose stem cells (ATCC® PCS -500-011™) were expanded and differentiated into osteocyte-like cells (hOC) according to ATCC instructions. Cells were cultured in a computer-controlled bioreactor (Flexcell Int) for mechanical loading (3.4%, 2Hz, 5h). Static cultures were used as control. Relative expression of 84 key genes of the WNT signalling pathway (Sabiosciences) was quantified by RT-qPCR. Relative protein expression was estimated by western blotting. The secretome was analysed by quantitative mass spectrometry (TripleTOF 6600, SCIEX) using SWATH and processed using OneOmics (SCIEX) software.

Results: The relative gene expression remained unchanged in mechanically MLO-Y4 and hOC. Regarding protein quantification, active β -catenin and Cyclin D1 showed an up-regulation trend in mechanically stimulated MLO-Y4 but this was not statistically significant. A total of 917 proteins were identified in the MLO-Y4 secretome, ~12% present exclusively under mechanical active conditions. The secretome obtained under loading contained 14 cyclin-dependent kinases (CDKs) including CDK6, a critical regulator of osteoblasts and osteoclasts differentiation. A total of 329 proteins were identified in the supernatant of hOC, ~9% present exclusively under mechanical stimulation. Unlike MLO-Y4, no CDKs were identified in this cell type. The small ubiquitin-like modifier (SUMO) 2 and 3 were present in the secretomes of mechanically loaded MLO-Y4 and hOC.

Conclusion: Mechanically stimulated osteocyte-like cells secrete a specific set of proteins which could impact bone health and regeneration.

Identifying Triad Risk Factors In Ultramarathon Runners**

Kira F. Skaggs¹, Michael Fredericson, FACSM¹, Emily K. Miller¹, Megan Roche¹, Tracy B. Hoeg², Kristin Sainani¹, Emily Kraus¹. ¹Stanford University, Palo Alto, CA. ²University of California-Davis, Sacramento, CA.
(No relevant relationships reported)

Ultramarathon running has gained popularity in the past decade, necessitating a better understanding of the health benefits and risks of this sport. The Female Athlete Triad (Triad) and a similar condition reported in males are common in endurance athletes, but the prevalence of triad risk factors in ultramarathon runners is unknown

PURPOSE: To identify the prevalence of Triad risk in ultramarathon runners.
METHODS: Runners who qualified to compete in a 100-mile endurance race were recruited pre-race to complete a survey assessing eating behaviors, menstrual history, training, and injury history; and dual-energy x-ray absorptiometry to assess bone

mineral density (BMD). A cumulative Triad risk score was calculated using energy availability, body mass index (BMI), age of menarche and oligomenorrhea (for women), BMD, and history of bone stress injury.

RESULTS: 123 runners (40 female and 83 male) participants had a mean age, respectively, of 41.8 and 46.2 years. 57.5% of females and 26.5% of males received moderate cumulative risk scores; 5.0% of females and 4.8% of males were classified as high risk. 62.5% of females and 39.7% of males scored moderate or high risk for low energy availability, with 13% reporting a history of clinical eating disorders. Mean female and male BMI was, respectively 21.2 kg/m²(SD=2.1) and 22.9 kg/m² (SD=2.6). 15% of females and 0% of males scored moderate or high risk for low BMI, determined to be anything less than 18.5 kg/m². 15% of females and 28.9% of males had BMD Z-score<-1.0, and 6.0% of males had a Z-score<-2.0. 37.5% of females and 79.5% of males reported at least one prior bone stress injury.

CONCLUSIONS: Triad risk factors were common among ultramarathoners, particularly in men.

ACKNOWLEDGEMENTS: Supported with grants from the Western States Endurance Run Foundation and the Napa Medical Research Foundation. Laboratory testing was done in partnership with InsideTracker

Associations Between Measures Of Body Composition And Bone Mineral Density In Adults**

Meghan E. Garvey. *University of Massachusetts Boston, Boston, MA.* (Sponsor: Dr. Sarah M. Camhi, FACSM)
Email: meghan.garvey@simmons.edu
(No relevant relationships reported)

PURPOSE: To provide a better understanding of the associations of bone mineral density (BMD) with lean mass (LM) and fat mass (FM) as these are currently not well understood.

METHODS: National Health and Nutrition Examination Survey (NHANES 2003-2004 & 2005-2006 cycles) participants (44.1 \pm 14.2 years old, 49.6% female) were included in this analysis if they underwent dual energy x-ray absorptiometry (total BMD g/cm², FM kg, and LM kg) and had complete data for age, sex, race, height (cm), physical activity (PA) (minutes per week), dietary calcium (mg/day), and smoking history.

Hierarchical linear regression models were built to determine associations between BMD with FM and LM (Model 1), adjusting for demographics (Model 2: age, sex, race, and height) and behavioral factors (Model 3: PA, dietary calcium, and smoking history). Interaction terms (FM*sex, FM*age group, LM*age group, and LM*race) were included in Models 2 and 3. Due to significant interactions Model 3 was stratified further by sex and age. Adjusted R² were compared between models to determine fit.

RESULTS: The associations between LM and BMD remained unchanged between all models. There were robust negative linear associations between FM and BMD (β = -0.002, p<0.001) and positive linear associations between LM and BMD (β = 0.006, p<0.001) in Model 1. When stratified by sex, the negative association in Model 3 between FM and BMD was found to have a larger amplitude in men when compared to women (β = -0.004, p=0.02; β = -0.002, p=0.03 respectively), whereas the associations between LM and BMD were consistent between sexes (β = 0.006, p<0.001; β = 0.006, p=0.002 respectively). When stratified by age, a larger negative beta between FM and BMD were found in 45+ as compared to 20-44 year age group (β = -0.007, p<0.001; β = -0.005, p<0.001 respectively) whereas a larger positive beta between LM and BMD were found in 45+ as compared to 20-44 year age group (β = 0.007, p<0.001; β = 0.005, p<0.001; respectively).

DISCUSSION: LM had consistent positive linear associations with BMD in all models and with stratification. The negative associations between FM and BMD varied between men and women, and between age groups. The exact mechanisms driving these differences with FM by sex and age require further investigation.

Effect Of Exercise On Opg And Rankl As Bone Metabolic Markers: A Systematic Review And Meta-analysis**

Jiyeon Kim¹, Jinho Park², Kyungun Kim³, Minsoo Kang, FACSM⁴, Sukho Lee². ¹University of Houston, Houston, TX. ²Texas A&M University-San Antonio, San Antonio, TX. ³University of Central Missouri, Warrensburg, MO. ⁴The University of Mississippi, University, MS. (Sponsor: Minsoo Kang, FACSM)
Email: jkim224@central.uh.edu
(No relevant relationships reported)

Bone metabolism is determined by the balance of bone formation (osteoblast) and bone resorption (osteoclasts). Osteoprotegerin (OPG) and receptor activator of nuclear factor κ B ligand (RANKL) signaling are important factors that regulate bone metabolism.

However, there are conflicting results about effectiveness of exercise on these factors.
PURPOSE: The purpose of this review is to investigate the effect of different types of

exercise and their intervention period on bone metabolism (i.e., OPG/RANKL ratio) through meta-analysis and to examine the influence of moderating variables (e.g., age, gender, type of exercise, intervention duration) on bone metabolism. **METHODS:** The review was conducted according to the Preferred Reporting Items for Systematic Review and Meta-Analyses guidelines. The following databases were used to conduct the research: Academic Search Complete, MEDLINE, and SportDiscus. Keywords used were "exercise" AND "OPG" AND "RANKL" AND "bone". The inclusion criteria for these articles were that: 1) human subjects, 2) the blood collected before and after exercise; 3) the peer-reviewed journals published in English. Out of 161 articles, 10 were eligible to be included in this study. Comprehensive meta-analysis v.3 software was used to compute the effect size (Cohen's d) based on a random effect model and to conduct moderator analyses. **RESULTS:** The results indicate that there were moderate and positive effects of exercise training on bone metabolism (OPG/RANKL ratio) ($ES=.572$, 95% $CI=.220$, $.925$, $p=.001$). Moderator analysis results showed that exercise type (resistance, endurance, a combination of both) partially explained the heterogeneity of ESs ($Q_{between}=7.704$, $df=2$, $p=.021$). The endurance exercise has the highest ES across the groups ($ES=1.343$, 95% $CI=.670$, 2.016). However, gender, age, and intervention duration did not influence on the size of the effect. **CONCLUSION:** The exercise training significantly improves a bone metabolism marker (OPG/RANKL ratio), and the endurance exercise seems to be more effective type of exercise.

BONE MINERAL DENSITY, BODY COMPOSITION AND BLOOD PRESSURE IN YOUNG AND MENOPAUSAL RUNNERS AND NON-RUNNERS

Doris J. Morris, Inbar Naor-Maxwell, L. Jerome Brandon, FACSM. *Georgia State University, Atlanta, GA.* (Sponsor: L. Jerome Brandon, FACSM)
 Email: dmmorris21@student.gsu.edu
 (No relevant relationships reported)

The onset of menopause brings with it various changes in bone mineral density (BMD) and body fat (BF) distribution. Physical activity has been identified as a protective factor from many diseases, especially those that result in physical limitations. Weight bearing activities are recommended for osteoporosis prevention. However, it is unclear how chronic running affects the BF% and BMD in healthy menopausal (MEN) women. **PURPOSE:** This cross-sectional study was designed to assess the effects of chronic running on BMD and BF% in MEN women. The BMD and BF% was compared in young (YNG) and MEN women with and without a running (RUN; NOR) history. **METHODS:** We recruited 169 Women (57 YNG/NOR (34.1 9.9 yrs.), 34 MEN/NOR (55.4 10.4 yrs.), 51 YNG/RUN (40.0 8.7 yrs.), and 27 MEN/RUN (56.9 8.9 yrs.) and evaluated them for differences and relationships between BMD, blood pressure (BP) and BF%. **RESULTS:** Although the MEN women were older, the MEN women did not differ for weight, BMI or body fat%, but did differ for BMD (MEN 1.17 vs YNG 1.24). Weight and central adiposity as measured by waist circumference was related to BMD ($p < 0.05$) in both RUN and NOR. Consistent with expectation, both MEN/RUN and MEN/NOR had lower BMD ($p < 0.05$) than the YNG/RUN and YNG/NOR. The MEN/RUN had a higher BP than the other groups and this may have contributed to their BMD response not being higher than the NOR. **CONCLUSIONS:** Although further study is needed to validate the findings in this study, these data indicate that a history of running does not result in a higher BMD in MEN women. This may have been partially due to the fact that body composition was not different between the groups and therefore the runners were not placing greater stress on the bones.

Relationships Of Bone Mineral Density And Muscular Performance In College Students

Erick Ramirez, Alexandra Khartabil, Yadira Marin, Guillermo Escalante, Bryan Haddock, FACSM, Zhaojing Chen. *California State University, San Bernardino, San Bernardino, CA.* (Sponsor: Bryan Haddock, FACSM)
 (No relevant relationships reported)

The skeletal system is adapted to mechanical loading such as gravity and muscle contraction. The current gold standard to assess the skeletal health is to use the Dual Energy X-ray Absorptiometry (DXA) to measure bone mineral density (BMD), however, the DXA is costly and not portable. Muscular performance assessment, such as grip strength and jump power, are fairly simple and affordable measurements. **PURPOSE:** To investigate the relationships between BMD and muscular performance in healthy young adults. **METHODS:** Thirty healthy college-age individuals, ten males (23.7 ± 1.9 years; 171.9 ± 6.7 cm; 81.8 ± 11.4 kg) and twenty females (23.1 ± 1.9 years; 161.8 ± 6.1 cm; 64.9 ± 15.3 kg), volunteered for the study. Scans of total body, lumbar spine, dual femur and dual forearm were obtained by the iDXA by a licensed technician. Muscular performance was assessed by grip strength, single-leg vertical jump, knee extension and flexion. Pearson's correlations were used to examine the relationships between BMD, muscular performance, and body composition.

RESULTS: Radius BMDs were significantly correlated with grip strength at their corresponding side ($r = 0.684$ on the right and $r = 0.744$ on the left, $p < 0.001$ for both). Total hip BMDs and femoral neck BMDs had strong correlations with hamstring peak torque (PT) and jump peak power (PP) at their corresponding side ($p < 0.001$ for all) but not quadricep PT (Table 1). We also found strong correlations between all sites BMD and body composition variables: total mass, total bone free lean mass (BFLM), legs BFLM, and arms BFLM ($p < 0.05$). **CONCLUSION:** Our results suggest that muscular performance assessments of grip strength, vertical jump and knee extension are potential alternative tools to estimate bone mineral density in young adults. Further study in a large population and all ages are needed for future investigation.

Table 1. Selected Pearson's Correlation Coefficients (n=30)

BMD Sites	Muscular Performance	R-value	P-value
Right Total Hip	Hamstring PT	.610	0.000
	Jump PP	.640	0.000
Right Femoral Neck	Hamstring PT	.690	0.000
	Jump PP	.722	0.000

PT: Peak Torque; PP: Peak Power

Female Distance Runners Display Altered Bone Remodeling In Fasted Blood And 24 Hour Urine Biomarkers

Jennifer A. Higgins, Brian P. Carson, Philip M. Jakeman. *University of Limerick, Limerick, Ireland.* (Sponsor: Matthew P Herring, FACSM)
 Email: jennifer.higgins@ul.ie
 (No relevant relationships reported)

An increase in underlying bone remodeling is associated with increased fracture risk. The International Osteoporosis Foundation recommend overnight fasted plasma C-terminal cross linked telopeptide type 1 collagen (CTX) and N-terminal propeptide of type 1 procollagen (PINP) as bone turnover markers (BTM) of homeostatic bone remodeling. Reflected by an increase in plasma CTX, endurance exercise increases bone resorption acutely for a number of hours post-exercise. Female distance runners (FDR) engage in frequent weight-bearing endurance exercise that may alter homeostatic bone remodeling and fracture risk.

PURPOSE: To compare bone remodeling in FDR and non-athletic controls (CON). **METHODS:** Daily 24 h urine samples and fasted morning blood samples were collected for 7 consecutive days of habitual activity in 7 FDR (training volume ≥ 60 km/week; mean \pm SD age: 24.1 ± 4.6 y, height: 1.70 ± 0.05 m, mass: 58.5 ± 5.5 kg, fat %: $18 \pm 4\%$) and 11 CON (≤ 3 h/week intentional vigorous physical activity; mean \pm SD age: 23.9 ± 4.1 y, height: 1.67 ± 0.05 m, mass: 64.5 ± 4.4 kg, fat %: $33 \pm 6\%$) who provided prior informed consent for a study which had ethical approval. Plasma CTX and PINP was measured by automated immunoassay (Roche Diagnostics) and urinary N-terminal cross linked telopeptide type 1 collagen (NTX) by ELISA (Osteomark). Data were pooled and analyzed independent of participant. Data violated the assumption of normality and are reported as the median (IQR). Groups were compared by Mann-Whitney U test.

RESULTS: Median CTX was 31.4% lower ($0.393(0.147)$ vs $0.573(0.333)$ ng/ml; $p < 0.001$; $d=0.7$) and PINP was 14.5% lower ($55.12(32.39)$ vs $64.43(16.73)$ ng/ml; $p=0.012$; $d=0.5$) in FDR compared to CON. In contrast, median 24 h NTX was 36.7% higher in FDR ($434.2(572.7)$ vs $317.6(302.6)$ nM bone collagen equivalents; $p=0.033$; $d=0.4$) compared to CON.

CONCLUSION: Lower overnight fasted CTX and PINP are deemed devoid of influence exerted by previous exercise or food intake and may indicate an adaptive, regulatory effect of chronic exercise training on systemic (homeostatic) bone remodeling in FDR. By contrast, 24 h urine NTX captures total bone resorptive activity, including response to exercise and diet accrued during the previous 24 h and appear to confirm significantly greater net daily bone resorption in FDR compared to CON.

(Sponsor: Chia-Hua Kuo, FACSM)
 Email: zhumajjian@gmail.com
 (No relevant relationships reported)

BACKGROUND: Handgrip strength is thought to be correlated to bone mineral density and muscle mass. **PURPOSE:** To determine the relationship between handgrip strength and body composition measures (bone mineral density and muscle mass) in large scale. **METHODS:** We have recruited 728 volunteers aged ≥ 20 y. Maximal handgrip strength and average handgrip strength were measured in 10-consecutive attempts with maximal efforts. Rest interval between each grip was 3 s. Bone density and muscle mass of all participants were measured using iDXA. **RESULTS:** Our data show that average handgrip strength of 10 repeated tasks was highly linearly correlated with lean body mass ($r=0.76$, $p<0.01$) and moderately correlated with bone mineral density ($r=0.60$, $p<0.01$), respectively. The maximum grip strength of 10 attempts deems low correlation with muscle mass ($r=0.33$, $p<0.01$) and bone mineral density ($r=0.23$, $p<0.01$). **CONCLUSIONS:** Multiple grip tests seems to be superior in reflecting muscle mass and bone mineral density than single maximal value of handgrip strength.

 (No relevant relationships reported)

The Trabecular Bone Score (TBS) is an estimate of the healthiness of bone microarchitecture that is based on the mathematical reconstruction of 3D micro-computed tomography (μ CT) scans using 2D Dual-energy X-ray Absorptiometry (DXA). Compared to bone mineral density (BMD), TBS is a relatively new DXA-derived metric for predicting fracture risk. **PURPOSE:** This study examined the associations between classically measured vertebral bone mineral density (BMD) and TBS in inactive older adults. **METHODS:** For the present analyses, we included pre-training data from 19 older adults ($X \pm SD$; 71 ± 4.2 y, 4 black, 6 males) participating in an ongoing exercise intervention (REALPA). Whole-body and lumbar spine scans were acquired using a Hologic Horizon[®]A DXA scanner to determine BMD. TBS iNsite[™] was used to determine the TBS score from lumbar spine DXA scans. Multivariate analyses were used to determine associations between whole-body and lumbar spine BMD with TBS scores, and sex differences were assessed by t-tests. **RESULTS:** A strong correlation between both whole-body BMD and lumbar spine TBS ($r=0.815$, $p<0.0001$) was observed; this was also true for lumbar spine BMD and lumbar spine TBS ($r=0.834$, $p<0.0001$). Sex differences were found (males vs. females) for Whole-body BMD (g/cm^2 ; 1.156 ± 0.12 vs 0.972 ± 0.10 , $p<0.009$), lumbar spine BMD (1.150 ± 0.20 vs 0.920 ± 0.15 , $p<0.05$), and lumbar spine TBS (1.409 ± 0.10 vs 1.285 ± 0.09 , $p<0.05$). **CONCLUSION:** The sex differences for BMD and TBS are consistent with the literature, with males having higher BMD and TBS. Strong correlations between BMD and TBS suggest that TBS bone has construct validity. However, future studies are still warranted to determine whether TBS scoring provides clinically meaningful insight into fracture risk beyond traditional BMD. Furthermore, future research studies are warranted to determine whether exercise induced changes TBS are sensitive markers for exercise induced bone remodeling, which would provide additional insight into the clinical utility of TBS. This study was supported by the NIH 5R21AG058181-02.

Bone Mineral Density Amongst Collegiate Male Athletes Across Endurance And Strength-based Sports
 Matthew VanSumeren, Valerie Smith-Hale, Alyssa Pollard-McGrandy, Linda Jimenez. Wayne State University, Detroit, MI. (Sponsor: Tamara Hew-Butler, FACSM)
 Email: msvansum@gmail.com
 (No relevant relationships reported)

PURPOSE: The primary aim is to compare body composition, specifically bone mineral density (BMD) and associated Z-score, in male National Collegiate Athletic Association (NCAA) athletes across five different sports. Secondary measures include lean body mass (LBM) and body fat percentage (BF%). **METHODS:** In this observational, cross-sectional study, five collegiate sports team athletes representing endurance-dominant (soccer, running, swimming) versus strength-based sports (football, basketball) consented to participate in a pre-season whole-body dual energy x-ray absorptiometry (DXA) scan. One-way ANOVA (Brown-Forsythe) with multiple comparisons tests were used to statistically compare BMD (and associated Z-score), LBM, and BF% values between sports, with significance set at $p<0.05$. **RESULTS:** 165 male athletes participated, with ANOVA tests revealing statistical differences between sports for all body composition parameters measured ($p<0.0001$). Football players ($n=99$) demonstrated the highest while swimmers ($n=19$) had the lowest BMD ($1.37 \pm 0.10 g/cm^2$ vs. $1.14 \pm 0.07 g/cm^2$, $p < 0.001$). There were no differences ($p>0.05$) in BMD between football vs. basketball ($n=16$) players ($1.33 \pm 0.09 g/cm^2$) or soccer players ($N=20$; $1.26 \pm 0.06 g/cm^2$) compared to cross-country runners ($N=11$; $1.17 \pm 0.07 g/cm^2$). While BMD was similar ($p>0.05$) between swimmers and cross-country runners. In comparisons between sports for Z-scores ($F=39.73$; $p<0.0001$), football players had the highest scores (1.48 ± 0.09) followed by basketball players (0.77 ± 0.75), soccer players (0.42 ± 0.77), cross country (0.00 ± 0.57) and swimmers (-0.57 ± 0.77). Basketball players had the highest LBM (78.7 ± 8 kg) next to football (72.0 ± 12 kg) while football had the highest %BF ($24 \pm 6\%$) across sports. **CONCLUSION:** Football and basketball requires greater high intensity resistance training over endurance (vertical + non-vertical loading) training, whereas cross country, swimming and soccer requires greater endurance over resistance training. Furthermore, soccer and cross-country have similar running demands and showed no significance in BMD. We believe that the osteogenic contributions of resistance training on BMD are underappreciated and warrant further investigation as a strategy for maximizing skeletal health in young adults.

Female Runners With Multiple Bone Stress Injuries Have Smaller Bone Area Compared To Healthy Runners
 Kristin L. Popp¹, Sara Rudolph², Signe Caksa², Julie M. Hughes¹, Adam S. Tenforde³, Kathryn E. Ackerman, FACSM⁴, Mary L. Boussein⁵. ¹United States Army Research Institute of Environmental Medicine, Natick, MA. ²Massachusetts General Hospital, Boston, MA. ³Harvard Medical School, Boston, MA. ⁴Boston Children's Hospital, Boston, MA. ⁵Beth Israel Deaconess Medical Center, Boston, MA. (Sponsor: Kathryn Ackerman, FACSM)
 Email: kpopp@mgh.harvard.edu
 (No relevant relationships reported)

Bone stress injury (BSI) is an overuse injury reported in up to 20% of female runners. Many runners sustain recurrent BSI. However, the role of impaired bone properties and other risk factors in those with recurrent BSI remain to be characterized. **PURPOSE:** To identify bone features that distinguish women with a history of multiple BSI. **METHODS:** We enrolled 41 female runners, ages 18-30, with a history of 1 lower extremity BSI (1 BSI; $n=15$), ≥ 3 lower extremity BSI (multi BSI; $n=12$), or no BSI ($n=14$), for this cross-sectional study. We collected high-resolution peripheral quantitative CT (HR-pQCT) scans of the distal tibia, areal bone mineral density (aBMD) by dual-energy x-ray absorptiometry, bone material strength index (BMSi) using microindentation (Osteoprobe), and questionnaires. **RESULTS:** There were no differences between groups in age, BMI, age of menarche, or aBMD. Multi BSI had higher Eating Disorder Examination Questionnaire (EDE-Q) scores and prevalence of amenorrhea than no BSI ($p<0.05$). Adjusting for height and weight, multi BSI had smaller total tibial bone area ($p=0.049$, Fig.), and a trend for greater total and trabecular volumetric BMD (vBMD; $p=0.07$, $p=0.09$, respectively) compared to no BSI. 1 BSI had higher BMSi compared to no BSI and multi BSI ($p=0.04$), and lower cortical porosity compared to no BSI ($p=0.048$). Among the cohort, BMSi was significantly associated with cortical porosity ($p=0.04$), but not with cortical vBMD, cortical tissue mineral density, or aBMD. EDE-Q score was inversely associated with total bone area ($p=0.02$). **CONCLUSIONS:** Our findings suggest runners with multi BSI have smaller bones and higher EDE-Q scores than no BSI. Total and trabecular vBMD appear to be higher

WEDNESDAY, MAY 27, 2020

in multi BSI compared to no BSI, though due to the small sample size, differences were not significant. Collectively, our findings suggest several bone properties and eating behaviors distinguish women with multi BSI and 1 BSI from no BSI.

- 316** Board #132 May 27 10:30 AM - 12:00 PM
A Two-year Examination Of Bone Mineral Density In Division I Cross-country Runners
 Michael P. Martinez, William P. McCormack, Hawley C. Almstedt, Todd C. Shoepe. *Loyola Marymount University, Los Angeles, CA.*
(No relevant relationships reported)

There have been few longitudinal studies beyond one year examining bone mineral density (BMD) in collegiate distance runners. Weight-bearing activity such as running tends to be osteogenic, however runners often experience bone injuries and may have site-specific deficiencies compared to norms. **PURPOSE:** Examine the BMD of Division I cross country runners across a two-year time frame. **METHODS:** BMD of 19 collegiate cross-country runners (12 men & 7 women) were measured via dual energy x-ray absorptiometry at the beginning of the season for three consecutive years (v1, v2, v3). A repeated measures multivariate analysis of covariance (whole body lean mass as covariate) was used to compare BMD values of men and women runners at four sites: AP spine (APBMD), femoral neck (FNBMD), whole body (WBBMD), and the non-dominant forearm (FABMD). **RESULTS:** Women had a significant decrease from v1 to v2 ($1.240 \pm 0.048 \text{ gm}\cdot\text{cm}^{-2}$ vs $1.194 \pm 0.048 \text{ gm}\cdot\text{cm}^{-2}$, $p=0.003$) and v1 to v3 ($1.240 \pm 0.048 \text{ gm}\cdot\text{cm}^{-2}$ vs $1.185 \pm 0.043 \text{ gm}\cdot\text{cm}^{-2}$, $p=0.002$) in WBBMD and men had a significant increase from v1 to v3 ($0.414 \pm 0.029 \text{ gm}\cdot\text{cm}^{-2}$ vs $0.450 \pm 0.028 \text{ gm}\cdot\text{cm}^{-2}$, $p=0.018$) and v2 to v3 ($0.425 \pm 0.026 \text{ gm}\cdot\text{cm}^{-2}$ vs $0.450 \pm 0.028 \text{ gm}\cdot\text{cm}^{-2}$, $p=0.003$) in FABMD. Men and women had similar BMD at all sites. Z-score analysis using <-1.0 as the cutoff for low BMD revealed that two women had a low z-score at the AP spine at all three time points, one woman had a low z-score at the FN at all three time points, and low WB z-scores increased from one to three women across the three visits. For the men at the AP spine, low z-scores decreased from three to one across the three visits, at FN no men had a low z-score, and there was only one male with a low z-score for WB (v3). For available data at the forearm, one woman and six men had low z-scores at v3. **CONCLUSIONS:** The AP spine in women may be a site of interest with 28.6% of women with low z-scores. It appears that running may not have an osteogenic effect on WBBMD in female collegiate distance runners over two-years, which may be explained by dietary intake. For males, BMD was consistent across two years, with a significant increase in the FABMD, however, 50% of men had a low z-score at this site. Males of this age may still be accruing bone at the AP spine and FA.

Bilateral Bone Strength Differences In Division II Female Volleyball Players

Claudia Romero Medina, Daniel Den Briones, Jorge Gonzalez, Sena Harlley, Vanessa R. Yingling PhD., FACSM. *California State University East Bay, Hayward, CA.* (Sponsor: Vanessa R. Yingling, Ph.D., FACSM)
(No relevant relationships reported)

Loading (exercise) increases bone strength and reduces the likelihood of fractures later in life. However, questions remain as to the specific loading parameters that optimize bone strength. Past research investigating the effect of loading on bone strength have reported significant bilateral differences in bone characteristics favoring the dominant arm in male racket-sport players (Haapasalo et al., 2000) and former professional baseball pitchers (Warden et al 2014). Results also emphasized positive lifelong effects of loading on bone. Volleyball players primarily utilize a dominant side; therefore they are an excellent model to investigate the effects of bilateral loading on bone. **PURPOSE:** To determine bilateral differences in bone strength, including bone architecture, size and density in the radius. **METHODS:** 16 Division II female volleyball players (mean age 19 years + 1.15, height 1.74 + 0.69 m, weight 69.81 + 8.14 kg, body fat 23.86 + 5.73%) underwent peripheral quantitative computed tomography (pQCT) scans to measure bone strength on both the dominant and non-dominant radius. Trabecular bone variables (4% epiphyseal site) included trabecular bone mineral density (BMD.tb), total bone mineral content (Total BMC), total area (TotA), and compressive strength index (BSIc). Cortical bone variables (66% diaphyseal site) included cortical density (CoD), cortical area (CoA), strength strain index (pSSI), and moment of inertia (J). One-tailed paired T-tests were performed to compare the variables. **RESULTS:** No significant side to side differences were found. The side to side percent (%) differences found at the 4% site were BMD.tb (-0.45%), Total BMC (0.99%), TotA (-0.63%). The side to side percent (%) differences found at the 66% site were CoD (-0.97%), CoA (1.90%), pSSI (0.31%), J (5.23%). **CONCLUSION:** Volleyball may not result in loading significant enough to cause bilateral bone strength differences. Limitations include possible prevalent bilateral strength differences in the humerus, consideration of starting age (pre or post menarche) of playing volleyball, comparison of males and females of different sports.

Exercise Therapy For Bone Health: Translation To Clinical Practice

Belinda R. Beck, FACSM¹, Lisa J. Weis². ¹GRIFFITH UNIVERSITY, GOLD COAST, Australia. ²The Bone Clinic, Brisbane, Australia.
 Email: b.beck@griffith.edu.au
Reported Relationships: B.R. Beck: Ownership/interest/stock; Owner and Director, The Bone Clinic.

We previously reported that high-intensity resistance and impact training (HiRIT) is safe and improves risk factors for osteoporotic fracture in postmenopausal women and older men with low bone mass under trial conditions (LIFTMOR and LIFTMOR-M trials). We have now established a translational research Clinic implementing HiRIT in practice alongside systematic longitudinal monitoring of musculoskeletal and functional outcomes to determine effectiveness and feasibility as osteoporosis prevention and therapy in the 'real world'. **PURPOSE:** The aim of the current report is to present 4 year outcomes from the Clinic. **METHODS:** All Clinic clients undergo testing for height, weight, spine (LS), total hip (TH) and femoral neck (FN) bone mineral density (BMD), lean and fat mass, back extensor strength (BES), and functional indices of fall risk at their baseline visit, and annually thereafter. Twice-weekly supervised HiRIT with balance training and a dietary consult is provided. Compliance and injuries are comprehensively monitored. In the absence of a control group, program effectiveness is determined from one-sample t-tests of percent change from baseline. **RESULTS:** We report outcomes from 275 clients (94.9% female) who have completed a minimum of 12 months HiRIT (63.6±7.1 yrs, 162.3±6.8 cm, 60.6±10.0 kg, LS T-score -2.0±1.1, FN T-score -2.0±0.7, compliance 69.1±39.6%). 70 clients were on bone medications at baseline but only 18 at follow-up. Improvement was observed in weight (0.8±3.8%, $P<0.0001$), LS (2.2±5.1%, $P<0.0001$), TH (1.0±3.7%, $P<0.0001$) and FN BMD (1.4±4.8%, $P<0.0001$), lean mass (2.3±5.5%, $P<0.0001$), fat percent (-4.5±10.7%, $P<0.0001$), functional reach (7.2±13.4%, $P<0.0001$), timed up and go (-9.8±12.0%, $P<0.0001$), tandem walk (-20.6±35.1%, $P<0.0001$), sit to stand (-9.9±15.9%, $P<0.0001$), BES (20.6±35.1%, $P<0.0001$), and kyphosis (5.1±54.8%, $P<0.05$). Clients increased daily dietary calcium (23±67%, $P<0.0001$) and total calcium (19±68%, $P<0.0001$). 20 injuries were sustained in a total of 31,483 training sessions, the majority being minor muscle strains. **CONCLUSION:** We show that, when supervised in clinical practice, an evidence-based, targeted, high-intensity resistance and impact training program is safe and highly effective osteoporosis therapy for older men and women with low bone mass.

319 Board #135 May 27 10:30 AM - 12:00 PM

Acute Response Of Biochemical Bone Turnover Markers Induced By Three Different Jumps For Postmenopausal Women

Eva W. Helge¹, Anders O. Madsen¹, Niklas R. Jørgensen², Rizky S. Prawiradilaga¹. ¹University of Copenhagen, Copenhagen N, Denmark. ²Rigshospitalet, Glostrup, Glostrup, Denmark. Email: ewhelge@nexs.ku.dk
(No relevant relationships reported)

High-impact training has shown to induce benefits in bone structure, -mineralization and -strength. However, a dose-response relationship has not been established, and the acute response of biochemical bone turnover markers (BTM) after jumping has not been examined.

PURPOSE: To compare the acute BTM response and the associated ground reaction forces (GRF) induced by three different jumps for postmenopausal women. **METHODS:** In a randomized controlled cross-over study over three days, twenty-nine postmenopausal women (age (mean±SD): 60.0±5.6 years) were randomly assigned to 6x10 repetitions of three jumps: counter-movement jump (CMJ), drop jump (DJ), diagonal-drop jump (DDJ). A fourth day without jumping served as control (C). Blood samples were collected before (PRE), after (POST), and 2-hours after (2Hr) exercise. Procollagen type-1 amino-terminal propeptide (P1NP), Osteocalcin (OC) and C-terminal telopeptide of type-1 collagen (CTX) were evaluated by a fully automated immunoassay system (iSYS, Immunodiagnostic Systems Ltd., Bolton, England) by the method of Chemiluminescence. Peak sagittal (Fx), transversal (Fy), and vertical (Fz) GRF were measured by an AMTI (©Advanced Mechanical Technology Inc., Watertown, MA 02472-4800 USA) SGA6-4 force platform and the combined three-axis peak GRF was calculated. The BTM differences between PRE, POST, and 2Hr were tested with linear mixed models, and the differences in GRF between the jumps were tested with repeated ANOVA. Linear regression analyses were used to assess the correlation between ΔBTM and the associated GRF in each type of jump. **RESULTS:** At POST, P1NP was increased (p<0.01) by 7.7±1.8% (CMJ), 9.4±1.3% (DJ), and 10.6±1.6% (DDJ), which were higher (p<0.01) than C. OC was increased (p<0.05) by 5.5±1.8% (DJ), which was higher (p<0.05) than C. CTX was not significantly changed at POST. There were no significant differences in ΔBTM between the jumps at any time point. In CMJ, ΔP1NP POST correlated (p<0.05) with the combined three-axis peak GRF (r=0.71). **CONCLUSION:** The acute, jumping-induced increase in P1NP and OC without any rise in CTX indicates an osteogenic change in bone turnover in favor of bone modeling, which based on the relationship between the combined three-axis peak GRF and the acute P1NP response after CMJ seems to be dose-dependent.

The Effect Of Age On The Lumbar Spine Of Cricket Fast Bowlers

Laura Keylock¹, Katherine Brooke-Wavell¹, Pete Alway¹, Nick Peirce², Mark King¹. ¹Loughborough University, Loughborough, United Kingdom. ²England and Wales Cricket Board, Loughborough, United Kingdom. Email: L.M.Keylock@lboro.ac.uk
(No relevant relationships reported)

Senior cricket fast bowlers (FB) have high lumbar spine bone mineral, particularly on the contralateral side to their bowling arm. It is thought that bone possesses its greatest ability to adapt to loading during adolescence but is unknown at what age asymmetry develops in FB and how adaptation develops with age.

PURPOSE: To determine how lumbar bone mineral and geometrical properties differ according to age in FB. **METHODS:** With NHS and institutional ethics approval, 107 elite adolescent and senior male FB aged 14 to 35 years received a single AP lumbar spine DXA scan (GE Lunar iDXA, GE Healthcare, USA). Bone mineral density (BMD) and bone mineral content (BMC) were derived for each vertebra, along with average vertebral height and width, area and Z-score (Lunar enCore v17, GE Healthcare, USA). Custom regions of interest derived the bone mineral in the lateral third of the non-dominant (ND) and dominant (D) sides of the vertebral body (relative to bowling arm). FB were split into 14-15 (n=27), 16-17 (n=28), 18-19 (n=22), 20-24 (n=16), and 25+ (n=14) age groups. ANOVAs were used to compare the age group means for each variable, with FFM as covariate. **RESULTS:** Lumbar spine BMD, BMC, Z-score, area, width and height significantly differed between age groups at all vertebral levels (P<0.01), but differences in area and height were no longer significant with FFM included as a covariate (P≥0.38). Mean BMD (± SD) L1-L4 Z-scores increased progressively with age from +0.83 ± 1.24 at age 14-15 to +2.69 ± 1.17 at age 25+. BMD and BMC on the ND and D sides significantly differed with age (P≤0.04) and side (P<0.01), and by age on each side (P≤0.04) as highlighted at L3 in figure 1. **CONCLUSIONS:** Adaptation to fast bowling, in terms of whole vertebra and site-specific bone mineral, substantially increases with age particularly on the ND side.

Feasibility Of Using A Bisphosphonate In Sleeve Gastrectomy Patients For Bone Loss Prevention

Ashlyn A. Swafford¹, Jamy D. Ard², Peri C. Gearren³, Adolfo Z. Fernandez³, Sherri A. Ford¹, Beverly A. Nesbit¹, Kylie K. Reed¹, Kristen M. Beavers¹. ¹Wake Forest University, Winston Salem, NC. ²Wake Forest School of Medicine, Winston Salem, NC. ³Wake Forest Baptist Health, Winston Salem, NC. (Sponsor: Peter Brubaker, FACSOM) Email: swafaa18@wfu.edu
(No relevant relationships reported)

Among older adults with severe obesity, the sleeve gastrectomy (SG) procedure yields rapid weight loss and cardiometabolic improvement; however, it is also associated with significant bone loss and increased fracture risk. Bisphosphonate use reduces osteoporotic fracture risk and may be effective in minimizing bariatric surgery associated bone loss; yet, this hypothesis has not been formally tested.

PURPOSE: The purpose of this study is to determine the feasibility of recruiting, enrolling, treating, and following 24 SG patients (40+ years old) into a randomized controlled trial (RCT) examining the efficacy of Risedronate, a bisphosphonate, use (versus placebo) in the prevention of bariatric surgery associated bone loss. **METHODS:** Feasibility metrics include recruitment, retention, adherence, and adverse event reporting. Self-reported demographic characteristics and dual energy X-ray absorptiometry (DXA) acquired T-scores and 10-year major osteoporotic fracture (MOF) and hip fracture risk were also collected at baseline. **RESULTS:** Study recruitment occurred over 17 months (3/5/18-8/31/19). A total of 70 patients met initial eligibility criteria and were referred by the clinic; of those, 32 were screened by telephone (n=8 excluded after screening), and 24 were randomized to Risedronate or placebo (recruitment yield: 34%; n=12/group). On average, participants were 56±7 years old at baseline, with a BMI of 44.8±6.1 kg/m². The majority of the study sample was female (83%), white (79%), and postmenopausal (75%). Three participants (12%) presented with osteopenia, and MOF and hip fracture risk was low (5.0±3.2% and 0.3±0.4%, respectively). Data collection is ongoing. As of 11/3/2019, two participants have withdrawn, three mild adverse events have been reported (out of 125 contacts; one related and two unrelated), and among active participants, 95% of pills (124 out of 131 total) have been taken (n=22>80% compliant with medication protocol). **CONCLUSIONS:** Use of Risedronate as a novel therapeutic to preserve bone density among SG patients appears feasible and well tolerated. Forthcoming intervention effects will be used to generate effect size estimates to appropriately power a subsequent trial.

322 Board #138 May 27 10:30 AM - 12:00 PM

LARC Implant Use Does Not Exacerbate Bone Loss Associated With Hindlimb Unloading

Heather C. Allaway, Jon P. Elizondo, Sarah E. Little, Harry A. Hogan, Susan A. Bloomfield, FACSOM. Texas A&M University, College Station, TX. (Sponsor: Susan Bloomfield, FACSOM) (No relevant relationships reported)

Combined oral contraceptives (COC; ethinyl estradiol and progestin) reduce exercise-induced gains in bone mineral density (BMD), especially by suppressing bone turnover. Long-acting reversible contraceptives (LARC; progestin-only) provide many practical advantages over COC and will likely be recommended for female astronauts on long-duration missions; however, the impact on bone health with unloading is unknown. **Purpose:** To determine if LARC use will blunt loss of bone associated with hindlimb unloading (HU)

Methods: Virgin female Sprague-Dawley rats (n=52; 4-mo-old) were singly housed and randomly assigned to placebo (PL) and LARC groups, via an implanted slow-release etonogestrel pellet (0.00ug/d vs. 0.30ug/d). A week later, animals were further randomized to weight bearing (WB) and HU groups (n=13/subgroup) for 6 weeks. Calcein injections were delivered 9 and 2 days prior to termination. Pre/post-HU, proximal tibia metaphysis (PTM) and the tibia mid-diaphysis (TD) were scanned with *in vivo* peripheral quantitative computed tomography. At termination tibiae were stored for mechanical testing and dynamic/static histomorphometry. Univariate and repeated measures 2-way ANOVA were used.

Results: Despite increasing their food intake during HU (p<0.01), HU animals lost weight and weighed less than WB animals starting on HU week 2 (p<0.01). Irrespective of pellet type, HU resulted in a loss of total and cancellous volumetric BMD (vBMD) at the PTM (p<0.01), reduced cortical thickness at the PTM and TD (p<0.01), and reduced endosteal and periosteal mineralization (MS/BS, MAR, and BFR; p<0.02) at the TD compared to WB animals. Irrespective of loading group, at the PTM LARC animals lost cancellous vBMD (p<0.05), but had an increase in osteoid (organic bone matrix; p<0.04) compared to PL animals. PTM BV/TV and Tb.Th were greater in PL-WB animals compared to PL-HU animals only (p<0.04). Similarly, ultimate force was greater in PL-WB animals compared to PL-HU animals only (p<0.02).

Conclusions: On balance, LARC implantation did not blunt nor worsen the bone response to unloading. LARC appear to be a viable option for premenopausal female astronauts selected for long-duration missions.

Differences In Bone Mineral Density At The Femoral Neck And Lumbar Regions Across Female Soccer Players, Olympic Lifters And Power Lifters

Lisa Griffin, Woohyoung Jeon, J. Michael Harrison, Phillip Stanforth. *University of Texas at Austin, Austin, TX.*
Email: l.griffin@austin.utexas.edu

(No relevant relationships reported)

Power lifting can improve total body bone mineral density (BMD), but improvements in the regions most susceptible to injury (femoral neck and lumbar vertebrae) have not been demonstrated. Soccer players, who engage in odd-impact loading, have greater BMD at the femoral neck than sedentary controls. Olympic lifting involves both high- and odd-impact loading at the femoral neck and lumbar regions, but comparisons in BMD across sport-specific athletes have not yet been made.

PURPOSE: To examine differences in total BMD and BMD at the femoral neck and lumbar vertebrae between female power lifters (PL), Olympic lifters (OL), soccer players (SP) and recreationally active individuals (RA).

METHODS: Thirty-seven females participated in this study: 10 PL, 8 OL, 8 SP, and 11 RA (mean age = 24.5 ± 7.9 years). Total BMD, BMD at lumbar vertebrae L1-L4, and BMD at the femoral neck of the dominant leg were measured along with body composition (total fat mass, lean mass, and percent body fat) with dual-energy x-ray absorptiometry. Body composition components were compared across groups with a one-way ANOVA. BMD measures were compared across groups with an ANCOVA with weight, height, and body mass index as covariates. Tukey's tests were used for post-hoc analysis. Significance was accepted at $P < 0.05$.

RESULTS: All three athletic groups had greater total BMD than RA (1.071 ± 0.066 g·cm⁻²). OL (1.306 ± 0.08 g·cm⁻²) had greater total BMD than PL (1.071 ± 0.07 g·cm⁻²), but it was not different than SP. At the femoral neck, OL (1.127 ± 0.09 g·cm⁻²) and SP (1.212 ± 0.10 g·cm⁻²) [but not PL (1.075 ± 0.16 g·cm⁻²)] had greater BMD than RA (0.971 ± 0.99 g·cm⁻²). BMD at the femoral neck was greater in SP than in PL, with no difference between OL and PL. At lumbar spine sites L2 - L4, there was no difference across the three athletic groups. OL and PL had a greater BMD than RA at L2-4, whereas SP had greater BMD than RA at only at L4. There was no difference across all groups at L1.

CONCLUSION: Olympic lifting includes both high- and odd- impact movements in addition to high-force loading. Olympic lifters showed similar BMD at the femoral neck as soccer players and similar BMD in the lumbar spine as power lifters. Thus, Olympic lifting may have greater BMD effects in the two key regions that are susceptible to injury compared to sports that do not combine power and odd-impact training.

Middle-and Long-term Endurance Runners Exhibit Healthier Fat Distribution Compared To Matched Controls

Ulrike H. Mitchell¹, Bruce Bailey¹, Patrick Owen². ¹Brigham Young University, Provo, UT. ²Deakin University, Melbourne, Australia. (Sponsor: Allen Parcell, FACSMM)

(No relevant relationships reported)

PURPOSE: Aerobic exercise training has many known cardiovascular benefits that may promote healthy ageing. Long-term long-distance running is a common aerobic exercise modality, but the number of individuals involved in endurance running decreases with increasing age. This cross-sectional study assesses structural findings, e.g. body composition, bone mineral density and muscle mass, obtained from middle-aged long-term endurance runners, and compares the findings with matched non-runners. **METHODS:** Total and regional lean and fat mass (kg) and total body percent lean and fat mass (%) were assessed by DXA and analyzed using enCORE software version 17. Sagittal Magnetic Resonance images using a T2-weighted sequence captured the cross-sectional area and thickness of the multifidus from L1 to L5.

RESULTS: Analyses included 10 male runners with a mean (standard deviation; SD) age of 49(4)yr, height of 178.9(4.9)cm, weight of 67.8(5.8)kg and body mass index (BMI) of 21.4(1.4)kg/m² that had been running 82.6(27.9)km/wk for 23(13)yr and nine non-runner sex-, age-, height- and weight-matched controls with a mean(SD) age of 51(5)yr, height of 176.0(7.8)cm, weight of 72.8(7.1)kg and BMI of 23.7(2.1) kg/m². Only BMI statistically differed between the groups (P=0.010). Runners had 4.4kg greater mean total body lean mass than controls, which equated to 10percentage-points greater mean total body percent lean mass, albeit only the latter was significant (P=0.001). Runners also had 14% greater trunk lean mass. Moreover, runners had less total body (8.6kg), arm (58%), leg (52%), trunk (73%), android (91%) and gynoid fat mass (64%). No differences were observed between groups for BMD outcomes. No between-group differences in multifidus size were observed.

CONCLUSIONS: Middle-aged long-term male runners exhibit lower total body fat percentage and healthier fat storage distribution, but no different BMD compared sex-, age-, height- and weight-matched non-running participants. Other than cardiovascular benefits, long-term endurance running seems to also provide structural benefits.

Reliability Of Leg Length Measures Using Dual Energy X-ray Absorptiometry (dxa) Scans In Young Children.

Lilly A. Bradley, Tori L. Vogelaar, Jody L. Clasey, FACSMM. *University of Kentucky, Lexington, KY.* (Sponsor: Jody L Clasey, FACSMM)

(No relevant relationships reported)

Dual energy x-ray absorptiometry (DXA) scans were originally used to determine total body and regional bone mineral content and areal density measures. Advances in DXA scanning technology and accompanying software analyses provides total body and regional soft tissue analyses, the ability to analyze uniquely created regions of interest, and anatomical measures including structural angles and segmental lengths.

PURPOSE: To determine the intratester and intertester reliability of leg length measures using total body DXA scans. **METHODS:** Total body DXA scans from 53 young children were acquired and the right and left leg lengths were determined twice (nonconsecutively) by two investigators (Invest 1 and Invest 2). Leg lengths were determined as the vertical distance from the most proximal point of the head of the femur to the proximal aspect of the medial malleolus of the tibia following view enlargements of the legs on the DXA analyses computer screen. Group mean differences, explained variance, and calculation of the 95% confidence intervals were determined and results are expressed as mean ± SE, and significance $p < 0.05$.

RESULTS: Intratester reliability for Invest 1 right leg length (66.48 ± 1.01 versus 66.49 ± 1.02 cm; $r^2 = 0.999$) and left leg (66.64 ± 1.00 versus 66.60 ± 1.01 cm; $r^2 = 0.998$); and for Invest 2 right leg length (66.25 ± 1.01 versus 66.26 ± 1.00 cm; $r^2 = 0.999$) and left leg (66.43 ± 1.00 versus 66.47 ± 1.00 cm; $r^2 = 0.999$) resulted in no significant group mean differences, and significant explained variance. Subsequently, the group mean of the right and the left leg lengths were used for both Invest 1 and Invest 2 to determine the intertester reliability. Similarly, no significant group mean differences and significant explained variance were found for the right leg length (66.49 ± 1.02 versus 66.26 ± 1.00 cm; $r^2 = 0.988$) and the left leg (66.62 ± 1.00 versus 66.45 ± 1.00 cm; $r^2 = 0.973$). Bland Altman plotting resulted in mean differences of 0.23 cm and 0.17 cm; with the 95% confidence intervals ranging from 2.55 to -2.08 cm and 2.60 to -2.26 cm for the right and left legs, respectively. **CONCLUSION:** Leg lengths measured from total body DXA scans provide highly reliable measures and may provide greater accuracy than traditional measures using anthropometric tapes due to the elimination of soft tissue.

Bone Density Is Lower And Differentially Related To Body Composition In Adults Using ADHD Medications

Shannon L. Mathis¹, Sims K. Lawson¹, Harshvardhan Singh², Gary R. Hunter, FACSM², Gordon G. MacGregor³. ¹University of Alabama Huntsville, Huntsville, AL. ²University of Alabama Birmingham, Birmingham, AL. ³Alabama College of Osteopathic Medicine, Dothan, AL. (Sponsor: Gary R. Hunter, FACSM)
 Email: shannon.mathis@uah.edu
 (No relevant relationships reported)

Stimulant medications, such as amphetamines, lead to increased activation of osteoclast-mediated bone resorption resulting in decreased bone mass and are first-line medications for Attention-Deficit Hyperactivity Disorder (ADHD). **PURPOSE:** To determine the effect of stimulants on bone mineral density (BMD) and body composition in young adults with ADHD. **METHODS:** Stimulant (methylphenidate or amphetamine) users (ADHD; 14 male, 11 female) and 28 healthy controls (CON; 17 male, 11 female) participated (N=53, 19-27 years of age). Physical activity (PA) was measured with Bone-Specific Physical Activity Questionnaire. Whole body (WB) bone mineral content (BMC), BMD z-scores (to adjust for gender, race, body weight, and age) of the lumbar spine (L1-L4), total hip, and femoral neck, body composition, and relative skeletal mass index (RSMI) were measured by dual X-ray absorptiometry. Independent sample t-tests, multiple regression, and step-wise regression were used to analyze the data. **RESULTS:** Independent sample t-test showed no differences in age, percent body fat, or RSMI between the groups. In the ADHD group, PA was lower compared to CON (-15.9, $p = .003$). WB BMC was lower in ADHD vs. CON (-304.5 g, $p = .02$); and, BMD z-scores of WB ($z = -0.9$, $p = .01$) and lumbar spine ($z = -0.77$, $p = .04$) were lower in ADHD than CON with no differences in total hip and femoral neck. Linear regression analysis showed group and RSMI were independently related to WB BMD z-scores ($r = -0.68$, $p = .05$; $r = 0.33$, $p = .005$, respectively); PA was not related to WB BMD z-score ($r = 0.003$, $p = .75$). The WB BMD z-score was $z = 0.68$ lower in the ADHD group than the control group. When controlling for PA, sex, age, height, and weight, stepwise regression analyses showed that: In ADHD, lean mass was not related to BMD at any of the sites ($p > .05$), but fat mass was negatively related to hip ($r = -.58$, $p = .006$), neck ($r = -.72$, $p < .001$), and WB BMC ($r = -.76$, $p < .001$). In CON, lean mass was positively related to spine and hip BMD ($r = .45$, $p = .03$; $r = .45$, $p = .03$, respectively) and WB BMC ($r = .56$, $p = .004$); fat mass was negatively related to hip BMD ($r = -.43$, $p = .04$) and WB BMC ($r = -.56$, $p = .004$). **CONCLUSIONS:** Lower indices of bone health in the ADHD group and the differential relationship between muscle mass and bone density in ADHD vs. CON may be due to adverse metabolic effects of stimulant medication.

327 Board #143 May 27 10:30 AM - 12:00 PM
Effect Of High Intensity Intermittent Exercise On Blood Ionized Calcium And Serum Parathyroid Hormone

Jun Hamano¹, Takayuki Shimizu¹, Katsunori Tsuji¹, Yuzhong Xu¹, Masanari Togo¹, Wendy M. Kohrt, FACSM², Izumi Tabata, FACSM¹. ¹Ritsumeikan University, Kusatsu City, Shiga Prefecture, Japan. ²University of Colorado, Aurora, CO. (Sponsor: Izumi Tabata, FACSM)
 (No relevant relationships reported)

Purpose: Increased serum parathyroid hormone concentration (PTH) during moderate-intensity exercise has been reported, suggesting that such exercise may stimulate bone resorption. On the other hand, certain data also suggest that supramaximal intensity exercise causes neither a decrease in serum calcium nor increase in PTH. This study was undertaken to observe the effects of high intensity intermittent exercise (HIIE), which improves both aerobic and anaerobic fitness maximally, on bone metabolism. **Method:** Seven young subjects exercised on two days after an overnight fast. On the HIIE day, subjects performed 6-7 exhaustive 20-sec cycling bouts (170% VO_{2max}) with intervening 10-sec rest intervals. On the moderate-intensity exercise (MIE) day, subjects cycled for 60 min at 70% VO_{2max} . Blood was sampled before and after 10 min of warm-up at 50% VO_{2max} , and immediately after and 10, 20, 30, 60, 90 min after the HIIE. For MIE day, blood was obtained before, immediately after, and 10, 30, 60, 90 min after the exercise. **Result:** HIIE induced an increase in iCa (Pre: 1.13 ± 0.06 mmol/l, post: 1.22 ± 0.03 mmol/l, $p < 0.001$) and a decrease in PTH (Pre: 30 ± 5 pg/ml, 10 min after HIIE: 22 ± 45 pg/ml, $p < 0.05$), while MIE significantly elevated serum PTH without a change in iCa. No changes in serum C-terminal telopeptide of Type I collagen (marker of bone resorption) or osteocalcin (marker of bone formation) were observed up to 90 min after HIIE and MIE. **Conclusion:** It is concluded that HIIE does not induce a decrease in blood iCa or increase in PTH, suggesting that HIIE might not deteriorate bone metabolism.

328 Board #144 May 27 10:30 AM - 12:00 PM
Effect Of Running And Swimming On Bone Mineral Density Throughout The Lifespan

Eric Shamus¹, Taylor Millheim², Kenna Valdovinos¹. ¹Florida Gulf Coast University, Fort Myers, FL. ²Select Physical Therapy, Pembroke Pines, FL.
 Email: eshamus@fgcu.edu
 (No relevant relationships reported)

PURPOSE: Bone mineral density (BMD) is used as an indirect indicator of risk of osteoporosis and bone fracture. Both swimming and running have been found to have a positive effect on bone mineral density. A comparison of the effects of swimming and running on bone mineral density in humans has not yet been performed. The purpose of this study was to compare the effects of running and swimming on bone mineral density in young individuals versus mature individuals and to compare intrinsic variables of body weight, height, gender, years swimming or running, distance ran or swam per week, and hours of physical activity per week.

METHODS: This was a quantitative, correlational study that sought to determine whether statistically significant differences in bone mineral density exist between swimmers and runners across the lifespan. Heel bone mineral density of each participant was assessed using the GE Achilles Ultrasonometer.

SUMMARY OF RESULTS: This study included 54 total participants with 12 runners under age 30, 18 runners over age 30, 11 swimmers under age 30, and 13 swimmers over age 30. No statistically significant difference in bone mineral density existed between swimmers and runners in the young adult or mature adult groups ($P = 0.618$). Athlete weight was the only factor that had statistically significant differences in bone mineral density. The results do not indicate that the mode of activity (swimming/running) correlates with significantly different findings in BMD.

CONCLUSION: No correlation between mode of activity and bone mineral density can be established at this time. The degree of causality cannot be determined due to the study's correlational nature. The results demonstrate that swimming and running have similar effects on bone density. Athlete weight had statistically significant differences in bone mineral density. This indicates that the overall body weight plays a larger role in the formation/maintenance of bone mineral density than activity selection did in this study.

Association Between Dietary Cholesterol, Saturated Fat And Bone By Calcium Intake Levels.

Stephanie Marie Otto. Gustavus Adolphus College, St. Peter, MN.
 Email: sotto@gustavus.edu
 (No relevant relationships reported)

The role of diet in bone health has been widely researched. Numerous studies have concluded that dietary calcium is important for the development of healthy bone but the relationship between cholesterol and saturated fat, which may hint at the role of animal protein in bone health, has drawn less attention among researchers.

PURPOSE: The purpose of this study was to determine the association between dietary cholesterol and saturated fat intake, and bone mineral density (BMD) among women based on calcium intake levels. **METHODS:** A total of 41 women (38.90 \pm 7.92 years) were included in this study. Anthropometric data were collected and BMD (g/cm^2) was measured at the hips, femoral, neck, and lumbar spine with a Hologic dual energy x-ray absorptiometry machine. Dietary intake was assessed using a 3-day food diary. Participants were divided into two calcium intake groups based on average daily calcium intake: calcium sufficient group (calcium intake $\geq 75\%$ of the recommended intake) and a calcium deficient group (calcium intake $< 75\%$ of the recommended intake). **RESULTS:** Among the calcium sufficient group, a significant positive correlation ($p < .05$) was found between lumbar spine BMD and dietary cholesterol intake ($r = .41$, $p = .020$) even after controlling for dietary protein intake ($r = .41$, $p = .024$). A significant positive correlation was found between femoral neck BMD and saturated fat intake ($r = .37$, $p = .038$) but this association disappeared after controlling for protein intake. No significant correlations were found among the calcium deficient group. Among the calcium sufficient group, regression analysis indicated that dietary cholesterol was a significant predictor of lumbar spine BMD only $F(1,30) = 6.02$, $MSE = .03$, $p = .020$, $Adj. R^2 = .14$. **CONCLUSIONS:** Among a group of calcium deficient women, it appears that other nutrients are not associated with BMD. For women who are receiving an adequate amount of calcium, cholesterol and saturated fat intake are both associated with higher BMD. Of particular interest was the positive correlation between dietary cholesterol and lumbar spine BMD even after controlling for protein intake which might indicate the importance of animal sources of protein for bone health. Future research should examine the role of animal protein compared to non-animal protein on BMD. IRB# 1213-0223

Association Among Percent Body Fat, Areal Bone Mineral Density, And Handgrip Strength In Young AdultsSoJung Kim¹, Harshvardhan Singh², Eliana Casamassima¹.¹University of Massachusetts Lowell, MA. ²University of Alabama, Birmingham, AL.

Email: sojung_kim@uml.edu

(No relevant relationships reported)

PURPOSE: The purpose of this cross-sectional study was to examine the relationships among percent body fat (%BF), areal bone mineral density (aBMD) and non-dominant handgrip strength in healthy college-aged students. **METHODS:** Healthy college-aged women (n=73, 20.4±1.3 years; 163.5±7.1 cm; 64.7±11.3 kg) and men (n=59, 21.1±1.4 years; 177.4±7.7 cm; 77.7±10.6 kg) between the ages of 18 and 25 years were recruited from the University of Massachusetts Lowell. Body composition (%BF) and aBMD of the non-dominant side of femur (FN: femoral neck, TH: total hip) and lumbar spine (L1-L4) were measured by dual energy X-ray absorptiometry. Isometric handgrip test was measured by JAMAR Dynamometer, and the average of three trials of the non-dominant side was used for data analysis. The total bone-specific physical activity (tBPAQ, average of past and current BPAQ) score was used to obtain a comprehensive account of lifetime physical activity related to bone health. **RESULTS:** Partial correlation tests showed significantly negative relationships between %BF and aBMD of the non-dominant FN ($r_{\text{partial}} = -.387, p=.002$), TH ($r_{\text{partial}} = -.458, p=.0001$), and lumbar spine ($r_{\text{partial}} = -.299, p=.034$) in young women, while controlling for tBPAQ and BMI. Similarly, FN ($r_{\text{partial}} = -.453, p=.001$), TH ($r_{\text{partial}} = -.425, p=.001$), and lumbar spine ($r_{\text{partial}} = -.291, p=.034$) were found in young men. In addition, higher %BF had a negative impact on isotonic hand grip strength in both women ($r_{\text{partial}} = -.446, p=.0001$) and men ($r_{\text{partial}} = -.410, p=.002$), respectively. **CONCLUSIONS:** Our data suggests that regardless of BMI and physical activity, %BF can adversely affect musculoskeletal health in young adults. These results have important implications for prevention of future loss of aBMD in young adults, individuals who may be overweight or obese, and individuals undergoing weight loss.

Prior Tobacco Use Is Associated With Tibial Microarchitecture In U.S. Army Recruits: A Preliminary AnalysisColleen M. Castellani, Theresa N. Faller, Katelyn I. Guerriere, Julie M. Hughes, Stephen A. Foulis, Kathryn M. Taylor. *Military Performance Division, United States Army Research Institute of Environmental Medicine, Natick, MA.*

(No relevant relationships reported)

Tobacco use is common and is associated with less favorable bone properties in older adults at risk for osteoporosis. Baseline bone properties are related to stress fracture risk in military populations. Whether a history of tobacco use is associated with less favorable bone microarchitectural properties in military recruits is unknown.

PURPOSE: To examine the influence of prior tobacco use on bone microarchitecture using data from a large prospective field study (789 men and women from a larger planned cohort of 4000 U.S. Army recruits). **METHODS:** We collected high-resolution peripheral quantitative computed tomography images of the ultradistal tibia at the 4% site during the first week of basic combat training (BCT) from 556 male and 233 female recruits. Also, self-reported history of tobacco use was assessed via questionnaire. Generalized linear models stratified by sex were used to evaluate the relationship between a history of tobacco use and baseline bone microarchitecture. Models were further stratified by tobacco type. All models were adjusted for prior physical activity, recruit and parents' level of education, race/ethnicity, age, and body mass index (BMI). **RESULTS:** 21.29% of recruits reported prior tobacco use. Tobacco users were more likely to be male (25.5%, $p<.0001$) and white (26.8%, $p=.0007$). There were no differences in tobacco use by socioeconomic status, prior physical activity, or BMI. At the ultradistal tibia, tobacco use in female recruits was associated with lower indices of cortical thickness and cortical area, with decrements ranging from -2.53% to -10.46% depending on the method of tobacco consumption (all $p<.05$). In male recruits, use of tobacco pipe was associated with a 17.39% lower cortical thickness ($p=.026$). There were no significant differences reported in trabecular bone parameters associated with prior tobacco use in male or female recruits. **CONCLUSIONS:** These data show that recruits, particularly female recruits, with a history of tobacco use may enter BCT with some less favorable microarchitectural properties, potentially placing them at greater risk for stress fracture, although this remains to be determined.

(No relevant relationships reported)

The signaling pathway responsible for muscle hypertrophy following testosterone replacement therapy (TRT) and resistance training (RT) has not been elucidated after spinal cord injury (SCI). Furthermore, it is unclear whether evoking muscle hypertrophy improves mitochondrial citrate synthase activity (CS) and Complex III (CIII) activities after SCI. **PURPOSE:** To examine the effects of TRT+RT compared to TRT only on protein expression of markers associated with muscle hypertrophy, substrate utilization and mitochondrial biogenesis in men with SCI. **METHODS:** Twenty-two men with motor complete SCI were randomized to 16 weeks of TRT+RT or TRT only. Evoked progressive RT using neuromuscular electrical stimulation (2 lb. increments) was administered twice weekly. TRT patches (2-6 mg/day) were applied at bedtime. Muscle biopsies were captured before and after 16 weeks from the right vastus lateralis. Protein expression of markers associated with muscle hypertrophy were evaluated [FAK, total and phosphorylated Akt, total and phosphorylated mTOR] and substrate utilization and mitochondrial biogenesis [GLUT4, PGC1 α , total and phosphorylated AMPK]. Mitochondrial CS and CIII activity were also measured. **RESULTS:** TRT+RT demonstrated a 27.5% increase ($P=0.01$) in average fiber CSA compared to -9% decrease following TRT only. Circulating IGFBP-3 increased ($P=0.0001$) in both TRT+RT (1764±665 to 2548.5±853 ng/ml) and TRT (1918.5±587 to 2778±967 ng/ml). GLUT4 was elevated in the TRT+RT group compared to the TRT only ($P=0.005$). Total Akt ($P=0.06$) and phosphorylated Akt^{Ser389} ($P=0.049$) were also elevated in the TRT+RT group. Mitochondrial CS (34% $P=0.006$) increased in the TRT+RT group. **CONCLUSION:** Sixteen weeks of TRT+RT resulted in hypertrophy of myofibers that was associated with increased protein expression and markers of activation of Akt. This was further associated with elevations in GLUT4 protein expression and markers of mitochondrial function in persons with SCI.

(Sponsor: Ashraf Gorgey, FACSM)

(No relevant relationships reported)

Spinal cord injury (SCI) adversely affects testosterone levels and bone quality. Resistance training (RT) and testosterone replacement therapy (TRT) have been shown to improve muscle quality in humans following SCI. Such improvements to muscle quality may also result in improved bone quality. **PURPOSE:** To examine if combining open kinetic chain RT and TRT (TRT+RT) can be beneficial to trabecular bone quality following SCI. **METHODS:** Nine subjects with SCI were randomized into a TRT+RT group for a 16-week intervention. Each subject also underwent magnetic resonance imaging (MRI) prior to (BL) and following the intervention (PI). MRI microarchitecture techniques were used to evaluate trabecular bone quality, measured as plate width (PW; μm), trabecular bone thickness (TBTh; mm), trabecular bone spacing (TBSp; mm), and network area (NA; $1/\text{mm}$) for the right proximal tibia (ProxT) and distal femur (DistF). Mixed models with random effects were used to calculate differences between BL and PI (MD \pm SE) and were then transformed to effect sizes similar to Cohen's d (d, 95% CI [effect size]). **RESULTS:** Following the intervention, ProxT PW (MD: 30.56 \pm 22.52; d: 0.48, -0.21 to 1.17 [small]), TBTh (MD: 0.02 \pm 0.01; d: 0.70, 0.01 to 1.39 [medium]), and NA (MD: 0.04 \pm 0.02; d: 0.64, -0.05 to 1.33 [medium]) all increased from BL measures. In contrast, TBSp (MD: -0.25 \pm 0.17; d: -0.52, -1.22 to 0.17 [medium]) decreased from BL. The DistF similarly presented with increases in bone quality from BL for PW (MD: 11.7 \pm 42.70; d: 0.10, -0.60 to 0.79 [negligible]), TBTh (MD: 0.01 \pm 0.01; d: 0.29, -0.41 to 0.98 [negligible]), and NA (MD: 0.03 \pm 0.03; d: 0.39, -0.30 to 1.08 [small]), as well as decreases in TBSp

(MD: -0.22 ± 0.16 ; d: $-0.47, -1.16$ to 0.23 [small]). **CONCLUSIONS:** When combined with TRT, the mechanical stresses induced via open kinetic chain RT displays the potential to improve trabecular bone quality following a longer duration intervention. This was particularly evident within the ProxT as these effect sizes were comparably larger than the DistF. Such differences are likely due to the tissue stress induced on the ProxT through contractions of the quadriceps muscles. Supported by VA-RRD CDA2 (B7867-W).

Hypermobility Characterization In Participants With Down Syndrome Attending An Instructor Led Controlled Adaptive Exercise Setting

Bradley D. Clark, Amy L.B. Valdez, Daniela A. Rubin, FACSM. *Cal State University, Fullerton, Fullerton, CA.* (Sponsor: Daniela Rubin, FACSM)
Email: b1clark@csu.fullerton.edu
(No relevant relationships reported)

Introduction/Background: Joint hypermobility (JHM) and hypotonia are features shown in people with Down Syndrome (DS). Adaptive Exercise Programs adapt not only to the physical but also to behavioral and intellectual challenges. This study characterized JHM and related measures in a sample of adults with DS attending an adaptive exercise program. **Methods:** Thirteen adults with DS (11 males and 2 females, 28.5 ± 3.2 y height: 138.6 ± 45.8 cm, body mass = 78.22 ± 15.03 kg) participated. Participants attended adaptive exercise programming twice a week for ≥ 9 months. Tests included active range of motion (AROM) measured three times (median score reported), JHM was determined through the 9-point Beighton scale, upper body (hand-grip dynamometer) and lower body (30-second sit-to-stand) strength. **Results:** Means \pm SD for AROM included: shoulder extension = $21.3 \pm 8.9^\circ$, shoulder flexion = $179.0 \pm 9.7^\circ$, shoulder abduction = $174.9 \pm 8^\circ$, shoulder medial rotation = $59.2 \pm 13.2^\circ$, shoulder lateral rotation = $86.1 \pm 11.6^\circ$, hip extension = $14.3 \pm 5.8^\circ$, hip flexion = $94.0 \pm 13.6^\circ$, hip abduction = $27.8 \pm 8.4^\circ$, hip adduction = $17.1 \pm 4.5^\circ$, hip medial rotation = $31.5 \pm 6.3^\circ$, hip lateral rotation = $31.9 \pm 5.6^\circ$, ankle dorsiflexion = $16.6 \pm 8.2^\circ$, ankle plantarflexion = $44.9 \pm 8.2^\circ$, subtalar inversion = $25.9 \pm 6.0^\circ$, and subtalar eversion = $19.2 \pm 9.6^\circ$. Participants presented with: no JHM 38.4% (n=5) and with JHM 60.14% (n=8). Strength was 26.4 ± 6 kg and the sit-to-stand included 20 ± 6 movements. There were not significant correlations between JHM and muscle strength ($r = -0.338, p = .259$) or physical function ($r = -0.085, p = .220$). **Discussion/Conclusion:** Adults with DS that participated in an instructor-led adaptive exercise setting showed lower AROM compared to norms in adults without DS, potentially because of persistent hypotonia. Despite the sizable incidence of JHM, JHM was more prominent in hands (50% of 8). Participants showed comparable upper-body strength but higher lower body strength than shown in DS. The program focused on strengthening large muscle groups with less emphasis on wrist or hand muscles which can potentially explain why only 1/3 of participants presented with the overall JHM and good lower body strength. Future studies should evaluate changes in JHM, AROM and muscle strength in response to adaptive exercise training in DS.

Lean Mass Changes After 10-week Resistance Training Intervention In Adults With Down Syndrome

Emily M. Post, Madison L. Kackley, Lydia K. Caldwell, Matthew K. Beeler, Carl M. Marech, FACSM, Brian C. Focht, FACSM, Jeff S. Volek, William J. Kraemer, FACSM. *The Ohio State University, Columbus, OH.* (Sponsor: William Kraemer, FACSM)
Email: phillips.1649@osu.edu
(No relevant relationships reported)

PURPOSE: To examine changes in body composition (i.e. lean mass) after a 10-week resistance training intervention in individuals with Down syndrome. **METHODS:** Data was collected on willing 18 - 40-year-old moderately active men and women with Down syndrome (age 24.4 ± 6.3 years, height 149.2 ± 11.2 cm, weight 72.02 ± 24.5 kg). Twelve participants completed 24 resistance training sessions (duration 45-60 minutes per session). Dual x-ray absorptiometry (DXA) was used to assess body composition both pre- and post-intervention (i.e. body fat, lean tissue mass, fat tissue, bone density). A nonlinear periodized resistance exercise program was implemented; made of light, moderate, and heavy resistances. The participants began the first two weeks of the intervention with exercises using light 12-15 RM Zone repetitions and moderate 8-10 RM Zone progressing from 1-3 sets over the two-week period of time. After that flexible period, using light, moderate, and heavy (4-6 RM zone) for 3 sets were rotated with toleration of the work out noted each training session. The resistance training intervention utilized a body part bodybuilding training program 3 days per week (consisting of 1 upper body, 1 lower body, 1 full body exercises). The exercises consisted of body weight exercises, machine based, resistance bands, and free weight exercises. Each program was individualized per participant regarding specific exercises based off of movement kinetics, understanding, skill, and strength

levels. Participants were kept in a light to moderate intensity heart rate range via heart range chest monitoring straps. **RESULTS:** There was no significant difference between pre- and post-intervention for overall body mass ($p = 0.23$), body fat ($p = 0.75$), or bone mineral density ($p = 0.078$). However, there was a significant increase between pre- and post-intervention in lean mass ($p = 0.033$). **CONCLUSIONS:** A 10-week moderate resistance training intervention is a great enough stimulus to significantly increase lean muscle tissue in adults with Down syndrome. Therefore, implementing resistance training into an individual's weekly routine for adults with Down syndrome is a viable option to increase lean muscle mass, which could also increase potential strength and motor skill, then increasing overall quality of life.

336 Board #152 May 27 10:30 AM - 12:00 PM

Alterations In Musculoskeletal Function And Body Composition In Children With Autism Spectrum Disorder

Monica C. Orosa, Stephanie V. Rosales, Kauionalani P. Kekuawela, Areum K. Jensen. *San Jose State University, San Jose, CA.*
(No relevant relationships reported)

Autism Spectrum Disorder (ASD) is a neurological disorder characterized by impaired social interaction and atypical behaviors. Children with ASD appear to have weaker muscular function and low bone mineral density. Recent studies have indicated that adolescents with ASD develop obesity and bone fracture incidence at a higher rate compared to typically developing peers (TDC). Limited information is available to identify levels of obesity and its relation to muscular function and body composition in children with ASD before they start puberty.

PURPOSE: To determine whether differential body composition may affect muscular strength and function in children with ASD

METHODS: Total of 40 adults, TDC and children with ASD participated in the study. Muscular strength (i.e., torque, work, and power) during knee extension and flexion was measured at 90, 150, and 210 $^\circ$ /sec in the lower extremity using Humac Norm Isokinetic Dynamometer. Maximal isometric forearm muscular strength was measured using a handgrip dynamometer. Body mass index (BMI), waist-to-hip ratio, and whole-body scan from Dual Energy X-Ray Absorptiometry were used to identify the body composition.

RESULTS: Compared to control adults, TDC and ASD had lower BMI (20.1 ± 0.7 TDC, 22.3 ± 4.4 ASD vs. 27.2 ± 2.3 Adults, kg/m^2). All groups had similar percent body fat (26.4 ± 2.3 Adults, 29.8 ± 1.83 TDC, 32.9 ± 3.84 ASD, %) and percent lean body mass (69.5 ± 2.2 Adults, 66.8 ± 1.7 TDC, 64.4 ± 3.6 ASD, %). However, compared to TDC, ASD children had significantly lower bone mass percentage (2.7 ± 0.3 ASD vs. 3.2 ± 0.2 TDC, %). Waist-to-hip ratio was significantly higher for ASD (0.91 ± 0.04 ASD vs. 0.85 ± 0.01 TDC). The maximal forearm and leg strength were significantly lower in ASD compared to TDC normalized for their body weight (30.2 ± 5.2 ASD vs. 42.8 ± 2.5 TDC, kg). There is a significant inverse relationship with muscular strength and regional percent fat in the forearm.

CONCLUSION: These findings suggest that body composition appeared to influence muscular strength in children with ASD. Less regional fat and higher bone mass rather than the total body fat may contribute for higher leg or forearm muscular strength in children with ASD.

Acute Effects Of Photobiomodulation Therapy On Muscle Force Recovery In Persons With Multiple Sclerosis

Mitra Rouhani¹, Miguel Tolentino², Erik Queoff¹, Chris Cho², Jeri-Anne Lyons², Alexander V. Ng, FACSM¹. ¹Marquette University, Milwaukee, WI. ²University of Wisconsin-Milwaukee, Milwaukee, WI.
Email: mitra.rouhani@marquette.edu
(No relevant relationships reported)

Symptomatic fatigue, as well as muscle fatigue, are common in persons with multiple sclerosis (PwMS), and both can negatively affect quality of life (QOL). Photobiomodulation Therapy (PBMT), comprising light in a 600-1000 nm bandwidth, is an emerging therapeutic modality thought to enhance mitochondrial function. There is evidence that PBMT can improve muscle fatigue, inflammation, and psychological status and thus might be beneficial for PwMS.

PURPOSE: To investigate PBMT on muscle force recovery after a fatiguing contraction in PwMS. A secondary aim was to determine if self-reported symptom outcomes influenced the response to PBMT.

METHODS: Randomized double-blinded repeated-measures design. Ambulatory males and females (n=17, 14 females) with relapsing-remitting MS were evaluated pre- and post-PBMT in 4 visits over 4 weeks. The muscle function measurements consisted of 3 maximal voluntary contractions (MVCs) of Tibialis Anterior (TA) muscle

followed by 2 min. of intermittent isometric contraction at 45% MVC. PBMT was then administered to the TA muscle belly at 1 of 4 energies: 40J, 80J, 120J or placebo (active device: 3 pulsed wavelengths at the same time including 640nm, 875nm, and 905nm, placebo device: single pulsed wavelength at 640 nm). After PBMT, recovery MVC's were obtained. Baseline psychosocial measurements comprising depression (CES-D), fatigue (MFIS) and QOL (PROMIS) were obtained during visit 1. McNemar's test was used to test for each light dose compared to placebo and Spearman's correlations were compared with Fisher's r to z transformation.

RESULTS: All subjects were able to recover strength to within 12% of their initial strength during the 120J visit. However, 6/17 subjects did not recover to the same degree after the placebo. This difference in force recovery between high (120J) dose and placebo was significant with $p=0.03$. Muscle recovery correlations with depression and QOL differed between 120J vs. Placebo (0.35 vs. -0.44, $p=0.03$ and -0.09 vs. 0.67, $p=0.03$, respectively).

CONCLUSIONS: PBMT at 120J may improve muscle force recovery in PwMS. Those reporting greater depression, or lower QOL may benefit most from PBMT. Supported by a pilot grant from the National MS Society

Effect Of Longterm Resistance Training On Bone Mineral Density, Muscular Strength, And Balance In Cerebral Palsy

Victoria B. Kott, Gabrielle R. Trakhter, Alex R. Magana, Tiffany N. Raczynski, Ramon C. Ronquillo, Areum K. Jensen. *San Jose State University, San Jose, CA.*

(No relevant relationships reported)

Cerebral Palsy (CP) is a non-progressive neurological disorder caused by lesions in the brain leading to musculoskeletal dysfunction and immobility. Physical deconditioning in individuals with CP appears to accelerate muscle atrophy and osteoporosis; thus, adults with CP are more prone to fall and fracture. Balance is also related to the higher risk of fall in the general public, and resistance training is known to improve bone mineral density (BMD), muscular strength, followed by balance. However, equivocal results were reported whether resistance training has a positive effect on BMD, muscular function and balance in CP population.

Purpose: To determine the influence of long-term resistance training to BMD, muscular strength, and balance in adults with CP who have muscle atrophy and/or osteoporosis.

Methods: 26 adults with and without CP were tested before and after resistance training twice a week for one year. Dual-energy X-ray absorptiometry was used to measure local BMD at the lumbar spine, proximal femur, and radial/ulnar regions. Muscular strength (torque, work, and power) from the lower extremity was assessed at 90, 150, and 210 °/sec using the Humac Norm Isokinetic Dynamometer. The handgrip dynamometer was used for maximal isometric contraction. Balance was measured from the Berg Balance Test, and limits of stability test using the Biodex Balance System.

Results: After one year of resistance training, the CP group showed a significant improvement in BMD compared to before training [BMD at femoral neck (0.63 ± 0.08 pre vs. 0.88 ± 0.04 post, g/cm^2); however, they did not show statistical differences in muscular strength [extensor peak torque (27 ± 9 pre vs. 32 ± 10 post, ft-lbs), flexor peak torque (13 ± 4 pre vs. 12 ± 5 post, ft-lbs)], or balance on limit of stability test [e.g. overall score (32 ± 7 pre vs. 31 ± 6 post)]. However, after training, CP participants who exhibited greater BMD appeared to develop greater muscular strength followed by improved balance.

Conclusion: These findings suggest that long-term resistance training significantly improved BMD in CP adults without a dramatic improvement in muscular strength or balance. In addition, BMD appeared to play a role in enhanced muscular strength and balance in adults with CP, specifically only those who significantly gained BMD after resistance training.

A-45 Free Communication/Poster - Imaging and Assessment in Skeletal Muscle, Bone, and Connective Tissue

Six Months' Rehabilitation Exercise Affects Lower And Higher Muscle Echo Intensity In Elderly Individuals

Akito Yoshiko¹, Takashi Kaji², Takayuki Sawazaki², Hiroshi Akima³. ¹Chukyo University, Toyota, Japan. ²Kajinoki Medical Clinic, Gifu, Japan. ³Nagoya University, Nagoya, Japan.

(Sponsor: Katsumi ASANO, FACSM)

(No relevant relationships reported)

Muscle echo intensity (EI) reflects the content of fat and connective tissue within a skeletal muscle. Muscle EI becomes higher with aging and/or inactivity caused by increase of fat and connective tissues, and eventually it may induce lower muscle strength. We have previously reported that the EI improved after a few months' resistance and endurance training in elderly individuals. This result would be led by decreasing of fat and connective tissues (i.e. decrease higher EI area) and/or increasing of contractive muscle tissue (i.e. increase lower EI area); however, it is not well understood how the muscle EI change by several months rehabilitation exercise.

PURPOSE: The purpose of this study was to investigate the effects of 6 months rehabilitation exercise on gradation-based muscle EI area in elderly men and women. **METHODS:** Five men and women (2 men and 3 women; age, 75 ± 5 years; height, 156 ± 4 cm; weight, 53 ± 9 kg) participated in this study. They performed rehabilitation exercises consisting of resistance exercises, stretching, and aerobic exercises once or twice a week for 6 months because they needed long-term care during a part of daily living. B-mode ultrasonographic transverse image was taken from rectus femoris.

To obtain EI, region of interest (ROI) was set on rectus femoris as large as possible exclude fascia. Average muscle EI, which was shown by 256 gray scale level, was measured within a ROI. We also calculated cross-sectional area based on 256 grey scale level divided into 6 different components (e.g. 0-49, 50-99, 100-149, 150-199, 200-249 and 250-256 a.u.). **RESULTS:** Average EI decreased after six months exercise (72.70 ± 7.55 vs. 53.50 ± 15.51 a.u., $p < 0.05$). Lower ranged EI area was significantly increased after the exercise (0-49; 1.13 ± 0.88 vs. 1.93 ± 1.00 cm², $p < 0.05$). Middle to higher ranged EI areas were significantly decreased after the exercise (100-149; 0.44 ± 0.20 vs. 0.24 ± 0.15 cm², 150-199; 0.08 ± 0.05 vs. 0.03 ± 0.04 cm², $p < 0.05$).

CONCLUSIONS: Six months rehabilitation exercise improved muscle EI in elderly men and women. This result might be induced by decreasing fat and connective tissues and increasing contractile muscle tissue.

A Single-site, Retrospective Review Of Clinical Complications From Ultrasound-guided Tendon Scraping Procedures

Patrick J. Shaeffer, Stephanie C. Clark, Jacob L. Sellon, Jay Smith, Jonathan T. Finnoff, FACSM. *Mayo Clinic, Rochester, MN.*

(No relevant relationships reported)

Purpose: To evaluate the safety of ultrasound-guided tendon scraping procedures performed at a single center. **Methods:** This was a single center, retrospective chart review. Following Institutional Review Board approval, all tendon scraping procedures performed by three investigators (JTF, JLS, JS) from January 1, 2011 to September 1, 2018 were identified using the physicians' procedure logs and by searching the electronic medical record with the term "tendon scraping." Patient charts were reviewed to search for procedural complications and comorbidities. **Results:** Fifty-eight tendon scraping procedures performed on 48 people were included in the study. The average age and body mass index were 44.5 (17 to 69) and 28.15 kg/m² (22.33 to 45.36 kg/m²), respectively. There were 29 (60%) males and 19 (40%) females. No complications were reported in the 51 (88%) procedures with follow-up. Procedure location included 25 (43%) patellar tendons, 16 (28%) mid-portion Achilles-tendons, 14 (24%) insertional-Achilles-tendons, and 3 (5%) elbow common extensor tendons. Thirty (52%) procedures were performed on the right and 28 (48%) on the left. Seven (12%) procedures were performed using sterile gloves, sterile ultrasound gel, and sterile ultrasound transducer cover, while 51 (88%) were performed using the same plus a gown, cap, and mask. Comorbidities included hypertension (9 [19%]), hyperlipidemia (7 [15%]), unknown (5 [10%]), hypothyroidism (4 [8%]), migraines (4 [8%]), depression (3 [6%]), anxiety (2 [4%]), fibromyalgia (2 [4%]), obstructive sleep apnea (2 [4%]), tobacco use (1 [2%]), diabetes mellitus (1 [2%]), chronic obstructive pulmonary disease (1 [2%]), non-alcoholic steatohepatitis (1 [2%]), coronary artery disease (1 [2%]), peripheral neuropathy (1 [2%]), undifferentiated connective tissue

disorder (1 [2%]), Sjogren's syndrome (1 [2%]), hyperparathyroidism (1 [2%]), and HIV (1 [2%]). **Conclusion:** This study suggests that tendon scraping is a safe procedure. While we were unable to perform a sub-analysis to determine if there was an association between comorbid factors and increased complication rates, there were no complications reported in this study despite the presence of multiple comorbidities.

Does Muscle Architecture Affect Strength In Patients With Multiple Sclerosis?

ZEKIYE IPEK KATIRCI KIRMACI¹, TÜZÜN FIRAT², HANIFI AYHAN ÖZKUR¹, AYŞE MÜNİFE NEYAL¹, NEVİN ERGUN, FACSM¹. ¹SANKO University, GAZIANTEP, Turkey. ²HACETTEPE University, ANKARA, Turkey. Email: ikirmaci@sanko.edu.tr
 (No relevant relationships reported)

The alignment of the muscle fibers has a significant effect on the strength and function. A number of studies have suggested that the properties of muscle architecture are related to muscle strength in many pathological condition. However, there is no study describing the relationship between muscle strength and muscle architecture in multiple sclerosis (MS) patients. **PURPOSE:** To determine the muscle architecture (pennation angle, muscle fiber length and muscle thickness) of the lower extremity muscles in MS patients and to compare with healthy peers. **METHODS:** Fifteen patients with MS and 10 age and sex matched 10 matches healthy volunteers included in the study. Muscle thickness and pennation angle of the rectus femoris (RF), biceps femoris (BF), tibialis anterior (TA), gastro-soleus (GS) and gastrocnemius (GC) muscles were assessed by B-mode ultrasonography. The fascicle length was calculated with pennation angle and muscle thickness values. Muscle strength was assessed with using digital hand-held dynamometer. **RESULTS:** Pennation angles of RF, BF, TA were lower in MS patients (respectively, $p=0,042$, $p=0,023$, $p=0,002$). There was no difference in fiber length of all muscles. Only in rectus femoris, thickness was lower than control group ($p=0,015$). Moreover, there was a positive correlation between rectus femoris muscle thickness and knee extensor muscle strength ($p=0,014$, $r=0,744$). **CONCLUSIONS:** We found that the muscle architecture was affected in MS patients. Determining the muscle architecture alterations in patients with MS may provide building novel and efficient loading models in related muscles.

Measurement Of Muscle Thickness In The Forearms Of Rock Climbers Using Ultrasound

Michael J. Marsala¹, Anita D. Christie¹, Matt S. Stock², David H. Fukuda², Jeanette M. Garcia². ¹University of Western Ontario, London, ON, Canada. ²University of Central Florida, Orlando, FL. (Sponsor: Charles Rice, FACSM)
 (No relevant relationships reported)

The flexor muscles of the forearm are repeatedly found to be the rate limiting factor in performance for rock climbers. Previous studies have shown that cross sectional area (CSA) measurements via Magnetic Resonance Imaging (MRI) have a strong correlation to ultrasound measured muscle thickness (MT) in the forearm flexors. However, few studies have employed this relatively low-cost alternative to MRI to assessing forearm muscles of rock climbers. **PURPOSE:** To compare differences in MT of the finger flexors in the forearms of early-stage rock climbers and non-rock climbers using ultrasound. **METHODS:** The study consisted of 22 climbers (22.23 ± 3.01 year; 68% male) and 11 controls (21.91 ± 1.97 ; 55% male). Body fat percentage and BMI were measured in all participants. An image of the thickest portion of the forearm, from the ulna and radius to the muscle-skin interface, was captured with ultrasound, and MT was measured using Image J. Independent samples t-tests were conducted to compare MT over the ulna and radius between climbers and controls. **RESULTS:** Climbers had an average of 2.44 ± 1.24 years of experience, and had lower body fat percentages (19.14 ± 6.99) than controls (30.02 ± 7.6) ($p < .001$). BMI was similar for climbers and controls at 21.77 ± 3.23 and $22.62 \pm 22.62 \text{ kg/m}^2$, respectively. Both ulnar and radial MT values were significantly higher in climbers, $4.23 \pm .39 \text{ cm}$ and $2.32 \pm .39 \text{ cm}$ ($p < .001$) respectively, and $3.61 \pm .6 \text{ cm}$ and $1.84 \pm .31 \text{ cm}$ in controls ($p < .001$). **CONCLUSION:** Despite a relatively low average climbing experience rock climbers had larger MT values than controls. The present study demonstrated that ultrasound can be used to detect differences in flexor MT in rock climbers compared to controls. Future studies should examine longitudinal changes in MT in climbers as they progress in training.

Assessment Of Changes In Muscle Glycogen Content Across The Menstrual Cycle

Grant A. Chesbro, Brian A. Pribble, Ashley N. Fox, Daniel J. Larson, Christopher D. Black, FACSM, Rebecca D. Larson. University of Oklahoma, Norman, OK. (Sponsor: Christopher D. Black, FACSM) Email: gchesbro@ou.edu
 (No relevant relationships reported)

Muscle glycogen content (MGC) has the potential to impact exercise performance and has implications for timing of exercise testing & prescription. Previously difficult to assess, MGC can now be estimated non-invasively using ultrasound imaging. **PURPOSE:** The aim of this study was to compare changes in muscle glycogen scores across the menstrual cycle using ultrasound imaging. **METHODS:** Twenty-eight subjects (10 male; 18 female) ages 18-30 (24.0 ± 2.78) participated in this study. Subjects were divided into Control (CON; 10 male), Non-Contraceptive (NC; 8 Female), and Oral-Contraceptive (OC; 10 Female) groups. Measurements at 22, 56, & 73% of the thigh were taken on the vastus medialis, vastus lateralis, & rectus femoris of the dominant leg using ultrasound. Subjects were measured at the follicular, ovulatory & luteal phases of the menstrual cycle. Using ImageJ, muscle pixelation values were determined by capturing a $25 \times 8 \text{ mm}$ section of the muscle directly below the superficial aponeurosis. The mean of three images from each site were taken and adjusted for gain setting to calculate a total leg MGC score. A higher pixelation value corresponds to a lower MGC score and vice versa. A repeated-measures ANOVA (group X time) with post-hoc comparisons was performed to assess differences across groups and visits. **RESULTS:** No significant differences in MGC were observed between visits or groups (all $p > .05$). The CON (0.96 ± 0.21 , 0.82 ± 0.10 ; 0.86 ± 0.23) and the OC (1.05 ± 0.17 ; 0.94 ± 0.17 ; 1.01 ± 0.18) groups showed a tendency to increase MGC during the ovulatory visit but for the NC group (0.97 ± 0.15 ; 1.05 ± 0.27 ; 0.91 ± 0.15) to decrease (Figure 1). **CONCLUSIONS:** While there were no significant effects found, there was a trend for the MGC of the CON and the OC groups to increase during the ovulatory visit but for the NC to decrease. Further research is needed to fully understand the implications of these changes during the menstrual cycle and how it relates to exercise performance.

Reliability Of Ultrasound Panoramic Imaging Of Muscle Size For The Transversus Abdominis

Jade Kho, Lauren Adams, Rike H. Mitchell, A. Wayne Johnson. Brigham Young University, Provo, UT. (Sponsor: Allen Parcel, FACSM) Email: jadekho@gmail.com
 (No relevant relationships reported)

PURPOSE: The transversus abdominis (TrA) is a key muscle in core stability. Measurements of its morphology might shed some light on structure, function and pathology of core muscles. A new ultrasound technique, panoramic imaging, could be used to visualize the whole length of the muscle in one image. The purpose of this study is to assess the degree to which this technique produces stable and consistent results. **METHODS:** 6 female participants; age(years) = 21.3 ± 1.6 ; height(cm) = 167.5 ± 5.1 ; weight(kg) = 65.5 ± 11.0 volunteered for this study. With the participants in side-lying position, muscle length, muscle area and thickness were scanned using GE Logic S8 (6-15 MHz probe). The right and left TrA muscles were imaged twice on each subject at spinal levels L1, L3 and L5 and later measured by two separate investigators. Test-retest reliability was calculated using interclass correlation coefficient (ICC) (random subjects and fixed raters) along with the Standard Error of Measurement (SEM).

RESULTS: Our panoramic measures showed excellent intertester reliability for length, area and thickness measurements (ICC=0.981, 0.982, 0.985, respectively). In addition, the SEM for length, area and thickness were SEM= 0.178, 0.078, 0.046, respectively.

CONCLUSIONS: Our method of assessing TrA morphology showed excellent reliability in the three dimensions measured and had low error rates that were equal to or better than those associated with other muscles previously measured. Panoramic imaging seems to be a reliable technique that could be used to visualize the whole TrA muscle in one image. Comparison to MRI images would further help establish its validity.

Validity Of Lower Leg Muscle Cross-sectional Area Measurements Using Ultrasound Imaging Compared To MRI

Aaron W. Johnson, Christopher Thompson, Victoria Violette, Dustin A. Bruening, Sarah T. Ridge. *Brigham Young University, Provo, UT.* (Sponsor: Pat Vehrs, FACSM)
 Email: wayne_johnson@byu.edu
 (No relevant relationships reported)

Quantification of muscle size can enhance assessment of musculoskeletal conditions in both clinical and research settings. Magnetic resonance imaging (MRI) is often considered a gold standard for assessing muscle morphology, while ultrasound imaging (US) is gaining recognition for its utility in musculoskeletal imaging. In the lower leg and foot, there is a need to validate US based assessment of muscle size compared to MRI in musculoskeletal imaging.

Purpose: To validate muscle size measured from US images compared to images captured using MRI.

Methods: Eighteen people (female n = 10, age = 31 ± 15 y, ht = 176 ± 11 cm, wt = 76 ± 18 kg) had their leg muscle size of the tibialis anterior (TA), tibialis posterior (TP), and fibularis longus (FL) assessed with both US and MRI at 30% of the distance from the knee joint line to the lateral malleolus, while the flexor digitorum longus (FDL) and fibularis brevis (FB) were assessed at the 50% point along the same line. Cross sectional area (CSA) was manually traced from two separate US and MRI images for each muscle and averages were calculated. Statistical analysis included comparison of MRI and US measures using the Pearson product correlation.

Results: High correlations were seen between US and MRI size measurements (TA r = 0.90, p=0.003; TP r = 0.94, p=0.000; FL r = 0.97, p=0.000; FDL r = 0.86, p=0.000; FB FDL r = 0.94, p=0.000. CSAs from MRI were larger than those measured from US by an average of 0.17 cm².

Conclusion: Measurements of CSA using US in selected leg muscles were comparable to those on MRI scans with MRI assessment larger than US. This difference may be due to difficulty in seeing fascial borders in the MRI images. Muscle CSA measurements from US appear to provide valid assessment of leg muscle size and may be used in clinical and research settings to quantify muscle morphology.

Between-limb Differences In Ultrasound Spatial Frequency Analysis Parameters Following Acute Hamstring Strain Injury

Scott K. Crawford, Christa M. Wille, Mikel R. Stiffler-Joachim, Kenneth S. Lee, Bryan C. Heiderscheid. *University of Wisconsin-Madison, Madison, WI.*
 (No relevant relationships reported)

Treatment following hamstring strain injury (HSI) is complicated by a lack of prognostic indicators and high rates of re-injury. Spatial frequency (SF) analysis, a quantitative ultrasound method to assess structural tissue organization, could complement clinical evaluations. **PURPOSE:** To characterize differences in SF parameters between injured and uninjured limbs following acute HSI in Division I collegiate athletes. **METHODS:** Ultrasound imaging was performed within one week of HSI, also confirmed by MRI. Longitudinal B-mode images (Aixplorer, Supersonic Imagine, Aix-en-Provence, France) were acquired by a single musculoskeletal-trained sonographer using a linear array transducer (2-10 MHz) at the injury site of maximum tenderness and corresponding location for the uninjured limb. A region of interest (ROI) was drawn about the site of injury and location-matched on the images of the uninjured limb. A 2D Fourier Transform was performed on all possible 5 mm square kernels within the ROI. Peak spatial frequency radius (PSFR), a parameter corresponding to the frequency of the fascicular banding pattern, and Mmax%, a ratio comparing the prominent banded pattern relative to the background, were computed for each kernel. PSFR and Mmax% from all kernels were averaged across respective ROIs. Paired t-tests were used to compare parameter differences between limbs. **RESULTS:** Seven male athletes sustained HSI (mean age = 19.1 ± 0.8 yrs). PSFR (1/mm) was lower (p = 0.005) in the injured limb (0.81 ± 0.22) compared to the uninjured limb (0.95 ± 0.18). Mmax% was also lower (p = 0.023) in the injured limb (1.44 ± 0.41) compared to the uninjured limb (2.03 ± 0.56). Both measures indicated decreased tissue organization in the injured limb, characterized by disruption of the reflected fascicular banded pattern. **CONCLUSION:** SF analysis successfully detected differences between injured and uninjured muscle tissue. Although differences in SF parameters between limbs cannot differentiate whether alterations are due to mechanical disruption of fascicles or presence of edema, this method may have promise in identifying structural changes following HSI and in monitoring changes throughout recovery. Supported by NBA & GE Healthcare Orthopedics and Sports Medicine Collaboration and NIH Grant UL1TR002373 and TL1TR002375.

Spatial Frequency Analysis Identifies Altered Local Micromorphology In Adolescent Athletes With Achilles Tendinopathy

Lucie Risch¹, Greg Bashford², Kornelia Kulig³, Hannes Kaplick¹, Frank Mayer¹, Michael Cassel¹. ¹University of Potsdam, Potsdam, Germany. ²University of Nebraska-Lincoln, Lincoln, NE. ³University of Southern California, Los Angeles, CA.
 (No relevant relationships reported)

Site specific intratendinous Achilles morphology measured with ultrasound image spatial frequency analysis (SFA), quantifies the degree of collagen fiber density and organization. As tendon pain varies in location, and is not always related to hypoechogenicity, it is of interest to establish if spatial frequency parameters discriminate regions of tendon pain where hypoechoic alterations are not readily observable.

Purpose: This study aims to analyze intratendinous micromorphology in adolescent athletes (AA) with Achilles tendinopathy and without sonographic evidence of tendinosis.

Methods: 22 AA (14m/8f, 13.2±1.4 y, 161±11 cm, 47±11 kg) with Achilles tendinopathy (history of tendon pain and pain on palpation) and no visible sonographic hypoechogenicity or focal tendon thickening were included in this analysis. Longitudinal ultrasound scans of the Achilles tendon were acquired. SFA was performed on regions of interest (ROI) corresponding to tendon pre-insertion and midportion, as well as the site of subjectively-reported tendon pain on palpation. Higher values of SFA parameters suggest greater collagen fiber density and alignment. Calculated SFA parameter values were compared using a one-factorial or Wilcoxon ANOVA ($\alpha < 0.05$).

Results: Significantly lower values for three SFA parameters were found at the symptomatic area as compared to tendon pre-insertion ROI, and for two parameters at the symptomatic area as compared to tendon midportion ROI (Table 1).

Conclusion: As indicated by SFA, intratendinous morphology was altered at the painful area, whereas standard ROIs reveal comparable values to previous findings in healthy AA. These results indicate that painful, yet sonographically inconspicuous regions of tendons, have lower fiber density and alignment.

Table 1: SF parameters at tendon pre-insertion (I), midportion (M), and pain site (P) [mean ± SD]

A Time Course Of Changes In Echo Intensity Following Resistance Exercise In Untrained Individuals

Noam Yitzchaki, Wenyuan G. Zhu, Tayla E. Kuehne, Ecaterina Vasenina, Samuel L. Buckner. *University of South Florida, Tampa, FL.*

(No relevant relationships reported)

It has been suggested that changes in echo-intensity (EI) measured through ultrasound can detect the presence of muscle swelling. However, the time course of changes in EI has never been examined relative to a non-exercise control condition following naïve exposure to exercise. **PURPOSE:** To examine the changes in biceps muscle thickness (MT), EI and isometric strength (ISO) before, immediately after, and 24, and 48 hours after 4 sets of biceps curls. **METHODS:** 27 resistance trained individuals visited the laboratory 4 times. During visit 1, paperwork and maximum strength were measured. During visit 2 (2-7 days later) participant's MT and ISO were measured in both arms before performing 4 sets of biceps curls in a randomized arm. Additional measures were taken immediately after exercise, as well as 24 and 48 hours after exercise. MT images were saved for EI measurement. Results are displayed as means (SD). **RESULTS:** For MT there was an interaction (p < 0.001). MT increased from pre [2.88 (.64) cm] to post [3.27 (.67) cm] exercise and remained elevated above baseline 24 [2.92 (.66) cm] and 48 [2.98 (.68) cm] hours post. There were no changes for MT in the control group from pre [2.88 (.66) cm] to post [2.88 (.66) cm] exercise, or 24 or 48 hours post. For EI there was an interaction (p = 0.012). In the experimental group EI increased from pre [22.9 (9.6) AU] to post [29.1 (12.3) AU] exercise and was depressed below baseline 24 hours post [20.4 (9.9) AU]. For the control condition, EI was different between pre [24.8 (10.2) AU] and 48 hours [21.5 (10.7) AU]. In addition, EI were lower 24 [23.3 (11.4) AU] and 48 hours post exercise compared to immediately post exercise [27.4 (13.0) AU]. For ISO, there was an interaction (p < 0.001). In the experimental condition ISO decreased from pre [40.6 (14.7) Nm] to post exercise [24.8 (9.4) Nm] and remained depressed 24 [32.2 (11.3) Nm] and 48 hours [33.9 (11.4) Nm] post exercise. **CONCLUSIONS:** Naïve exposure to resistance exercise produced a swelling response, which was elevated 48 hours post exercise. This swelling was accompanied with a prolonged decrease in ISO, which is likely indicative of muscle damage. Despite an increase in MT, EI was only elevated immediately post exercise. In addition, EI changed in the control condition despite no changes in MT.

Influence Of Achilles Tendon Structure On Passive Mechanical Characteristics

Lauren E. Pacinelli, Jeffrey A. Williams, Emanuel F. Serrano, Ryan M. Thiele. *Kansas State University, Manhattan, KS.*

(No relevant relationships reported)

Investigations into tissue (muscle and tendon) stiffness have focused on the whole musculotendinous unit through imaging and dynamometry. However, few studies have examined the relationship between individual structural components of the tendon (e.g., thickness, cross-sectional area, and length) and their contributions on isolated mechanical characteristics of the free tendon (FT) (e.g. elasticity, stiffness, etc). **PURPOSE:** Evaluate the relationship of FT structure (length, FT_L; cross-sectional area, FT_{CSA}; thickness, FT_T) and the mechanical characteristics (stiffness; ST; elasticity; EL, and mechanical stress relaxation time; MSRT) as assessed by myotonometry (MYO). **METHODS:** Ten male (mean ± SD: age = 20.7 ± 1 year) participants laid in a prone position with their ankle at 90°. Ultrasonography (US) FT_{CSA} (cm²) and FT_T (cm) images were scanned in a transverse position at 4 cm proximal to the osteotendinous junction. FT_L (cm) was captured in the extended-field of view setting starting at the calcaneal tuberosity and ending at the most distal muscle fascicles of the soleus. All US image measurements were analyzed using a third-party image analysis software. FT mechanical properties were assessed via MYO, through 5 automated mechanical oscillations and the average ST (N/m), EL, and MSRT (ms) measures were identified and used for statistical analysis of each variable. Pearson product-moment correlation coefficients (r) were used to examine the relationships between FT_L, FT_{CSA}, FT_T, and ST, EL, and MSRT with a level of significance of p ≤ 0.05. **RESULTS:** A significant, strong correlation for FT_T and MSRT (r = 0.637; R² = 0.406; p = 0.048), and a

significant, strong, negative correlation for FT_L and ST (r = -0.676; R² = 0.457; p = 0.032) were observed. There were no significant correlations between FT_T and EL or FT_L and FT_{CSA} with ST, EL, and MSRT (p ≥ 0.05). **CONCLUSION:** These findings indicate that a greater FT_T may contribute to improved compliance of the Achilles tendon; subsequently increasing relaxation time following mechanical oscillation. Taken together, isolation of structural and mechanical characteristics may provide a greater understanding of the viscoelastic characteristics of the FT.

Lateral Abdominal Muscle Symmetry And Risk Of Sports Injury In Baseball Players

Ming-Yang Chen, Yi-Liang Kuo, Chun-Yu Chou. *National Cheng Kung University, Tainan, Taiwan.*

Email: rickychen840118@gmail.com

(No relevant relationships reported)

Lateral abdominal muscles play a significant role in trunk control and rotation during baseball batting. Repetitive and unidirectional baseball batting could lead to asymmetric hypertrophy of lateral abdominal muscles. This adaptive change may subsequently impose abnormal loads on the spine and predispose baseball players to sports injury. No study has examined whether adolescent baseball players present lateral abdominal muscle asymmetry and its relationship with risk of sports injury. **PURPOSE:** This study aimed to compare the thickness of lateral abdominal muscles on both sides of the trunk, and to investigate whether asymmetry of lateral abdominal muscle thickness was correlated with risk of sports injury in high school baseball players. **METHODS:** Fifteen position players from a high school baseball team (right-handed batting and throwing; aged 16.0 ± 1.1 years, height 172.6 ± 5.0 cm, weight 73.3 ± 10.8 kg) completed the Functional Movement Screen (FMS) testing. B-mode ultrasound images were recorded from the external abdominal oblique (EO), internal abdominal oblique (IO), and transverse abdominis (TA) at the end of expiration in the crook-lying position. The absolute thickness of each lateral abdominal muscle for both sides was determined and compared using paired t-tests. The relationship between the asymmetry ratio (difference between two sides expressed as a percent of the dominant side) and FMS composite score was analyzed using the Spearman correlation coefficient. **RESULTS:** The EO thickness was significantly greater in the dominant side than in the non-dominant side (6.85 ± 1.13 vs. 5.05 ± 1.46 mm, p < 0.001), and the TA thickness was significantly greater in the non-dominant side than in the dominant side (4.21 ± 0.85 vs. 3.49 ± 0.60 mm, p = 0.003). Only the asymmetry ratio of TA was significantly correlated with the FMS composite score (r = 0.54, p = 0.040). **CONCLUSIONS:** High school baseball players showed side-to-side thickness asymmetry in the EO and TA. The significant correlation between the TA asymmetry ratio and FMS composite score suggests an increased risk of sports injury. High school baseball teams should consider integrating TA training into players' routine training program. Supported by the Ministry of Science and Technology of Taiwan (MOST 108-2410-H-006-098)

Evaluation Of Muscle Swelling After Concentric Muscle Contraction Using Bioelectrical Impedance Analysis

Ayano Imai¹, Ayame Iwata¹, Chisa Inaka², Yusuke Sakaue², Kazushige Goto¹. ¹Ritsumeikan university, Shiga, Japan. ²Toray Engineering Co., Ltd, Shiga, Japan.

Email: sh0167vr@ed.ritsumei.ac.jp

(No relevant relationships reported)

Resistance exercise using concentric and eccentric muscle contraction (i.e., dumbbell curl exercise) decreased significantly bioelectrical impedance analysis (BIA) (Atsuta et al. 2019). However, the influence of muscle contraction type on exercise-induced BIA change remains unclear. **PURPOSE:** The purpose of the present study was to examine time course changes in muscle swelling evaluated by BIA following concentric-muscle contraction. **METHODS:** Nine male subjects (20.0 ± 0.8 yrs, 175.4 ± 2.4 cm, 65.2 ± 6.3 kg) performed isokinetic (60 deg/s) concentric knee extension (6 repetitions × 10sets, 60 s rest period between sets). Before and during 24 h of post-exercise, time course changes in BIA (locally evaluated BIA for vastus lateralis muscle), maximal voluntary contraction (MVC) of knee extension exercise, muscle thickness (evaluated by ultrasound) for vastus lateralis muscle and thigh circumference were evaluated. Blood samples were also drawn to investigate blood lactate, serum creatine kinase (CK) and myoglobin levels. **RESULTS:** Blood lactate and CK levels were significantly increased after exercise (P<0.05). Moreover, the MVC was significantly decreased immediately after exercise

(before exercise: 269.2 ± 30.4 Nm, immediately after exercise: 233.6 ± 28.7 Nm, P<0.05). However, BIA value, muscle thickness and circumference did not change significantly after the exercise (p>0.05 for all variables).

CONCLUSIONS: Resistance exercise consisting of concentric muscle contraction did not affect local BIA. The finding was not consistent with that in our previous study using the resistance exercise consisting of both concentric and eccentric muscle contraction.

A Time-Efficient NIRS Protocol For Cross- And Within-limb Comparisons Of Muscle Oxidative Capacity

David N. Proctor, FACSM¹, Rewais B. Hanna¹, Jigar Gosalia¹, Zachary Hobson¹, Jocelyn Delgado¹, Alaina Demalis¹, Giampietro L. Vairo¹, Swapan Mookerjee², Brian A. Irving³, Kevin K. McCully, FACSM⁴. ¹Penn State University, University Park, PA. ²Bloomsburg University, Bloomsburg, PA. ³Louisiana State University, Baton Rouge, LA. ⁴University of Georgia, Athens, GA.

Email: dnp3@psu.edu

(No relevant relationships reported)

The non-invasive determination of muscle mitochondrial oxidative capacity via Near Infrared Spectroscopy (NIRS) typically involves voluntary contraction of a single limb and requires as many as 22 brief ischemic occlusions per measurement. This limits the number of oxidative capacity measurements that can be completed in a given test session and also makes cross-limb muscle comparisons challenging. **PURPOSE:** To establish the efficacy of a recently developed protocol that utilizes fewer (i.e. 6) ischemic occlusions combined with surface electrical stimulation (E-stim) in both limbs simultaneously. **METHODS:** The test employs 2 upper thigh cuffs and 2 NIRS sensors placed directly over the vastus lateralis (VL) muscles (supine position) or the semi-tendinosus (ST) muscles (prone position). Metabolic rate is temporarily increased via E-stim pads placed above and below each NIRS sensor. A standard 6Hz frequency is employed using a pre-modulation setting, with the intensity (mV) increased sufficient to raise metabolic rate (≥ 3 fold), but within the tolerance of each participant. The mitochondrial capacity protocol involves 4 separate sets of 30 sec of E-stim followed by 6 x 5 sec cuff inflation/5 sec cuff deflation cycles. Analysis consists of calculating oxygenation recovery rate constants (Tc) for each muscle (i.e., 4 repeated measurements per muscle, per limb) using a customized software program. **RESULTS:** Within a group of moderately active younger adults without a history of knee surgery (n=3), Tc averaged 34.8 sec in the VL and 40.2 sec in the ST (p = 0.21). Variability of repeated tests (CV % based on 4 replicates/muscle) averaged 9.9% in the VL (n=14 subjects) and 11.1% in the ST (n=3 subjects). Compared to the traditional unilateral 22-cuff occlusion method, this protocol enabled twice as many replicates per muscle in significantly less time (~30 min less). **CONCLUSIONS:** This bilateral E-stim protocol is time efficient and has the potential to facilitate within- and cross-limb comparisons of muscle mitochondrial capacity.

(No relevant relationships reported)

Background: Many individuals with end-stage osteoarthritis undergo elective total hip/knee arthroplasty (THA/TKA) to relieve pain and improve mobility and quality of life. However, ~35% suffer long-term mobility impairment following surgery. Previously, we have shown this may be in part due to muscle inflammation susceptibility (MuIS⁽⁺⁾), an overt pro-inflammatory state localized to skeletal muscle

surrounding the diseased joint, found in some but not all TKA/THA patients. **Purpose:** We are interrogating the hypotheses that a) MuIS⁽⁺⁾ status will result in a differential perioperative expression profile that may partially explain low functional outcomes, and b) resistance training rehabilitation will more effectively overcome MuIS⁽⁺⁾ status than usual care for effective recovery post-surgery. **Methods:** Muscle samples were leveraged from our ongoing two-site, randomized, controlled trial (N=84). Participants were dichotomized to MuIS status (+/-) based on surgical (SX) muscle gene expression of Fn14 which drives pro-inflammatory signaling via NFκB. MuIS^(+/-) samples were probed for pro-inflammatory gene and protein expression targets, and indices of skeletal muscle function. Preliminary perioperative comparisons were made using two-tailed T-tests; alpha P<0.05. **Results:** 84 participants (29M/55F; 62±8yrs; BMI 30.7±5.4kg/m²) undergoing THA/TKA were assessed. Thus far, 37 have been clustered as MuIS⁽⁺⁾ (n=14, ~4-fold greater Fn14 mRNA) or MuIS⁽⁻⁾ (n=23). SX thigh muscle mass (TMM), quadriceps power and torque were lower (P<0.05) than the contralateral limb (CTR). Additionally, skeletal muscle fibrosis and type II cross-sectional area were greater in the SX leg and MuIS⁽⁺⁾ respectively (P<0.05). Tumor necrosis factor-α receptor and IL-6 trended higher in MuIS⁽⁺⁾ (P>0.05). Phosphorylated (p)-RPS6 was lower in the SX leg and p-4E-BP1 was significantly lower in MuIS⁽⁺⁾ (P>0.05). **Conclusions:** Preliminary results suggest patients undergoing TKA/THA exhibit more inflammation on the SX limb, accompanied by lower TMM, torque and power. MuIS⁽⁺⁾ leads to greater inflammation and blunted anabolic signaling, highlighting the profound impact of muscle inflammation and emphasizing the potential value in perioperative MuIS assessment to inform optimal post-surgical care. Myostatin Mediates Quadriceps Muscle Atrophy And Fibrosis Rapidly After ACL Transection In Novel Murine Model

Camille R. Brightwell¹, Ted G. Graber², Rosario Maroto², Brian Noehren, FACSM¹, Christopher S. Fry¹. ¹University of Kentucky, Lexington, KY. ²University of Texas Medical Branch, Galveston, TX. (Sponsor: Brian Noehren, FACSM)

Email: cbr376@uky.edu

(No relevant relationships reported)

Anterior cruciate ligament (ACL) injury results in quadriceps muscle atrophy and strength loss that may never fully recover. Underlying mechanisms driving these maladaptations have not been thoroughly investigated.

PURPOSE: Develop an animal model recapitulating observed clinical phenotype after ACL injury to identify the early molecular and morphological signature within quadriceps muscle and clarify the rapidity with which therapies should be administered. **METHODS:** Surgical ACL transection (ACL-T) was performed unilaterally on mice (n=5) followed by 5-Ethynyl-2'-deoxyuridine (EdU) injection. 7d after ACL-T, quadriceps muscle was harvested from injured and uninjured limbs. Immunoblotting measured myostatin signaling, and immunohistochemical techniques assessed morphology. In vivo knee extensor peak torque was measured on a separate group of mice (n=3) before and 7d after ACL-T. **RESULTS:** Myostatin and p-SMAD3 expression increased 7d after ACL-T by 131% (1.6 ± 0.2 vs 0.7 ± 0.1 AU, p=0.02) and 174% (1.1 ± 0.1 vs 0.4 ± 0.1 AU, p<0.01). Fibroblast density increased (Tcf4+/fiber: 45%, p=0.08; Tcf4+/mm²: 106%, p=0.04), as did fibroblast proliferation (215%, p=0.02). Extracellular matrix (ECM) content increased 53% (p=0.03), along with a 31% decrease in fiber cross sectional area (CSA) (1394 ± 91 vs 2011 ± 134 μm², p<0.01). Knee extensor peak torque decreased 21% (p=0.04). Myostatin signaling was correlated with fiber CSA and fibrotic indices 7d after ACL-T (Table 1). **CONCLUSIONS:** Myostatin signaling is starkly and rapidly upregulated 7d after ACL-T in mice, promoting robust decrements in muscle size, quality, and function. Our findings suggest that myostatin-mediated muscle dysfunction represents a modifiable therapeutic target. Pharmacological myostatin inhibition immediately after ACL injury, preceding surgical and loading interventions, may mitigate quadriceps maladaptations and partially preserve strength. Support: R01 AR072061, T32AG000270

Table 1. Elevated myostatin signaling mediates ECM accumulation and myofiber atrophy in quadriceps muscle 7 days after ACL transection.

The Effect Of Robotic Gait Training On Spinal Cord Transected Rat Femurs
 Michele LeBlanc¹, Michael Soucy², Moustafa Moustafa-Bayoumi³, Dalziel Soto⁴, Jeff A. Nessler⁴. ¹California Lutheran University, Thousand Oaks, CA. ²Oregon State University, Corvallis, OR. ³Helwan University, Cairo, Egypt. ⁴California State University, San Marcos, CA.
 Email: mleblanc@callutheran.edu
 (No relevant relationships reported)

Robotic locomotor training has been shown to be effective for significantly improving body composition and making some moderate, but not significant, changes in bone mineral density in individuals with spinal cord injury (Karalis et al., 2017). The effect of the training on other important mechanical properties of bone is unknown. **PURPOSE:** To determine the effects of 8 weeks of robotic locomotor training on mechanical properties of rat bones. **METHODS:** Twelve female Sprague-Dawley rats received spinal cord transections at 5 days old. At 3 weeks old, half of them were randomly assigned to a Training group and half to a Control group. The Training group received 5 minutes of robotic gait training with 90% body support for 5 days a week for 8 weeks. The Control group received no exercise. At the conclusion of the 8 weeks, the animals were euthanized and the right femurs were harvested for testing. Anthropometric measures and 3-point bending tests using an Instron material testing system (Norwood, MA) were performed. Independent t-tests were used to determine differences between the two groups ($p < 0.05$). **RESULTS:** There was no difference in body mass between the two groups prior to group assignments, but after 6 weeks of training the Control group had greater mass ($p = 0.035$) and at the end of training this difference continued (mass = 210.3 ± 36.0 g vs. 166.7 ± 14.5 g; $p = 0.012$). The Control group's femur mass was significantly larger ($p = 0.041$), but when considered as a percentage of body mass, the Training group's femur mass was larger ($p = 0.014$). Peak load and rupture loads were not different between the two groups, but when normalized for body mass the Training group had larger load values than the Control group ($59.0 \pm 2.7\%$ and $53.3 \pm 12.1\%$ for the Training and $52.4 \pm 2.0\%$ and $41.6 \pm 8.7\%$ for Control; $p = 0.001$ and $p = 0.035$, respectively). The deflection at rupture was greater for the Control group (0.75 ± 0.09 mm vs. 0.59 ± 0.14 mm; $p = 0.025$), as was the energy absorbed (57.0 ± 6.1 mJ vs. 39.6 ± 12.1 mJ; $p = 0.009$). There were some differences in midshaft diameters, but the cross-sectional areas were not different between the two groups. **CONCLUSION:** Rats who experienced training had stronger and more massive femurs than those who experienced no training. This work was supported by NSF 0850516.

Effect Of Gastrocnemius Post-exercise Needling Treatment On Achilles Tendon Tendinopathy Prevention
 Bo Wang, YuYi Liu, Lin Wang. Beijing Sports university, Beijing, China.
 Email: wangbodc002@163.com
 (No relevant relationships reported)

PURPOSE: Long-term post-exercise high intensity gastrocnemius tension can induce the Achilles tendon tendinopathy. The gastrocnemius post-exercise needling treatment can reduce gastrocnemius tension. Therefore, the gastrocnemius post-exercise needling may decrease the risk of Achilles tendon tendinopathy by reduce gastrocnemius tension. **METHODS:** 32 male 12 weeks old SD rats divided into 4 groups: the needling group (NED group); exercise group (EX group); exercise and needling group (EXNED group) and control group (CON group). The animal treadmill protocol was 60% average VO_2 max intensity (16.5m/min) eccentric running at -11° condition lasting 90 minutes for 24 days. The EXNED and NED groups accepted needling treatment with 0.25mm diameter needle which penetrate 5mm on gastrocnemius for 5 minutes after exercise each day. Gastrocnemius and Achilles tendon were harvested at the 26th day then measured collagen I/III, MMP-1, mechanical growth factor (TGF- β , IGF-1) expression and cell apoptosis ratio by western-blot, Immunofluorescence and TUNEL staining. Data was analyzed by SPSS 20.0. **RESULTS:** The gastrocnemius TGF- β in EX group was significantly higher than other three groups (0.20 ± 0.01 VS 0.11 ± 0.01 , 0.13 ± 0.02 , 0.14 ± 0.01 , $P < 0.05$); IGF-1 was no significant difference. In Achilles tendon, TGF- β in EX group was significantly higher than other three groups (733.58 ± 306.82 VS 291.92 ± 156.19 , 153.74 ± 114.96 , 192.67 ± 112.36 , $OD/\mu m^2$, $P < 0.05$); IGF-1 was no significantly difference either. Collagen I in EX and EXNED group were significantly lower than CON and NED group (557.26 ± 210.54 , 798.89 ± 122.06 VS 958.59 ± 176.41 , 1133.60 ± 251.62 , $OD/\mu m^2$, $P < 0.05$); collagen III in EX group was significantly higher than other three groups (1101.25 ± 196.37 VS 393.03 ± 60.13 , 492.25 ± 103.16 , 779.32 ± 140.25 , $OD/\mu m^2$, $P < 0.01$), and it was significantly higher in EXNED group than in CON and NED group (779.13 ± 140.42 VS 393.17 ± 60.15 , 492.20 ± 103.11 , $OD/\mu m^2$, $P < 0.05$). The MMP-1

in the EX group was significantly higher than other three groups (624.09 ± 176.62 VS 393.51 ± 119.66 , 264.9 ± 78.4 , 289.4 ± 85.68 , $OD/\mu m^2$, $P < 0.05$). Cell apoptosis ratio was no significant difference. **CONCLUSION:** The gastrocnemius post-exercise needling treatment can decrease the risk of Achilles tendon tendinopathy by reduce gastrocnemius tension.

Effects Of Hip-knee Muscle Strengthening Combined With Whole-body Vibration Training On Patellofemoral Pain Syndrome
 Xiaohui HOU, Zhangxiang Wu, Jiugen Zhong, Xinbo Fu, Jinzhu Wang. GUANGZHOU SPORT UNIVERSITY, GUANGZHOU, China.
 Email: lilyhxx@163.com
 (No relevant relationships reported)

PURPOSE: This study aimed to investigate the effect of whole-body vibration (WBV) training combined with hip-knee muscle strengthening training on adult patellofemoral pain syndrome(PFPS). **METHODS:** Thirty-six adults with PFPS were included in this study and randomly assigned to either a combined training group (Group 1) that received WBV training plus hip-knee muscle strengthening training (n=18) or a control group (Group 2) that performed hip-knee muscle strengthening training only (n=18). Group 1 performed 18 sessions to strengthen knee extensors, hip abductor and lateral rotator muscles for 40minutes per session (20minutes WBV training plus 20minutes hip-knee strengthening training) three times a week for six weeks. Group 2 performed the same number of sessions (2x20 minutes hip-knee strengthening training only per session) to strengthen the muscles of the hip and knee. All patients were evaluated using a Visual Analog Scale (VAS), Anterior Knee Pain Scale (AKPS), and Short Form-36 (SF-36) before and after treatment. **RESULTS:** The results were statistically significant between before and after treatment in terms of VAS ($p < 0.001$) and AKPS ($p < 0.001$), Physical Functioning ($p < 0.001$), Role-Physical ($p < 0.001$), Bodily Pain ($p < 0.05$), General Health ($p < 0.05$) and Social Functioning ($p < 0.05$). However, no significant differences were observed in Role-emotional ($p = 0.19$), Vitality ($p = 0.15$) and Mental Health ($p = 0.32$). No significant between-group differences were found in all this scale ($p > 0.05$). **CONCLUSIONS:** The WBV training plus hip-knee strengthening training and hip-knee strengthening training can both effectively improve pain, knee function and quality of life on adult patients with PFPS. However, whether the WBV training is more effective than hip-knee strengthening training need to be further research.

Relationship Between Isokinetic Muscle Strength Test Of Knee And Hip In Knee Osteoarthritis Patients
 Chun Zhang¹, Chun jiang He¹, Hai Shen². ¹Chengdu Sports University, ChengDu, China. ²Sichuan Provincial Orthopedic Hospital, ChengDu, China.
 Email: 767903515@qq.com
 (No relevant relationships reported)

The prevalence of Knee Osteoarthritis(KOA) is increasing, most of the kinesiotherapy is focus on improving the strength of knee muscles. However, the relationship between periarticular muscle strength of Knee and Hip in KOA in old people remains unknown. **PURPOSE:** To explore the relationship between periarticular muscle strength of Knee and Hip. **METHODS:** Forty patients with Knee Osteoarthritis (24females and 16males, Age: 55.31 ± 7.05 years) were enrolled in the study. The Isomed-2000 dynamometer was adopted to measure the peak torque/body weight (PT/BW) and peak work/body weight (PW/BW) of knee and hip at 60° -s-1 and 180° -s-1, respectively. Pearson Correlation Analysis and multiple Regression analysis were used to measure the muscle strength between knee flexors-extensors and hip flexor-extensor, adductor-abductor. **RESULTS:** (1) Pearson Correlation Analysis showed that in the case of 60° -s-1 and 180° -s-1, the results of Isokinetic muscle strength of flexion and extension knee were correlated with the results of PT/BW and PW/BW of flexion and extension hip, adduction and abduction hip in most cases ($p < 0.05$); (2) Multiple regression analysis showed that there was a positive linear relationship between knee flexor, extensor and hip flexor PT/BW at 60° -s-1 ($r = 0.342$, $p = 0.002 < 0.05$; $r = 2.824$, $p = 0.007 < 0.05$, respectively); There was a positive linear relationship between knee flexors and hip extensors ($r = 2.305$, $p < 0.05$). At 180° -s-1, there was a negative linear relationship between hip extensor and knee flexor ($r = -2.417$, $p = 0.02 < 0.05$), and a positive linear relationship between knee flexors and hip adductors ($r = 2.772$, $p = 0.008 < 0.05$). **CONCLUSION:** In this test, the knee flexor and extensor function was affected by the same hip muscle strength. In the case of 60° -s-1, the hip flexor is not only involved in the knee extension function. The knee flexors are also controlled by the hip flexors. Therefore, Practitioners with KOA should not only focus on the function of the knee muscles, but also the use of the muscles around the hip joints.

Correlation Between The Elbow Ulnar Collateral Ligament And Generalized Joint Hypermobility In Young Adults

Kaylee R. Fichthorn¹, Lacy Mroz¹, Peter Reuter¹, Arie van Duijn². ¹Florida Gulf Coast University, Fort Myers, FL. ²Florida Gulf Coast University, fort myers, FL. (Sponsor: Mitchell L. Cordova, FACSM)

Email: krfichthorn9132@eagle.fgcu.edu

(No relevant relationships reported)

Joint hypermobility is largely understood as a dysfunction of collagen fibers within the connective tissues of ligaments and tendons, allowing for a range of motion which is markedly increased over validated normal values. Generalized Joint Hypermobility (GJH) is defined using a Beighton score of $\geq 5/9$. Additionally, previous studies have used microscopic imaging to determine these relationships, and there has yet to be a published study looking into the correlation between the sonographically determined length and width of ligaments, and GJH in a college-aged population in North America.

PURPOSE:

To determine the relationship between the length and width of the anterior bundle of the Ulnar Collateral Ligament (UCL) of the elbow and GJH.

METHODS:

Three hundred and thirty undergraduate students (age 19.24 ± 2.07 yrs) enrolled in A&P I classes completed the Beighton score, including measures of elbow hypermobility. Ultrasound images of the participants' ulnar collateral ligament were obtained in both arms under a gravity induced valgus force in supine.

RESULTS:

Overall, 48 of 330 participants (14.6%) reported generalized joint hypermobility (GJH) based on a Beighton score ≥ 5 . Sixty-three participants reported hypermobility in at least one elbow; there was no difference in prevalence of hypermobility between elbows (Right: $r = .483, p < .001$; Left: $r = .465, p < .001$). Hypermobility in one elbow was strongly correlated with hypermobility in both elbows ($r = .828; p < .001$). We found moderate correlations between UCL thickness and joint gapping for left and right elbows ($r = .422, r = .324, p < .001$).

We found no difference in UCL thickness or joint width between participants with hypermobile elbows and those without (e.g., right elbow joint width under valgus stress: Normal = $.231799$, Hypermobile = $.228415$; $t(251) = .301, p = .763$) Left elbow joint width under valgus stress was weakly correlated ($r = .167, p = .006$) with GJH overall but not specifically with left elbow hypermobility.

CONCLUSION:

There was no relationship between Beighton score and UCL anterior bundle thickness or joint width under gravity induced valgus stress. There was no statistically significant difference in UCL thickness or joint width in participants with elbow hypermobility and those without.

Effect Of Forearm Flexors/extensors Strength Training On Functional Capacity After Open Carpal Tunnel Release

Evangelos Tzanis¹, Dimitrios Bourlos², Maria Maridaki³, Michael Koutsilieris¹, Anastassios Philippou¹. ¹Medical School, National and Kapodistrian University of Athens, Goudi - Athens, Greece. ²251 Airforce General Hospital, Goudi - Athens, Greece. ³School of Physical Education and Sport Science, National and Kapodistrian University of Athens, Dafne - Athens, Greece.

Email: vagtzanis@yahoo.gr

(No relevant relationships reported)

Carpal tunnel syndrome (CTS) is a common peripheral neuropathy of the upper extremity. Open release surgery for CTS may affect post-operative functional capacity of the operated hand. **PURPOSE:** This pilot study examined the effects of a progressive strength training program of the forearm flexors and extensors on functional and clinical parameters after open carpal tunnel release (OCTR). **METHODS:** Seven patients with CTS (5 females and 2 males (age: 57.7 ± 4.8 yrs, height: 169.0 ± 2.5 cm, body mass: 82.0 ± 4.1 kg, BMI: 28.7 ± 1.4) underwent OCTR and then were randomly divided into two groups, the control group (CG; $n=4$) which received usual physical therapy care, and the intervention group (IG; $n=3$) which, in addition to the usual care, followed a 9-week strength training program of the wrist flexors/extensors (3 sets of 10 reps, 4 days/week) started 3 weeks after surgery. Hand grip strength (HGS Test), hand pinch strength (HPS Test) and sensibility (Two-point Discrimination Test-TPDT) were assessed before and 3, 6 and 12 weeks after surgery, while load for strength training was set at 2% of the maximal grip strength and was readjusted accordingly during the experimental period. Patients also completed the Boston Carpal Tunnel Questionnaire (BCTQ) before and 12 weeks after surgery. Two-way ANOVA was used for statistics and data are presented as mean \pm SE. **RESULTS:** No significant main effect was found for groups or time ($p > 0.05$) in HGS (IG: 31.1 ± 8.2

kg, CG: 27.2 ± 4.6 kg), HPS (IG: 8.0 ± 4.6 kg, CG: 8.5 ± 4.2 kg) and TPDT (IG: 2.0 ± 0.2 , CG: 2.5 ± 0.3) at 12 weeks compared to pre-surgery values: HGS (IG: 27.6 ± 12.9 kg, CG: 28.7 ± 6.5 kg), HPS (IG: 7.1 ± 4.1 kg, CG: 8.8 ± 4.4 kg) and TPDT (IG: 2.3 ± 0.4 , CG: 3.3 ± 0.4). In BCTQ, no differences were found between groups ($p > 0.05$), however a significant main effect for time ($p < 0.05$) was revealed at 12 weeks (IG: 1.8 ± 0.68 , CG: 1.5 ± 0.4) compared to pre-surgery (IG: 3.8 ± 0.76 , CG: 3.4 ± 0.5). **CONCLUSION:** Our findings suggest that the addition of the selected muscle strength training program to usual care after OCTR does not appear to add significant benefits to the functional recovery of those patients. Further research utilizing a larger number of patients and other strength training protocols is needed to reveal the potential role of wrist muscle strength training in functional capacity of patients with CTS after OCTR.

362 Board #178 May 27 10:30 AM - 12:00 PM

THE EFFECTS OF ISOLYTIC AND STATIC POSTERIOR SHOULDER STRETCHING IN INDIVIDUALS WITH SUBACROMIAL IMPINGEMENT SYNDROME

HALIME EZGI TURKSNAN¹, SEVGI SEVI YESILYAPRAK¹, MEHMET ERDURAN¹, CEM OZCAN². ¹Dokuz Eylul University, Izmir, Turkey. ²Gazi Hospital, Izmir, Turkey.

Email: hezgi.trksn@gmail.com

(No relevant relationships reported)

Static posterior shoulder stretching exercise (PSSE) in modified cross-body position (MCBP) improves posterior shoulder tightness (PST) and glenohumeral internal rotation deficit (GIRD). Isolytic stretching (isotonic eccentric contraction) is a form of muscle energy technique. The effects of isolytic PSSE were not investigated in shoulder pathologies.

PURPOSE: To investigate the effects of isolytic and static PSSE in MCBP on shoulder internal rotation (IR) and external rotation (ER) range of motion (ROM) and strength, PST, subacromial space (SAS), supraspinatus tendon thickness (SsTT), supraspinatus tendon occupation ratio (STOR), functionality and disability level in individuals having subacromial impingement syndrome (SIS) with GIRD.

METHODS: Sixty-three participants having SIS with GIRD were randomly divided into three groups. Isolytic Stretching Group (ISG) and Static Stretching Group received standard physiotherapy and isolytic or static PSSE in MCBP. The control group (CG) received physiotherapy without PSSE. Shoulder ROM and PST were assessed with bubble inclinometer, strength with hand-held dynamometer, SAS (at 0° and 60° scapular plane shoulder elevation), SsTT, and STOR with ultrasonography, functionality and disability level with Modified Constant-Murley Scale and Quick Disability of the Arm-Shoulder-Hand Questionnaire. GIRD was determined by the difference in bilateral shoulder IR ROM. Data were analyzed with two-way ANOVA with repeated measures.

RESULTS: All groups improved in terms of shoulder mobility, strength, SAS, STOR, functionality, and disability level after 4-weeks of treatment ($p < 0.05$). IR ROM and SAS increased, PST, GIRD, and STOR decreased more in stretching groups compared to CG ($p < 0.001$). Improvements in stretching groups were similar ($p > 0.05$). ER ROM, strength, functionality, and disability levels improved more in ISG compared to CG ($p < 0.05$).

CONCLUSIONS: Standard physiotherapy including PSSE in MCBP is superior to treatment program without PSSE to improve shoulder mobility, SAS and STOR. Both isolytic and static stretchings are equally effective. Standard physiotherapy plus isolytic PSSE provided a greater improvement in ER ROM, strength, functionality and disability levels compared to treatment program without PSSE. Research was not founded.

Effects Of Age And Duration Of Manual Wheelchair Use On The Incidence Of Shoulder Pathology

Omid Jahanian, Brianna M. Goodwin, Meegan G. Van Straaten, Jonathan D. Barlow, Naveen S. Murthy, Melissa M. B. Morrow. Mayo Clinic, Rochester, MN.

Email: Jahanian.Omid@mayo.edu

(No relevant relationships reported)

Rotator-cuff injuries are one of the most common causes of shoulder related disability in manual wheelchair (MWC) users with spinal cord injury (SCI), which could lead to decreased quality of life. **PURPOSE:** To investigate the prevalence of rotator-cuff and biceps tendon tears in MWC users with SCI and the effects of age and duration of wheelchair use on incidence of the shoulder muscle tendon pathology. **METHODS:** Under Mayo Clinic IRB approval, forty-two MWC users were recruited (34 males, age (SD): $41.3 (12.1)$ yrs, injury level: C6-L1, years of MWC use (SD): $10.7 (10.8)$ yrs). A standard clinical MRI protocol was used to image the bilateral shoulders of all participants. The MRIs were assessed by a board-certified musculoskeletal radiologist. Spearman's correlation and logistic regression were used to investigate the association of age and duration of wheelchair use with the presence of the shoulder muscle tendon tears. **RESULTS:** The total prevalence of the shoulder muscle tendon tears (involving dominant or non-dominant shoulder) was 67%. The total prevalence of tendon tears in

the supraspinatus was 47% (partial = 26 and full = 5), infraspinatus was 36% (partial = 21), subscapularis was 40% (partial = 23), and biceps was 12% (partial = 4 and full = 2). The incidence of rotator-cuff and biceps tendon tears was significantly associated with both age ($r = 0.545, p < 0.001$) and the duration of wheelchair use ($r = 0.406, p = 0.008$). The results from a logistic regression model with age and the duration of wheelchair use as predictors indicated that for each 1-year increase in age (when holding the duration of wheelchair use constant) the predicted odds of any rotator-cuff or biceps tendon tear increased by 13% ($p = 0.02$). **CONCLUSION:** Similar to previous studies, this study found high prevalence of shoulder muscle tendon tears in MWC users. This is notably higher than what has been reported for the able-bodied population. Since duration of wheelchair use and age correlate positively with tendon tears, early intervention should be studied to determine if the decline of tendon health can be slowed in this population. Further longitudinal investigation with a larger population of MWC users with SCI is underway to further elucidate the evolution of shoulder pathology due to MWC use. Supported by NIH Grants R01 HD84423-01 and NCATS UL1 TR002377.

Impaired Ankle Proprioception In Individuals With Chronic Nonspecific Low Back Pain

Xinyi XU¹, Yujie Tong¹, Xiaochun Tian¹, Gordon Waddington², Roger Adams², Jeremy Witchalls³, Doal El-ansary⁴, Adrian Pranata⁴, Jianhua Lin⁵, Peijie Chen¹, Jia Han¹. ¹Shanghai University Of Sport, ShangHai, China. ²University of Canberra, Canberra, Australia. ³University of Canberra, Canberra, Australia. ⁴Swinburne University of Technology, Melbourne, Australia. ⁵University of Sydney, Sydney, Australia. Email: 13912349235@163.com
(No relevant relationships reported)

PURPOSE: Ankle proprioception plays a crucial role in balance control. Previous research indicates that individuals with chronic nonspecific low back pain (CNLBP) rely more on ankle than lumbar proprioception in maintaining balance compared to controls. This study aimed to explore if individuals with CNLBP demonstrated any difference in ankle proprioception compared to healthy controls.
METHODS: Twenty-six participants with no ankle injuries in the last 3 months volunteered in this case-control study. Thirteen CNLBP participants (9 Females, age 29.3±9.6yrs old) and 13 were healthy controls (6 Female, age 25.8±8.2yrs old). The Örebro Musculoskeletal Pain Questionnaire (OMPQ) and the Oswestry Disability Index (ODI) were administered for the CNLBP group. Left and right ankle proprioception was assessed by using the Active Movement Extent Discrimination Apparatus (AMEDA) in standing. To assess ankle proprioception, participants were required to actively invert their ankles to a physical stop and to discriminate between 4 possible ankle inversion angles (10°, 12°, 14° and 16°). The receiver operating characteristic curve (ROC) was generated and the mean Area under the ROC Curve (AUC) was calculated to give each participant an ankle proprioceptive acuity score.
RESULTS: The mean proprioceptive discrimination AUC scores for CNLBP and healthy controls were 0.756±0.361 and 0.793±0.04. CNLBP participants demonstrated significantly worse proprioception than healthy controls ($p=0.02, 95\%CI= [61.70\%-89.4\%]$). In healthy controls, there is significant and strong correlation between left and right ankle proprioception ($r=0.747, p=0.003$), but not significant in the CNLBP group ($r=0.139, p=0.650$).
CONCLUSION: The findings of the present study confirm that the ankle proprioception is impaired in individuals with CNLBP. In addition, a common motor program may be used to bilateral ankle movement control in healthy people that demonstrate impairment in people with CNLBP. These findings provide a possible explanation for impaired balance in individuals with CNLBP and may have implications for physiotherapy intervention.

FE Analysis Of Meniscus Injury In A Square Stance Tennis Forehand Drive-a Case Study

Jingqiu Zhou¹, Hesheng Song², Jingguang Qian³, Yu Liu¹, Hongwei Jiang⁴, Peng Lu⁴. ¹Shanghai University of Sport, Shanghai, China. ²Guizhou Normal University,Shanghai, China. ³Nanjing Sport Institute, Nanjing, China. ⁴Tennis Academy of China, Nanjing, China. (Sponsor: Barbara Ainsworth, FACSM)
Email: htwhndxl@163.com
(No relevant relationships reported)

Meniscus tears are common among tennis players. Currently, little is known regarding knee joint kinematic and kinetic characteristics during a square stance tennis forehand that may lead to an increased risk of a meniscus injury.**PURPOSE:**To study loading characteristics of meniscus during a square stance tennis forehand swing using a dynamics model and a three-dimensional (3D) finite element model.**METHODS:** Two female Chinese players (age 14 y) with 6 years of competitive tennis experience

performed three square stance tennis forehand drives. Of the two players, one had a lateral meniscus tear of the left knee joint and the other had no history of knee injury. Three-dimensional kinematic motion and ground reaction force data were collected using VICON and AMTI (120 Hz/1200Hz) and then imported into the OpenSIM software to obtain movement data of the tibia and femur. CT and MRI were used to image a healthy human knee that included the femur, tibia, cartilage layers, menisci and ligaments. 2D data were imported into Mimics software to develop a 3D finite element model of the healthy human knee. The 3D model was imported into HyperWorks software to compute the 3D finite-element models of the knee. Last, the loading data of the movement obtained from OpenSIM was imported and transformed into HyperWorks to obtain the distribution stress of the meniscus. **RESULTS:** Compared with the non-injury player, the athlete with the meniscus tear exhibited excessive tibia rotation, showed a higher level of biomechanical stress of the lateral meniscus and demonstrated greater peak value (figure 1, figure 2). **CONCLUSION:** In the acceleration stage of the square stance tennis forehand, differences were observed in the tibial rotation of the healthy and injured players leading one to speculate that the rotation of the knee joint may be related to meniscus injury. Additional studies are needed to verify this speculation and to infer causality.

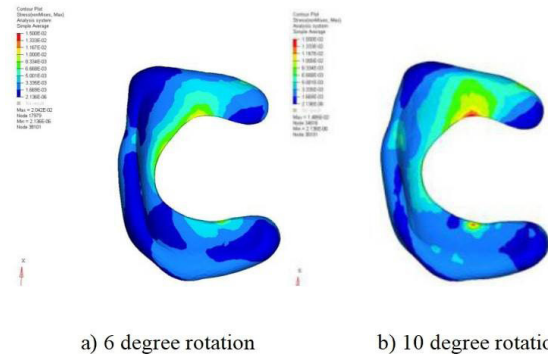

Figure 1. Stress distribution of the meniscus of the injured player

Figure 2. Peak stress distribution of the meniscus of the healthy player

Genetic Predisposition Related To Overuse Injuries In Athletes: Genome-wide Association Study In Estonian Elite Athletes.

Agnes Maegi¹, Sulev Kõks², Ele Prans³, Eve Unt⁴, Maie Tali⁴. ¹Tartu University Hospital, Tartu, Estonia. ²The Perron Institute for Neurological and Translational Science, Perth, Australia. ³University of Tartu, Tartu, Estonia. ⁴Tartu University Hospital, University of Tartu, Tartu, Estonia.
(No relevant relationships reported)

Injuries in sports are the most common causes where athletes are forced to change their training plans temporarily, or more, to interrupt trainings and competitions for a certain time. Several genome-wide association studies have concluded that variations in DNA sequence interacting with non-genetic risk factors may play an important role in the etiology of injuries, including overuse injuries.
PURPOSE: To identify potential loci (chromosomal regions) that are associated with the tendinopathy of Achilles and patellar tendons.
METHODS: Study group consisted of 121 elite athletes (21 females and 100 males), current and former Estonian national team members, in the age range 27.5±5.1 years, involved in 16 different sports. The case group (n=42) consisted of athletes with patellar and Achilles tendinopathies, and the control group (n=79) was formed by athletes without these injuries. The electronic health record system was used to find

clinical diagnoses of the respective injuries of the athletes participating in this study. Peripheral venous blood samples for DNA extraction and genotyping for known SNPs (SNP arrays) from all study subjects were collected. The comparison of allelic frequencies of these SNPs was made between cases and controls. For statistical analysis, we used the software PLINK. To estimate the magnitude of the effectiveness OR was used to estimate the magnitude of the effectiveness, and *p*-values for the significance of ORs were calculated using the χ^2 -test. The *p* value of 10^{-8} was set as a threshold for genome-wide statistical significance. To display significant SNPs, the Manhattan plot was used.

RESULTS: Association analysis revealed 2 genes that could be important as risk factors for investigated injuries, the *PAPPA2* (chr 1: rs1158045, OR 13.8, $p=1.64 \cdot 10^{-5}$) and the *GNG12* (chr 1: rs28435277 OR 13.8, $p=1.64 \cdot 10^{-5}$) with the *p*-value remaining at the level of "suggestive significance" ($p=5 \cdot 10^{-5}$).

CONCLUSIONS: Our study results identified suggestive significance in allelic differences of *PAPPA2* and *GNG12* between case and control groups. It is important to continue with further research of genetic risk profile to understand the biological processes associated with injury risk.

Loading To Optimize Patellar Tendon Repair After Injury

Danielle Steffen, Keith Baar, FACSM. *University of California, Davis, Davis, CA.*
Email: dnsteffen@ucdavis.edu
(No relevant relationships reported)

PURPOSE: Tendinopathy is one of the most common musculoskeletal issues in jumping sports. In sports like basketball and volleyball, tendinopathy rates reach greater than 45%. Interventions to prevent or treat tendinopathies would improve an athlete's quality of life and team performance. The goal of any intervention to treat tendinopathy is to increase the content of directionally oriented collagen, decrease pain, and increase the tensile strength of the tendon. This study is designed to determine the molecular changes that promote tendon repair.

METHODS: Patellar tendon injury was induced in male Wistar Rats with a 2mm biopsy punch. Rats then recovered with normal cage activity for 15 days to allow a mature scar to form. Following scar formation, groups received either an isometric load (4 x 30 second contraction, 2 min rest) or an equivalent time under tension using dynamic loads (360 contractions lasting 333ms each). The injured region of the tendon was collected 18 hrs after loading and immediately frozen. RNA was isolated from the tendon for RT-qPCR determination of genes involved in tendon (collagen I, III, lysyl oxidase, and scleraxis) and fibrocartilage (collagen II, aggrecan, tenascin C, and Sox9) formation.

RESULTS: Tendon scar formation was confirmed by visual inspection. The injured region showed increased vascularity and greater volume. Our preliminary findings suggest that RNA within the tendon increases from $154.4 \pm 20.5 \mu\text{g}$ at baseline to $497.9 \pm 128.1 \mu\text{g}$ two weeks after injury. Acute isometric exercise of the scarred tendon decreased RNA in the injured region slightly to $341.1 \pm 16.8 \mu\text{g}$. At the time of submission the gene expression studies are being completed.

CONCLUSIONS: This pilot study confirms that following injury there is an increase in cell mass (greater RNA) in the scar. Further work on the expression of tendon and cartilaginous genes within the scar will help with the development of a loading program to repair patellar tendinopathy.

Early Physiological Changes To The Vastus Lateralis After Non-invasive Anterior Cruciate Ligament Injury

Emily R. Hunt¹, Steven M. Davi², Douglas W. Van Pelt¹, Christian Lattermann³, Esther E. Dupont-Versteegden¹, Timothy A. Butterfield, FACSM¹, Lindsey K. Lepley⁴. ¹University of Kentucky, Lexington, KY. ²University of Connecticut, Storrs, CT. ³Brigham and Women's Hospital, Harvard Medical School, Cambridge, MA. ⁴University of Michigan, Ann Arbor, MI.
(Sponsor: Timothy A. Butterfield, FACSM)
(No relevant relationships reported)

Insufficient recovery of quadriceps muscle strength is commonly reported after anterior cruciate ligament (ACL) injury. Although weakness is secondary to a complex manifestation of inhibition, the extent and time course of the morphological changes in muscle are largely unknown. Using a novel, translational animal model of ACL injury, a longitudinal study was performed to illuminate the mechanisms underlying acute muscle atrophy. **Purpose** To investigate the role of atrophic pathways after non-invasive ACL rupture. **Methods** Male Long-Evans rats were randomly assigned to 8 groups (n=8 per group): 1 control group and 7 ACL injury groups (6, 12, 24, 48-hours, and 1, 2, 4-weeks). The right hindlimbs of ACL injury rats were exposed to a single impulse, longitudinal tibial compression, to induce a non-invasive ACL rupture, followed by normal cage activity. After which rats were euthanized as per assigned group. Right and left vastus lateralis muscles (VL) were harvested, weighed and flash

frozen in liquid nitrogen. The VL were immunoreacted for dystrophin to quantify fiber cross sectional area (CSA), and RNA was isolated to measure the abundance of MuRF-1, MAFbx (markers of protein degradation) and 45s (marker of translational capacity). rRNA expression was determined using RT-PCR. One-way ANOVAs with Bonferroni post-hoc were used to determine differences between groups, and paired t-tests were used to detect VL differences between limbs ($P < 0.05$). **Results** ACL injury resulted in a decrease in muscle wet weight ($p=0.0003$) and a trend toward reduced CSA ($p=0.06$) at 1-week post injury, compared to control, 2- and 4-week time points. CSA of the ACL injured limb VL was smaller than the VL of the contralateral limb at 1-week only ($p=0.01$). MAFbx abundance was significantly increased at 48-hours post-ACL injury ($p=0.0001$), with no differences for 45s rRNA, total RNA concentration or MuRF-1. **Conclusions** Results indicate that ACL injury induces atrophy which is transient and not related to a decrease in ribosome biogenesis but likely due to increased protein degradation. Future studies should focus on a comprehensive analysis of atrophic pathways after ACL injury, to establish key therapeutic windows for targeting therapy-resistant quadriceps weakness after ACL injury. Supported by K01AR071503.

Epidemiology Of Acromioclavicular Joint Injuries At A Colorado Ski Resort

Naomi Kelley, Laura Pierpoint, Morteza Khodaei, FACSM.
University of Colorado School of Medicine, Aurora, CO.
(No relevant relationships reported)

Purpose: Acromioclavicular joint (ACJ) injuries are amongst the most common injuries in winter sports. The purpose of this study was to determine trends with respect to injury mechanism, environmental factors, associated injuries, and demographics amongst patients treated for acute ACJ injuries at the Winter Park Ski Resort clinic in Colorado. **Methods:** This was a retrospective descriptive analysis, specifically using an injured patient cohort from the Winter Park Ski Resort clinic. The timeframe used was from 2012 to 2017. All patients diagnosed with an ACJ injury when seen at the ski clinic at the mountain's base were included in the patient cohort. Chart review was performed to confirm diagnosis and obtain case details. **Results:** A total of 341 acromioclavicular joint injuries (6.7% of total visits) were encountered during the study period. The majority of ACJ injuries were grade I (41.3%) and mainly occurred in men (86.5%). The majority (96.8%) of the cases were primary ACJ injuries on the right shoulder (56.9%). The average age of patients with ACJ injuries was 30.0 years (range 10-72). More than half (62.2%) of ACJ injuries occurred due to snowboarding injuries and the remaining due to skiing injuries (37.8%). The most common mechanism of injury (93.5%) was fall to snow while skiing/boarding. Women were more likely to have a grade I ACJ injury than men (80.4% vs 35.4%; $P < 0.001$). Women with ACJ injuries were more likely to suffer the injury due to skiing than snowboarding (71.7% vs 28.3%; $P < 0.001$), compared to men who were more likely to suffer the injury due to snowboarding than skiing (67.5% vs 32.5%; $P < 0.001$). **Conclusions:** Most of the ACJ injuries were Class I and occurred mostly in men. Snowboarders were more likely to have an ACJ injury than skiers.

Increased ATFL Thickness Associates To Decreased Physical Activity Levels After Acute Lateral Ankle Sprain

Tricia J. Hubbard-Turner, FACSM¹, Michael J. Turner, FACSM¹, Kyeongtak Song², Chris Burcal³, Erik Wikstrom². ¹University of North Carolina @ Charlotte, Charlotte, NC. ²University of North Carolina @ Chapel Hill, Chapel Hill, NC. ³University of Nebraska @ Omaha, Omaha, NE.
Email: thubbar1@uncc.edu
(No relevant relationships reported)

Lateral ankle sprains remain one of the most common orthopedic injuries. Most concerning are the number of patients that develop long term ankle instability and have decreased activity levels. Despite these problems there are limited long-term studies examining changes after an acute lateral ankle sprain (LAS). **Purpose:** To examine the post-injury thickness of the anterior talofibular ligament (ATFL) and if that thickness relates to physical activity levels one year after an ankle sprain. **Methods:** Twenty college students (8 males and 12 females, age= 21.2 ± 2.4 yr., mass= 80.9 ± 21.6 kg, ht= 173.3 ± 10.6 cm) with an acute LAS and 20 healthy matched controls (8 males and 12 females, age= 21.9 ± 2.8 yr., mass= 79.1 ± 20.2 kg, ht= 172.5 ± 9.8 cm) participated in the study. ATFL thickness was measured with a LOGIQ Book diagnostic ultrasound. The examiner orientated the probe to visualize the cross sectional view of the lateral malleolus, lateral talar articular surface, and the neck of the talus. Once those landmarks and the ATFL were located, images were saved. Thickness of the ATFL was measured at the midpoint of the ligament between the attachments on the lateral malleolus and talus. The main outcome measures were the thickness of the ATFL (mm) at 3 days post LAS and 1 year post LAS, and physical activity levels as measured by the IPAQ and NASA physical activity scales. **Results:** There was a significant relationship between post-injury ATFL thickness and both the IPAQ and

NASA physical activity scales. As ligament thickness increased, "average time spent performing vigorous physical activity" significantly decreased ($p=.04$, $r^2=.86$) and "average time spent performing moderate physical activity" ($p=.02$, $r^2=.84$) also decreased one year after injury. As ligament thickness increased in subjects with a LAS, time spent walking ($p=.01$, $r^2=.92$), days per week where vigorous activity ($p=.02$, $r^2=.81$) or moderate activity ($p=.04$, $r^2=.85$) was pursued one year after their sprain significantly decreased. **Conclusions:** The changes in ATFL morphology may lead to the decreased physical activity levels by contributing to ligamentous laxity and/or perceptions of instability. Future research needs to focus on early interventions to ensure proper ligament healing occurs to restore joint function.

371 Board #187 May 27 10:30 AM - 12:00 PM

Sex Differences In The Morphology Of The Vastus Lateralis After An Anterior Cruciate Ligament Tear

Madalyn G. Romines, Lauren N. Erickson, Peter A. Hardy, Anders H. Andersen, Brian Noehren, FACSM. *University of Kentucky, Lexington, KY.*

(No relevant relationships reported)

Females are three times more susceptible to tear their anterior cruciate ligament (ACL) and have significantly weaker quadriceps after injury. Despite the high frequency of injury, little is known about whether the morphology of the quadriceps alters in a sex specific manner. Muscle imaging of volume, fibrosis, pennation angle, and fiber tract length could provide valuable insights into these differences. **PURPOSE:** To investigate sex differences in morphology of the vastus lateralis (VL) after ACL injury. **METHODS:** 24 ACL deficient patients (11M, 13F, 21.8 ± 5.0 y, 25.0 ± 3.7 kg/m², days since injury 24.6 ± 16.2) underwent magnetic resonance imaging including multi echo T1ρ, DTI, and 2D turbo spin echo. Data was post-processed in MATLAB, where a mono exponential decay curve was fitted to analyze the T1ρ signal. Muscle fiber bundles were tracked by taking the first eigenvector of diffusion tensor starting at the aponeurosis until the fiber exited the side or top of the selected slices. From these tracks pennation angle and fiber length were calculated. Muscle volume was calculated by manually outlining the border of the VL. Independent t-tests compared differences between males and females.

RESULTS: T1ρ times (M: 0.031 ± 0.003 s; F: 0.028 ± 0.002 s; $p = 0.06$) and pennation angle (M: 16.6 ± 2.6°; F: 14.9 ± 1.8°) of the involved limb was not significantly different between sexes; however, fiber length was significantly longer in females compared to males (F: 55.1 ± 6.2 mm; M: 48.3 ± 7.0 mm; $p = 0.04$). Volume of the vastus lateralis was not significantly different between sexes (M: 355.1 ± 117.5 cm³; F: 335.9 ± 97.1 cm³; $p = 0.6$). **CONCLUSIONS:** We show that ACL injury results in a sex specific difference in muscle fiber length. Fiber length is an important determinant in physiological cross-sectional area (PCSA). The longer fiber lengths seen in the females may lead to decreased PCSA which could have a negative influence on quadriceps muscle strength. Potentially, this longer fiber length prior to surgery may be one factor that drives differences in recovery of muscle strength after surgery. Future work is needed to examine how these morphological aspects change over time following ACL reconstruction.

Skeletal Muscle Metabolic Gene Profile Associates With Rheumatoid Arthritis Improvements Following High Intensity Interval Training

Brian J. Andonian¹, David B. Bartlett¹, Monica J. Hubal², Leslie Willis¹, Megan A. Reaves¹, William E. Kraus, FACSM¹, Kim M. Huffman¹. ¹Duke University School of Medicine, Durham, NC. ²Indiana University-Purdue University Indianapolis, Indianapolis, IN.

Email: brian.andonian@duke.edu

(No relevant relationships reported)

Rheumatoid arthritis (RA) is a systemic inflammatory disease characterized by exercise intolerance and increased risk for cardiometabolic disease. High intensity interval training (HIIT) improves both inflammation and cardiorespiratory fitness (CRF) in RA, however the mechanisms underpinning these therapeutic benefits are unclear.

PURPOSE: To identify baseline skeletal muscle pathways linking HIIT with improvements in RA inflammatory disease activity and CRF. **METHODS:** Participants with RA ($n=13$; mean age=63.9±7.2) underwent RA disease activity (DAS), physiologic, and biologic assessments pre- and post-10 weeks of supervised HIIT. Cardiopulmonary exercise testing measured CRF as $\dot{V}O_2$ peak (mL/kg/min). Skeletal muscle RNA was isolated from vastus lateralis biopsies. Illumina Human HT-12v4 Expression BeadChips and Ingenuity Pathway Analysis were used for quantitative whole genome RNA analyses. Differential Spearman correlations ($p<0.05$) assessed associations for baseline gene expression with Δ DAS and Δ CRF (post - pre). **RESULTS:** HIIT improved RA DAS (+23.8%; $p<0.001$) and CRF (+8.2%; $p<0.001$). Δ DAS was strongly correlated with baseline muscle expression of 46 genes ($0.80<r<-0.80$; * $p<0.001$); including genes encoding proteins involved in substrate energy

metabolism ($n=9$; LIAS, NDUFB3, GLDC, AGL, BCKDHB, PDK2, LDHB, ACS2, PANK2) and inflammatory pathways ($n=4$; FCRL6, TNFRSF19, CMT4, NKG7). In contrast, Δ CRF was strongly correlated with baseline expression of 16 genes; only 1 (NDUFB4) involved in cellular metabolism and 0 in inflammation. Novel network analysis revealed muscle upregulation of NF- κ B and MAPK/JNK pathways associated with greater improvements in DAS.

CONCLUSIONS: HIIT-mediated improvements in RA disease activity associate strongly with baseline alterations in skeletal muscle metabolic and inflammatory pathways. Thus, exercise training may improve RA inflammation via coordinated regulation of muscle and immune cell energy metabolism.

Effects Of Methyl Sulfonyl Methane On Knee Laxity In Females Throughout The Menstrual Cycle.

Vera Weijer, Tayler Smith, Karine Schaal, Dana Lis, Keith Baar, FACSM. *UC Davis, Davis, CA.*

Email: veraweijer@live.nl

(No relevant relationships reported)

Women have a ~4-fold greater risk of anterior cross ligament (ACL) rupture compared to men. ACL injury is associated with greater estrogen levels. Estrogen increases knee laxity, in part by blocking lysyl oxidase activity, thus decreasing collagen crosslinking and ligament stiffness. Methyl sulfonyl methane (MSM) supplementation is suggested to counter this effect.

PURPOSE: To determine whether MSM supplementation alters knee laxity over the menstrual cycle.

METHODS: Healthy women (ages 18-30) were followed over a 5-month period. Knee laxity measured using a GNRB knee arthrometer (Prothia, Worcester, MA) at menstruation and ovulation during baseline (month 1&2) and intervention phases (month 4 & 5). In a double-blinded manner, from month 3 participants were randomly assigned to daily ingestion of 3g of MSM or placebo (PLA; rice flower). Saliva samples were taken before all laxity measurements to determine estradiol levels (Salimetrics, Carlsbad, CA). Two-way ANOVA (supplementation and time) was used to determine differences with alpha set at $p < 0.05$. At time of submission data remains blinded.

RESULTS: Baseline knee laxity was the same in both groups at all time points ($n=20$, Group A $n=9$, Group B, $n=11$ due to dropout). Compared to baseline, the average knee laxity during the intervention period in Group A was significantly lower at ovulation compared to Group B ($p=0.036$). Upon analysis of estradiol levels and subsequent unblinding, the interaction between estrogen levels, laxity, supplement and time will be determined.

CONCLUSION: Knee laxity decreased at ovulation in Group A. MSM may show efficacy in decreasing knee laxity at ovulation in females and help to reduce ACL injury.

Asymmetric Somatosensory Nerve Excitability In Professional Rugby Players With History Of Calf Muscle Strain

Tomonori Kawai¹, Masayasu Takahashi², Satoshi Kunitsugu³. ¹School of Medicine Keio University, Tokyo, Japan. ²Konan Medical Center, Kobe, Japan. ³Professional Trainers Team, Nishinomiya, Japan.

(No relevant relationships reported)

Muscle Strain Injury has been notorious for its high incidence and high recurrent ratio in a wide variety of sports. Severe muscle strain alters morphological properties of the connective tissue. Connective tissue, especially fascia which surrounds muscles, is highly sensory innervated. Therefore, we hypothesize that previous muscle strain injury affects sensory nerve transmission. Altered proprioceptive feedback will affect the muscle function which consequently may lead to muscle strain re-injury.

PURPOSE: This pilot study aimed to compare the differences between injured and uninjured leg in sensory nerve excitability of the tibial nerve in professional rugby players. Moreover, we wanted to compare it with muscle-tendon junction stiffness of gastrocnemius muscles.

METHODS: Five male professional rugby players (age/ height/ weight, ± 3.9/181.2±10.5/101±12.46) who have a history of calf strain (confirmed by MRI) were selected. The measurement was performed at least 6 weeks after injury. To evaluate sensory excitability, we examined somatosensory evoked potentials (SEPs) elicited by tibial nerve stimulation on both injured and uninjured side. Muscle stiffness (strain ratio) was also assessed by strain elastography in both injured and uninjured leg. The relationship between SEPs and strain ratio was analyzed.

RESULTS: The SEPs of the injured side was lower than that of the uninjured side (mean latency injured side/uninjured side, 7.26 m/s±1.21/9.34 m/s±2.01, $p<0.05$). However, there was no difference in muscle stiffness between the legs (mean strain ratio injured side/uninjured side, 0.128/0.124, $p=0.37$). The relationship between SEPs and muscle stiffness was found on non-significant ($p=0.74$).

CONCLUSIONS: SEP of injured gastrocnemius muscle was lower than uninjured one in professional rugby players. However, muscle stiffness did not differ.

Oculomotor Function In Adolescent Athletes Following Concussion

Bianca Edison¹, Nicole Mueske¹, Tracy Zaslou¹, Gene Yu², Adriana Conrad-Forrest¹, Tishya Wren¹. ¹Children's Hospital Los Angeles, Los Angeles, CA. ²University of Southern California, Los Angeles, CA.

(No relevant relationships reported)

Purpose: Visual impairments affect up to 90% of patients post-concussion and may include deficits in fixation accuracy, smooth pursuit, saccadic latencies, vergence, accommodation, or vestibulo-ocular reflexes. Quantitative assessment of oculomotor function may provide a sensitive measure of concussion recovery since coordinated eye movements require the use of diverse and widely dispersed areas of the brain. This study quantified oculomotor function over time in adolescents following concussion, hypothesizing that initial deficits would resolve by the time of RTP and remain stable after RTP.

Methods: 13 adolescent athletes with mild to moderate concussion (7 male; mean age 15.1, SD 2.1, range 10-17 years) were prospectively evaluated at their initial visit (mean 18, range 4-43 days post-concussion), at the time of RTP clearance (mean 46, range 12-173 days post-concussion), and one month later (mean 26, range 20-41 days after RTP). 11 controls without past concussion or injury (3 male; mean age 12.3, SD 3.1, range 8-17 years) were tested at similar timepoints. Eye tracking was recorded as subjects followed a target moving on a screen in predefined patterns related to sinusoid and trapezoid smooth pursuit, vergence, saccade, and anti-saccade. Metrics characterizing the speed, accuracy, and variability of tracking were compared between groups and visits using t-tests and linear mixed-effects regression.

Results: At baseline, patients tended to have greater overshoot and greater variability in tracking compared with controls, though the differences were not statistically significant. Overshoot (coef -1.97, SE 0.98, $p=0.045$), variability of tracking (-1.04, SE 0.53, $p=0.048$), and variability of overshoot (-2.59, SE 1.04, $p=0.013$) decreased from baseline to RTP. Undershoot during sinusoid smooth pursuit tended to decrease from RTP to 1-month follow-up (-0.16, SE 0.09, $P=0.080$). The rate of convergence in the distance vergence task increased (0.27, SE 0.10, $p=0.005$) while the rate of divergence decreased (-0.32, SE 0.17, $p=0.068$) between these time points.

Conclusion: Possible deficits in eye tracking resolved by the time of RTP and generally remained stable or continued improving after RTP, suggesting that oculomotor function recovers sufficiently under current conservative treatment protocols.

Visual Input Affects Force Steadiness And Accuracy Among Chronic Ankle Instability Patients, Ankle Sprain Copers, And Healthy Controls

HYUNWOOK LEE¹, Seunguk Han¹, S. Jun Son², Hyunsoo Kim³, Ty Hopkins, FACSM¹. ¹Brigham Young University, Provo, UT. ²Cha University, Seongnam, Korea, Republic of. ³West Chester University, West Chester, PA. (Sponsor: J Ty Hopkins, FACSM)

Email: hyunwook.lee31@gmail.com

(No relevant relationships reported)

Chronic ankle instability (CAI) patients have demonstrated impairments of the sensorimotor system. The sensorimotor system plays an important role in steadily generating fine forces to control balance and functional movement. Submaximal force steadiness measures sensory, motor, and visual function via feedback mechanisms, which helps researchers and clinicians to comprehend sensorimotor deficits associated with CAI.

PURPOSE: This study aimed to identify effects of stroboscopic glasses on force steadiness and accuracy among CAI patients, ankle sprain copers, and healthy controls.

METHODS: Twenty CAI patients (M=10, F=10; 23±3 yrs, 174±11 cm, 76±17), 20 copers (M=10, F=10; 22±2 yrs, 176±10 cm, 69±10 kg), and 20 controls (M=10, F=10; 22±3 yrs, 174±7 cm, 80±24 kg) participated in this study. Subjects performed

a maximal voluntary isometric contraction (MVIC) of eversion, inversion, and hip abduction. Two days after MVIC tests, subjects performed 2 practices, followed by 3 testing trials of 10% and 20% of their MVIC for 15 seconds for submaximal force steadiness and accuracy measures with and without the stroboscopic glasses. The central 10-sec (20-80% of the total time) of three testing trials was analyzed. Main outcome measures were force steadiness, which was one standard deviation (SD), and force accuracy was a root mean square across the 10-sec data. Force steadiness and accuracy were analyzed by 3 (groups) x 2 (visual conditions) ANOVAS.

RESULTS: The CAI and copers subjects exhibited greater errors than controls in 20% eversion MVIC in force steadiness ($p<.0001$ and $p=.01$, respectively). CAI subjects demonstrated less steadiness in 20% eversion and hip abduction under strobe vision (SC) compared with eyes open (EO) ($p=.02$, both). Additionally, CAI subjects showed less accuracy than copers and controls in 20% eversion MVIC ($p=.0001$ and $p<.0001$, respectively). CAI subjects demonstrated less accuracy in 20% eversion under SC compared with EO ($p=.002$).

CONCLUSIONS: Individuals with a history of a lateral ankle sprain (LAS) showed reduced force steadiness than healthy controls. Only CAI patients relied more on visual input during force steadiness and accuracy tasks. A LAS injury (coper) reduced the ability to control fine force, but recurrence of LASs (CAI) altered reliance on visual input.

Effect Of Kinesio Taping On Postural Control In Individuals With Chronic Ankle Instability

Lin Wang, Lulu Yin. Shanghai University of Sport, Shanghai, China. (Sponsor: Stanley Sai-chuen HUI, FACSM)

Email: wanglin.sus@gmail.com

(No relevant relationships reported)

Chronic ankle instability (CAI), which is characterized by deficient postural control, may be improved through Kinesio Taping (KT) intervention. However, the effect of KT on postural control in individuals with CAI is controversial.

PURPOSE: This study aimed to investigate the acute effect of KT on postural control through computerized dynamic posturography (CDP) and perceived sensation in individuals with CAI.

METHODS: A total of 35 male adults with CAI participated in the study. Each participant received four random ankle taping, including KT, athletic taping (AT), sham taping (ST), and no taping (NT). Subsequently, a series of postural stability measurements was performed using CDP. The tests included sensory organization test (SOT), unilateral stance (US) test, limit of stability (LOS) test, motor control test, and adaption test (ADT). In addition, perception stability and comfort were measured through visual analogue scaling. One-way repeated measures analysis of variance was conducted to determine difference on postural control among KT, AT, ST, and NT.

RESULTS: No significant difference was observed for parameters in SOT, US test, and LOS test among four taping. In the motor control test, the amplitude scaling scores of KT were 35.87% lower than NT ($p<.001$) in forward-small slip and 21.58% lower than ST ($p=.035$) in backward-large slip. In ADT, sway energy scores were 7.59% greater in ST than this in AT ($p=.028$). For perception stability, KT was performed better than ST ($p<.001$) and NT ($p<.001$), and AT was performed better than ST ($p=.001$) and NT ($p<.001$). For perception comfort, KT was performed better than AT ($p=.001$) and NT ($p=.031$).

CONCLUSIONS: KT and AT could not facilitate postural control for CAI individuals during static and voluntary measurements. However, they could provide effective support to cope with sudden perturbation. In addition, KT improved perception stability and comfort, whereas AT improved perception stability but provided the least comfort.

Balance Training with Stroboscopic Vision is Superior to Balance Training Alone for Chronic Ankle Instability

Kyung-Min Kim¹, Fidel Hita-Contreras², Antonio Martínez-Amat², Soon-Mi Choi³, Agustín Albar Almazán², Mariola Estudillo-Martínez², David Cruz-Díaz². ¹University of Miami, Miami, FL. ²University of Jaén, Jaén, Spain. ³Midwestern State University, Wichita Falls, TX.

Email: kmk154@miami.edu

(No relevant relationships reported)

Stroboscopic Vision (SV) is characterized by intermittent visual obstruction via the use of goggles with lenses that can switch between opaque and transparent. Incorporating SV into physical training has been shown to induce more significant improvements in sports and medial fields. Given SV that has the potential to improve balance further, it may be effective to restore balance deficits in patients with chronic ankle instability (CAI). **PURPOSE:** To determine the efficacy of SV incorporated into balance training for CAI. **METHODS:** A total of 73 CAI patients were randomly assigned to one of 3 groups: balance training (BT, n=25), BT with SV (BTSV, n=24), and control (no intervention, n=24). BT consisted of progressive balance exercises (e.g., single-leg

stance/hopping on stable/unstable surface), and lasted for 6 weeks, 3 times per week, with a single session lasting about 20 minutes. BTSV was comprised of the same exercises as BT, but exercises were performed under SV. The following outcomes were assessed before and after intervention: (1) dynamic balance, quantified by Star Excursion Balance Test (SEBT) and (2) perceived joint instability, measured by Cumberland Ankle Instability Tool (CAIT). SEBT was composed of 3 directional single leg reaching tasks: anterior (A), posteromedial, and posterolateral. Reaching distances were normalized to height, with higher percentage values indicating better balance. CAIT was used to quantify the severity of ankle instability, with a lower score indicating worse ankle instability. For statistical analysis, we calculated pre-post change scores of each group for each outcome and performed a one-way ANOVA. **RESULTS:** There were significant group differences for all outcomes ($p < 0.001$). Both BT and BTSV groups significantly improved relative to the control group, with very large effect sizes (Cohen's $d = 1.46$ to 7.79). Besides, BTSV induced greater improvements for the SEBT-A performance ($p = 0.001$: pre-BT=78.0±3.5%, post-BT=85.7±3.5%; pre-BTSV=77.3±4.7%, post-BTSV=88.0±4.0%) and CAIT scores ($p = 0.042$: pre-BT=15.3±4.7pts, post-BT=20.8±4.7pts; pre-BTSV=15.1±4.8pts, post-BTSV=23.5±2.8pts). **CONCLUSION:** The current study was the first to demonstrate that CAI patients benefit from a visually challenging rehabilitation environment created by SV.

 (No relevant relationships reported)

Chronic ankle instability (CAI) patients have consistently displayed postural control deficits. Previous research postulated that CAI patients rely more on the utilization of visual feedback than controls to compensate for the proprioceptive deficits after lateral ankle sprains. However, little is known about how reduced visual feedback would alter dynamic postural control in CAI patients relative to controls and copers. **PURPOSE:** To identify the effect of visual feedback disruption via stroboscopic glasses on dynamic postural control among groups of CAI, copers, and control. **METHODS:** 20 CAI (10M, 10F, 23.6±3.9 yr, 174.5±11.8 cm, 76.3±17.5 kg), 20 copers (10M, 10F, 22.2±1.4 yr, 176.4±10.2 cm, 69.3±10.9 kg), and 20 control (10M, 10F, 22.6±2.7 yr, 174.4±7.2 cm, 80.0±24.4 kg) subjects were categorized according to the Foot and Ankle Ability Measure (FAAM) and Modified Ankle Instability Index (MAII) questionnaires. Each subject performed three trials of a single-leg-hop stabilization test with eyes open (EO) and stroboscopic vision (SV). Force data (200 Hz) were collected using an in-ground force plate to calculate the dynamic postural stability index (DPSI) and directional stability indices (medial/lateral, anterior/posterior, vertical). Two-way repeated ANOVAs (group × condition) were used to examine the differences between condition (EO, SV) and group (CAI, copers, control). **RESULTS:** Visual condition main effect was driven by differences between EO and SV during dynamic postural control ($p < 0.001$). Only CAI patients displayed altered DPSI scores between EO and SV ($p = 0.005$). However, no differences were observed in copers ($p = 0.31$) and controls ($p = 0.99$). Regardless of visual condition, CAI patients displayed dynamic postural control deficits relative to controls ($p = 0.003$) but no differences between CAI patients and copers ($p = 0.45$). For the directional stability indices, each group displayed no differences between visual conditions. **CONCLUSION:** CAI patients rely more on visual feedback during dynamic postural control than copers and controls. However, they may have decreased ability to compensate for the disrupted visual feedback during dynamic movement. Stroboscopic glasses could be effective visual-disruption devices during dynamic movement tasks regardless of lateral ankle sprain history.

Activities Of Hip Muscles In Response To Perturbed Walking In Individual With Chronic Ankle Instability
 Chiao-I Lin, Mina Khajooei, Alexandra Nair, Mika Heikkila, Hannes Kaplick, Engel Tilman, Frank Mayer. University of Potsdam, Potsdam, Germany.
 Email: chialin@uni-potsdam.de
 (No relevant relationships reported)

Chronic ankle instability (CAI) is not only an ankle issue, but also affects sensorimotor system. People with CAI show altered muscle activation in proximal joints such as hip and knee. However, evidence is limited as controversial results have been presented regarding changes in activation of hip muscles in CAI population. **PURPOSE:** To investigate the effect of CAI on activity of hip muscles during normal walking and walking with perturbations. **METHODS:** 8 subjects with CAI (23 ± 2 years, 171 ± 7 cm and 65 ± 4 kg) and 8 controls (CON) matched by age, height, weight and dominant

leg (25 ± 3 years, 172 ± 7 cm and 65 ± 6 kg) walked shod on a split-belt treadmill (1 m/s). Subjects performed 5 minutes of baseline walking and 6 minutes walking with 10 perturbations (at 200 ms after heel contact with 42 m/s² deceleration impulse) on each side. Electromyography signals from gluteus medius (Gmed) and gluteus maximus (Gmax) were recorded while walking. Muscle amplitudes (Root Mean Square normalized to maximum voluntary isometric contraction) were calculated at 200 ms before heel contact (Pre200), 100 ms after heel contact (Post100) during normal walking and 200 ms after perturbations (Pert200). Differences between groups were examined using Mann Whitney U test and Bonferroni correction to account for multiple testing (adjust α level $p \leq 0.0125$). **RESULTS:** In Gmed, CAI group showed lower muscle amplitude than CON group after heel contact (Post100: 18±7 % and 47±21 %, $p < .01$) and after walking perturbations (31±13 % and 62±26 %, $p < .01$), but not before heel contact (Pre200: 5±2 % and 11±10 %, $p = 0.195$). In Gmax, no difference was found between CAI and CON groups in all three time points (Pre200: 12±5 % and 17±12 %, $p = 0.574$; Post100: 41±21 % and 41±13 %, $p = 1.00$; Pert200: 79±46 % and 62±35 %, $p = 0.505$). **CONCLUSIONS:** People with CAI activated Gmed less than healthy control in feedback mechanism (after heel contact and walking with perturbations), but not in feedforward mechanism (before heel contact). Less activation on Gmed may affect the balance in frontal plane and increase the risk of recurrent ankle sprain, giving way or feeling ankle instability in patients with CAI during walking. Future studies should investigate the effect of Gmed strengthening or neuromuscular training on CAI rehabilitation.

Verbal Encouragement Improves Star Excursion Balance Test Performance In Patients With Chronic Ankle Instability
 Susan Saliba, Abbas Haider Jaffri. University of Virginia, Charlottesville, VA. (Sponsor: Jay Hertel, FACSM)
 Email: saf8u@virginia.edu
 (No relevant relationships reported)

PURPOSE: The Star Excursion Balance Test (SEBT) is a common dynamic balance test. Functional limitations on the SEBT are associated with CAI, but psychological constraints such as kinesiphobia or a lack of confidence may affect performance. The purpose of this study was to investigate the effects of verbal encouragement (VE) on maximum reach distance performance between CAI and healthy participants on the SEBT and to explore the role of kinesiphobia with this functional. **METHODS:** Thirty-four individuals: 17 CAI (10 F/7 M; age= 21.06±3.19yr; height=171.2±11.9 cm; weight=67.7±10.8 kg) and 17 healthy controls (10 F/7 M; age=19.41 ±1.23yr; height=169.35±6.36 cm; weight=64.89±8.76kg) volunteered. Independent variables included condition (VE vs No VE) and group (CAI vs Healthy). The Fear Avoidance Beliefs Questionnaire (FABQ) was administered. Participants completed 3 SEBT trials per condition, starting with No VE followed by VE to eliminate the effect of heightened motivation with a randomized order. Analysis of Variance (ANOVA) examined group differences and whether VE affected performance for Anterior (ANT), Posteromedial (PM), and Posterolateral (PL) reach distances. FABQ was compared between the CAI and Healthy groups using a t-test; all alpha levels were $< .05$ a priori. **RESULTS:** With No VE, a significant group-by-condition interaction was observed in both the ANT (CAI: 66.90 ± 5.50 vs Healthy: 70.65 ± 4.52) and PM (CAI: 77.60 ± 7.70 vs Healthy: 81.89 ± 8.25 reach directions, which diminished with VE: ANT (CAI: 70.43 ± 4.52 vs Healthy: 71.77 ± 5.10) and PM (CAI: 85.41 ± 7.19 vs Healthy: 86.45 ± 8.71), showing that the two groups behaved similarly with VE. There was no statistically significant interaction ($p = 0.48$) for the PL reach direction without VE (CAI: 73.60 ± 7.84 vs Healthy: 75.16 ± 11.72) or with VE (CAI: 80.18 ± 9.79 vs Healthy: 80.06 ± 11.93). The CAI group had significantly higher FABQ scores (10.53 ± 9.45) than the healthy group (0.41 ± 1.70) ($p < .001$). **CONCLUSIONS:** The CAI group had lower performance on the SEBT without VE, but with VE, the scores were comparable to healthy controls. Clinicians and researchers should acknowledge the impact that motivation and psychological stresses have on functional performance in patients with pathologies such as CAI.

Comparison Of Gender Differences In Ankle And Knee Proprioception
 Xiaoyue HU, Lin Wang. Shanghai University of Sport, Shanghai, China.
 Email: moonhxyy@163.com
 (No relevant relationships reported)

It was reported that in same sports program and training intensity, knee and ankle injury in female is 2-8 times higher than males. The decline of posture control is an important cause for sports injuries. Postural control is accomplished by the combination of proprioception, central and neuromuscular control. Proprioception is a crucial component in maintaining the body stability. **PURPOSE:** The purpose of this study was to investigate whether there exist gender differences in knee and ankle

proprioception between male and female in follicular cycle. **METHODS:** Twenty-four healthy college student (male: n=12, age: 23.08±1.8 years; height : 1.73±0.07m; weight : 59.83±12.69kg; female: n=12, age: 21.75±1.77 years; height : 1.64±0.64m weight : 56.25±6.77kg) were included in the study. Knee and ankle proprioception were measured by an electric-driven movable frame which was moved by an electric motor rotated the foot on an axis at a rate of 0.4°/s. The test results were averaged from five times movement in each direction such as knee flexion and extension; plantarflexion, and dorsiflexion in ankle joint. The independent t test was used to compare differences between proprioception of ankle and knee joint in males and follicular females. The significance level was p<0.05. **RESULTS:** There were no significant differences between proprioception of plantarflexion (male: 0.78±0.26 °; female: 0.65±0.27 °, p=0.215) and dorsiflexion (male: 0.64±0.18 °; female: 0.62±0.33 °, p=0.872) between males and follicular females. No significant differences were found on knee flexion (male: 0.54±0.21°; female: 0.54±0.32 °, p=1.000) and extension (male: 0.55±0.23 °; female: 0.43±0.17 °, p=0.132) in male and follicular female. **CONCLUSIONS:** There were no significant gender differences on ankle and knee proprioception. Therefore, proprioception may not be the cause of the decline in posture control of female.

Altitude Training Mask Alters Ankle Joint Kinetics During Treadmill Walking

Douglas W. Powell, FACSM¹, Alexis K. Nelson², Jay Hinton², Hailey B. Fong², Aaron Persinger², Melissa J. Puppa².
¹University of Memphis, Cordova, TN. ²University of Memphis, Memphis, TN.
 (No relevant relationships reported)

Elevation training masks are commonly used in strength and conditioning to simulate working in a hypoxic environment through resisted inspiration (RI). It is further suggested that RI improves the ability of the athlete's muscle to utilize available oxygen carried by hemoglobin. Though some data exists regarding gross training performance in elevation training masks, little data is available regarding the effect of elevation training masks on lower extremity joint biomechanics during an exercise task. **PURPOSE:** to determine the effects of an altitude training mask on ankle joint kinetics during a treadmill walking task. **METHODS:** Seven healthy young adults performed two 10-minute treadmill walking tasks at 1.6 m/s in each of two conditions: normal walking (CON) and with RI. Three-dimensional kinematics and ground reaction forces (GRFs) were simultaneously recorded using a 6-camera motion capture system (250 Hz) and instrumented treadmill (1500 Hz). Peak ankle plantarflexor moments and powers were determined from the second (M2) and tenth (M10) minutes of the treadmill walking task. Two repeated measures ANOVAs were used to determine the effects of time and condition on peak plantarflexor moments and powers. **RESULTS:** No time by condition interactions were observed for plantarflexor moments (p = 0.26) or powers (p = 0.18). The RI condition was associated with greater plantarflexor moments (p = 0.04) and powers (p = 0.01) than the CON condition. No effects of time were observed for plantarflexor moments (p = 0.84) or powers (p = 0.63). **CONCLUSIONS:** These findings demonstrate that ankle joint kinetics are greater when performing a treadmill walking task when wearing an elevation training mask. Given the constant mechanical demand, these data suggest that a multi-joint mechanical adaptation occurred in response to the elevation training mask. Subsequent research may seek to address changes in joint contributions to the walking task when wearing an elevation training mask.

Table 1. Mean ankle joint moments and powers during stance phase propulsion in the second (M2) and tenth (M10) of the CON and RI conditions.

Condition	Moment		Power	
	M2	M10	M2	M10
CON	-1.24 (0.32)	-1.25 (0.34)	2.11 (0.45)	2.12 (0.54)
RI	-1.25 (0.35)	-1.31 (0.35)	2.26 (0.54)	2.50 (0.50)

Influence Of Ankle Flexibility On The Single Leg Balance Test Using A Dynamic Balance System

Anna Blackley, Maggie McDermott, Moroni de Moors, Abigail McCarty, David Titcomb, Jared Hornsby, James Schoffstall, FACSM. Liberty University, Lynchburg, VA. (Sponsor: James Schoffstall, FACSM)
 Email: ablackley1@liberty.edu
 (No relevant relationships reported)

Ankle range of motion (ROM) is believed to be one of the contributing factors in balance deficits. Multiple studies have investigated balance in reference to vision, strength, vestibular function, proprioception, and sensation. However, most of these studies have utilized geriatric, athletic, or injured populations focusing on static

balance measures. **PURPOSE:** Although there are multiple factors that play a role in balance, the purpose of this study was to assess the influence of ankle flexibility on dynamic single leg balance in fit and unfit males. **METHODS:** Twenty-five male subjects (age = 22 ± 2 years; ht. = 179 ± 7 cm; wt. = 85.6 ± 15 kg) were recruited for this study. Ankle flexibility (which includes dorsiflexion, plantarflexion, eversion, and inversion) was measured in degrees for both legs with a goniometer. Subjects then completed four trials, of which the first two trials were familiarization, of the single leg balance test for each leg on a dynamic balance system. Mean stability index (SI) was calculated for the last two trials and both a Pearson Correlation and Independent T-test were utilized. **RESULTS:** No significant correlations between overall stability and dorsiflexion (p = 0.899), plantarflexion (p = 0.790), eversion (p = .704), and inversion (p = .550) on the left and right ankle were present (p < 0.05). However, there was a significant correlation between inversion of the left ankle and medial/lateral SI (p = 0.022); and between dorsiflexion of the left ankle and anterior/posterior SI (p = 0.049). No significant differences for ankle flexibility or SI occurred between unfit and fit individuals (p < 0.05). **CONCLUSION:** Results suggest ankle ROM may be a contributing factor in dynamic balance on the non-dominant leg.

The Relationship Between Perception Of Ankle Instability And Dynamic Balance In Individuals With A History Of Ankle Sprains

Melanie Hudson¹, Kimberly Migliarese¹, Thomas Wagnon¹, Kristen Jagger², Adrian Aron¹, Stephen Glass¹, Brent Harper³.
¹Radford University, Roanoke, VA. ²Regis University, Denver, CO. ³Chapman University, Irvine, CA. (Sponsor: Trent Hargens, FACSM)
 (No relevant relationships reported)

PURPOSE: Ankle sprains are common injuries which can progress to chronic ankle instability (CAI) and balance impairments. While objective data guide treatment for individuals with CAI, the patient's subjective experience is often overlooked and not counted in the adoption of plan of care. Individual perception of ankle instability is an important factor and has the potential to influence presentation of sensorimotor impairments either through neuromotor or fear-avoidance mechanisms. The purpose of this study was to explore the contribution of perception of unilateral and bilateral CAI on a dynamic balance test.

METHODS: Subjects were males and females 18-35 years old (n=25, age= 23.8 ± 1.8 yr.). All subjects completed the Cumberland Ankle Instability Tool (CAIT) to measure perceived ankle instability (lower CAIT scores are associated with greater perceived instability). Dynamic balance was assessed using 3 repetitions in each direction (anterior, postero-medial, and postero-lateral) of the Y-Balance Test (YBT). Asymmetries in CAIT scores and reach distances were calculated by subtracting right leg values from left leg values. Further comparisons were analyzed between groups of bilaterally highest (>80%) and lowest (<20%) combined CAIT scores.

RESULTS: There was a significant positive moderate correlation between CAIT asymmetries and asymmetries in the anterior reach (r=0.526, p=0.007) and the posteromedial reach scores (r= 0.554, p=0.004). Significant differences were found between participants with the highest (n=5) and lowest (n=5) bilateral CAIT scores in right posteromedial reach (101.60 ± 9.91 vs 86.80 ± 5.89, p=0.02), right posterolateral reach (96.40 ± 7.70 vs 76.80 ± 4.87, p=0.001), and right composite score (89.96 ± 5.93 vs 78.44 ± 3.85, p=0.007).

CONCLUSION: Subjects reporting increased perceived ankle instability demonstrated decreased YBT performance on the side of perceived instability. Decreased reach distances may be attributable to neuromuscular consequences of ankle injury, changes in movement strategy associated with apprehension, or both. In fact, the larger the perceived asymmetries the greater the performance deficits. These findings may help clinicians contextualize sensorimotor assessment results in patients with a history of ankle sprain.

Static Platform Model Evaluation For Study Of Sudden Ankle Movement.

Leandro Santos, Júlia Greve, Angélica Alonso, Raul Bolliger, César Augusto. Universidade de São Paulo, São Paulo - SP, Brazil.
 Email: leandro.dias@usp.br
 (No relevant relationships reported)

PURPOSE: Ankle sprains are very common in sports and can cause joint instability with clinical and performance consequences. The sudden ankle inversion platform that simulates the sprain movement evaluates the movements performed associated with the electromyography of the fibular and anterior tibial muscles. The aim of this research is to develop a sudden ankle inversion platform limited to 15° medial rotation, 20° plantar flexion, 20° inversion, and to evaluate the mechanical sprain movement associated with the electromyographic response of the fibular and anterior tibial muscles of soccer players. **METHODS:** A total of 30 soccer players between 16 and 19 years

old without history of ankle sprain were studied at the ankle assessment platform. Each athlete was randomly subjected to ankle sprain movement on the platform for 10 repetitions (five on each limb), associated with electromyography of the anterior tibial and fibular muscles. Friedman statistical tests were performed with related samples of nonparametric quantitative data, in cases where there was significance ($p < 0.05$) Dunn's post-test was performed. **RESULTS:** There was no statistical difference ($p > 0.05$) between latency of movement (0.9 ± 0.2 ms) and to reach the maximum range of motion during plantar flexion (78 ± 4.2 ms) and medial rotation (120 ± 2.3 ms). There was an increase in the angular velocity of inversion ($p < 0.05$) during the attempts (230 ± 20.6 °/s). There was no difference ($p > 0.05$) in latency time of the anterior tibial (25 ± 5.2 ms) and fibular muscles (33 ± 4.1 ms). **CONCLUSION:** The sudden static platform was reliable to evaluate the movements performed by the ankle during mechanical sprain, with no difference in the mechanical and electromyographic behavior evaluated during the 10 repetitions.

388 Board #204 May 27 9:30 AM - 11:00 AM
Side Comparison Of Knee Muscle Activities In Response To Perturbed Walking Of Unilateral Ankle Instability

Alexandra Nair, Chiao-I Lin, Mina Khajooei, Mika Heikkila, Tilman Engel, Frank Mayer. *University of Potsdam, Potsdam, Germany.*
 Email: alexandra.nair@hotmail.fr
 (No relevant relationships reported)

Acute ankle sprain leads in 40% of all cases to chronic ankle instability (CAI). CAI is related to a variety of motor adaptations at the lower extremities. Previous investigations identified increased muscle activities while landing in CAI compared to healthy control participants. However, it remains unclear whether muscular alterations at the knee muscles are limited to the involved (unstable) ankle or are also present at the uninvolved leg. The latter might potentially indicate a risk of ankle sprain or future injury on the uninvolved leg. **Purpose:** To assess if there is a difference of knee muscle activities between the involved and uninvolved leg in participants with CAI during perturbed walking. **Method:** 10 participants (6 females; 4 males; 26 ± 4 years; 169 ± 9 cm; 65 ± 7 kg) with unilateral CAI walked on a split-belt treadmill (1m/s) for 5 minutes of baseline walking and 6 minutes of perturbed walking (left and right side, each 10 perturbations). Electromyography (EMG) measurements were performed at biceps femoris (BF) and rectus femoris (RF). EMG amplitude (RMS; normalized to MVIC) were analyzed for 200ms pre-heel contact (Pre200), 100ms post heel contact (Post100) and 200ms after perturbation (Pert200). Data was analyzed by paired t-test/Wilcoxon

test based on presence or absence of normal distribution (Bonferroni adjusted α level $p \leq 0.0125$). **Results:** No statistical difference was found between involved and uninvolved leg for RF (Pre200: $4 \pm 2\%$ and $11 \pm 22\%$, respectively, $p = 0.878$; Post100: 10 ± 5 and $18 \pm 31\%$, $p = 0.959$; Pert200: $6 \pm 3\%$ and $13 \pm 24\%$, $p = 0.721$) as well as for BF (Pre200: $12 \pm 7\%$ and 11 ± 6 , $p = 0.576$; Post100: $10 \pm 7\%$ and $9 \pm 7\%$, $p = 0.732$; Pert200: 7 ± 4 and $7 \pm 7\%$, $p = 0.386$). **Discussion:** No side differences in muscle activity could be revealed for assessed feedforward and feedback responses (perturbed and unperturbed) in unilateral CAI. Reduced inter-individual variability of muscular activities at the involved leg might indicate a rather stereotypical response pattern. It remains to be investigated, whether muscular control at the knee is not affected by CAI, or whether both sides adapted in a similar style to the chronic condition at the ankle.

A-48 Free Communication/Poster - Biomechanics of Clinical Tests

Wednesday, May 27, 2020, 9:30 AM - 12:00 PM
 Room: CC-Exhibit Hall

Correlations Between Dual-task Costs In Clinic Versus Laboratory Movements

Patrick D. Fischer, Sean M. Callahan, James N. Becker, Keith A. Hutchison, Scott M. Monfort. *Montana State University, Bozeman, MT.*
 Email: patrick.fischer2@student.montana.edu
 (No relevant relationships reported)

Identifying increases in injury-relevant biomechanics when athletes are distracted by a secondary task may be important for assessing performance and injury risk in athletic environments. It is unknown if this dual task cost (DTC) measured during detailed motion capture testing is associated with DTC on simple clinical tests. Such a relationship may prove useful for improving clinically feasible return-to-play assessments.

PURPOSE: Investigate whether dual-task ability spans clinical and laboratory methods of assessment. **METHODS:** Twenty-three female soccer players (21 ± 3 yrs, 1.7 ± 0.1 m, 64 ± 10 kg) completed an agility drill requiring two 90° turns and one 180° turn. This was completed in isolation (baseline) and under three dual-task conditions: counting backwards by seven (S7), dribbling a soccer ball (BH), and combined ball dribbling and counting tasks (BHS7). Agility drill DTC (aDTC) was calculated as the percent change in completion time between dual-task and baseline conditions. A jump-land-jump task from a 30 cm box was also completed while 3D kinematics and kinetics were recorded. Dual task jump conditions included working memory (WM), working memory + visual attention task (WMV), and unanticipated working memory + visual attention task (UWMV) tasks. Biomechanical DTC (bDTC) was calculated as the percent change in peak knee valgus moment (pkVM) between dual-task jump landings and a single-task jump landing. Spearman's rho correlations were run between all combinations of aDTC and bDTC (Figure 1). **RESULTS:** Increases in aDTC for the S7 condition were associated with increases in bDTC for the WMV ($p = 0.49$, $p = 0.02$) and the WM ($p = 0.43$, $p = 0.04$) conditions. No other relationships reached significance (i.e., $p > 0.05$). **CONCLUSION:** Dual-task ability spanned clinical and laboratory assessments when the secondary task was an anticipated cognitive task. Further research is needed to establish the clinical utility of these relationships.

Figure 1: Spearman's Rho correlations for aDTC vs bDTC: (A) S7 vs WMV, (B) S7 vs WM, (C) S7 vs UWMV, (D) BH vs WMV, (E) BH vs WM, (F) BH vs UWMV, (G) BHS7 vs WMV, (H) BHS7 vs WM, and (I) BHS7 vs UWMV. * Indicates $p < 0.05$

Relationships Between Feedforward And Feedback Movement Control Strategies And The Star Excursion Balance Test.

Kristin A. Johnson. *University of Iowa, Iowa City, IA.*
 Email: kristin-a-johnson@uiowa.edu
 (No relevant relationships reported)

PURPOSE: The Star-Excursion Balance Test (SEBT) is commonly used to assess dynamic balance. While the maximum reach distance (MRD) of the posteromedial (PM) direction of the SEBT is lower in individuals with ankle and knee dysfunction, we do not know whether MRD relates to feedforward and feedback movement control strategies. The purpose of this study was to assess the relationships between MRD of PM-SEBT and muscle activation levels, reflex responses to unexpected perturbations, and kinematics during a single-leg squatting (SLS) task.

METHODS: 20 healthy participants performed the PM-SEBT and two, 9-condition SLS tasks on a custom-built device, once with a flexing and once with an upright trunk. SLS conditions varied by speed and resistance with one random perturbation induced per condition. Sagittal motion was captured via Vicon. EMG were recorded from the Quadriceps (Q), Hamstrings (H), Gluteus Medius (GMed), and Soleus (Sol). EMG and kinematics during feedforward (FF) (-50-0 ms) and feedback (short-latency reflex (SLR) 0-50ms, long-latency reflex (LLR) 50-200ms) motor control were compared to MRD. Pearson Correlations were calculated for SLS EMG and kinematics (hip, knee, and ankle) to MRD. Step-Wise Regression to predict MRD was performed using significantly correlated SLS variables.

RESULTS: Significant correlations between SLS EMG and MRD: FF H (Flexing: $p=0.014$, $R=-0.540$; Upright: $p=0.015$, $R=-0.537$), SLR H (Flexing: $p=0.044$, $R=0.454$; Upright: $p=0.017$, $R=-0.528$), SLR QH Ratio (Flexing: $p=0.020$, $R=-0.516$), LLR H (Flexing: $p=0.007$, $R=-0.581$; Upright: $p=0.011$, $R=-0.557$), and LLR QH Ratio (Flexing: $p=0.042$, $R=0.458$). Significant correlations between SLS kinematics and MRD: SLR Hip flexion (Flexing: $p=0.018$, $R=-0.522$) and LLR Hip flexion (Flexing: $p=0.021$, $R=-0.512$). Step-wise regression results: LLR H Flexing explained 33.8% of the variance in MRD ($p=0.007$, $R=-0.581$).

CONCLUSIONS: Greater Hamstrings activation during feedforward and feedback control (SLR, LLR) and greater hip flexion during feedback control of a perturbed single-leg squatting task were associated with poorer dynamic balance during the PM-SEBT.

Sex Differences In Lower Extremity Kinematics During Overhead And Single Leg Squat Tests

Peter Lisman, Joshua N. Wilder, Joshua Berenbach, James J. Foster, Bethany Essalhi. *Towson University, Towson, MD.*
 Email: plisman@towson.edu
 (No relevant relationships reported)

The Overhead Squat (OHS) and Single-Leg Squat (SLS) are two clinical tests commonly used by sports medicine practitioners to identify high-risk biomechanical movement patterns. Traditional scoring of these tests requires subjective judgement whereas new technology has allowed for automatic scoring and additional objective data. To date, few studies have examined sex differences in OHS and SLS performance and none measured with a marker-less motion capture system. **PURPOSE:** To determine if biomechanical differences exist between male and female collegiate athletes during performance of an OHS and SLS. **METHODS:** 75 female (18.1±0.4y; 166.9±6.5cm; 64.1±10.2kg) and 58 male (18.7±1.2y; 184.4±7.1cm; 86.9±15.2kg) collegiate athletes completed OHS and SLS testing as part of their pre-participation exam. Men's sports included football (n=24), baseball (n=19), lacrosse (n=10), and swimming (n=5); women's sports included track and field (n=23), field hockey (n=12), softball (n=12), lacrosse (n=9), swimming (n=7), soccer (n=6), golf (n=3), tennis (n=2), and gymnastics (n=1). Participants completed 4 OHSs followed by 4 SLSs on each leg. A Microsoft Kinect sensor using Athletic Movement Assessment software (PhysiMax®) was used to measure all kinematic variables. Differences between males and females were assessed with independent *t*-tests. **RESULTS:** For the OHS, males displayed greater peak knee varus (M: 25.7°±9.6°, F: 19.8°±8.2°; $P<0.001$), peak hip flexion (M: -93.6°±14.41°, F: -86.9°±14.5°; $P<0.05$), and peak trunk flexion angles (M: 11.5°±10.9°, F: 6.3°±9.2°; $P<0.01$). Females displayed greater peak ankle dorsiflexion angles (F: -28.7°±5.8°, M: -26.5°±6.3°; $P<0.05$). For the SLS (dominant limb), males displayed greater peak trunk flexion (M: 32.2°±5.6°, F: 27.6°±6.6°; $P<0.001$) and lateral pelvic angles (M: 4.2°±3.9°, F: 2.9°±2.7°; $P<0.05$). For the non-dominant limb, females displayed greater peak knee valgus angles (F: -12.5°±9.1°, M: -8.9°±9.1°; $P<0.05$) whereas males displayed greater peak trunk flexion angles (M: 31.7°±5.5°, F: 27.5°±6.9°; $P<0.001$). **CONCLUSION:** Male and female collegiate athletes displayed different movement strategies during performance of an OHS and SLS. Injury prevention programs may need to target sex-specific biomechanical patterns to improve movement capacity.

Difference In Healthy Male & Female EMG Activity During The Y Balance Test

Navpreet Kaur, Kunal Bhanot, Germaine Ferreira. *University of Saint Augustine for Health Sciences, AUSTIN, TX.* (Sponsor: Dr. John Mercer, FACSM)
 Email: nkaur@usa.edu
 (No relevant relationships reported)

Y balance test kit™ (YBT) is commonly used for the clinical assessment of dynamic balance. YBT is an instrumented version of the Star Excursion Balance test (SEBT) that has Anterior (A), Posteromedial (PM), and Posterolateral (PL) directions of the SEBT. Reach distance and kinematic difference on the YBT have been reported to differ across gender.

PURPOSE: To compare muscle activity of the lower extremity muscles between males and females on YBT on the stable and unstable surfaces.

METHODS: Surface EMG was collected on 10 male and 10 female healthy adults for gluteus maximus, gluteus medius (GMED), medial hamstrings, biceps femoris, vastus medialis, rectus femoris, vastus lateralis, anterior tibialis (AT), and medial gastrocnemius (MG) on the stance leg while performing YBT during stable and unstable conditions. During stable condition, the participant stood on the YBT kit to perform the test. Same activity was also performed on the unstable surface that was introduced using Theraband™ stability trainer which was placed on top of the foot placement site of the YBT kit. Independent *t* test assessed differences in EMG between males and females for each direction and each muscle during YBT for stable and unstable conditions separately with α at 0.05. EMG were reported as the percentage of the maximal voluntary isometric contraction (%MVIC).

RESULTS: Females showed significantly higher EMG than males for GMED (31±16 vs 15±8 %MVIC; $P=0.01$), AT (61±14 vs 42±14 %MVIC; $P<0.01$), and MG (60±29 vs 35±20 %MVIC; $P=0.04$) in PL direction on the stable surface. Similarly, on unstable surface females showed significantly higher EMG than males for TA in A (52±9 vs 35±8 %MVIC; $P<0.01$), PM (55±17 vs 37±14 %MVIC; $P=0.02$), and PL (67±18 vs 43±10 %MVIC; $P<0.01$) directions and for MG in A (61±22 vs 36±19 %MVIC; $P=0.01$) and PL (74±34 vs 42±22 %MVIC; $P=0.02$) directions of the YBT.

CONCLUSIONS: Females produced higher muscle activity than males mostly for the ankle muscles irrespective of the surface. Higher muscle recruitment could be an indication of reduced muscle strength in females. This difference in the muscle activation among the genders maybe one of the factors for increased susceptibility of female athletes to injuries.

Kinetic Factors Influencing Y-Balance Test Performance Kinetic Factors Influencing Y-Balance Test Performance

Sam Nelson, Scott Wilson, Sara Skammer, James Becker. *Montana State University, Bozeman, MT.*
 Email: james.becker4@montana.edu
 (No relevant relationships reported)

The Y-Balance Test (YBT) is a movement screen which assesses dynamic stability and neuromuscular control of the lower extremity. Several studies have analyzed kinematic predictors of YBT performance, but kinetic factors determining YBT performance are not well understood. **PURPOSE:** To determine relationships between sagittal, frontal, and transverse plane joint kinetics and YBT performance. **METHODS:** 31 healthy individuals (15M, 16F; age 23.1 ± 7.3; height 172.3 ± 9.1 cm; mass 59.05 ± 9.8 kg) participated in this study. Whole body kinematics were recorded using a motion capture system while dominant limb YBT trials were performed on a single force plate. Joint moments were calculated using inverse dynamics. Maximum reach distances normalized to leg length in the anterior (A), posterior-medial (PM), and posterolateral (PL) directions were calculated. Joint moment values at maximum reach in each direction were determined. All joint kinetic variables which were correlated with max reach distances at the $p < 0.1$ level were entered into a stepwise linear regression. **RESULTS:** In the A direction, a model containing knee extensor moment explained 21% of the variance in reach distance ($p = .01$). In the PM direction, a model containing hip extensor and knee rotator moments explained 67% of the variance in reach distance ($p < .001$). In the PL direction, a model containing hip extensor moments explained 34% of the variance in reach distance ($p=.001$). **CONCLUSIONS:** Performance on the YBT is primarily influenced by the joint moments at the hip and knee. These results support previous claims that YBT performance is an indicator of neuromuscular control of the lower extremity, and at the hip and knee in particular. Further studies should evaluate the extent to which muscular strength influences both the moments generated during YBT and relationships between joint kinetics and YBT performance.

Table 1: Stepwise multivariable regression results for relationship between joint moments at peak reach direction and YBT performance.

Reach Direction	Variables in Final Regression Model	Beta	p-value	Lower 95%	Upper 95%
Anterior	Knee extensor moment (Nm/kg)	0.044	0.01	0.012	0.077
Posteromedial	Hip extensor moment (Nm/kg)	-0.125	<0.001	-0.175	-0.076
	Knee rotator moment (Nm/kg)	-0.248	<0.001	-0.362	-0.134
Posterolateral	Hip extensor moment (Nm/kg)	-0.164	0.001	-0.251	-0.076

The Association Between Previous Injury And Two Lower Extremity Functional Tests

Sara Chatham, Meghan Warren, Monica Lininger. *Northern Arizona University, Flagstaff, AZ.* (Sponsor: Lynda Ransdell, FACSM)
Email: sac352@nau.edu
(No relevant relationships reported)

Previous injury to the lower extremity may increase an athlete's risk for future injury. Functional screening is one way to determine if an athlete is at a higher risk of future injury. By assessing athletes' performance on these tests, there is potential for medical providers to implement intervention strategies to decrease risk of future injury. **PURPOSE:** To determine the association between previous history of injury and two lesser known lower extremity functional tests, the single-leg hip bridge (SLHB) and the single-leg wall-sit (SLWS). **METHODS:** Sixty-eight recreationally active (participation in exercise or sports for at least 3 days per week for 30 minutes) individuals completed this cross-sectional study. Each participant completed continuous repetitions of a SLHB until failure and repeated on the contralateral leg, as well as a SLWS test, bilaterally, where they were required to hold a single-leg wall sit position until failure. Simple linear regression models were conducted to assess the association between previous injury and the SLHB score and SLWS time. A Poisson regression model was used to assess the association with previous injury for the right and left leg scores on the SLHB. **RESULTS:** Seventy participants were screened for this study. Of the 70, 2 were excluded, leaving 68 total participants (21 men, 22.4 ± 5.7 years old, 181.96 ± 6.78 cm, and 78.66 ± 10.60 kg and 47 women, 23.3 ± 1.7 years old, 166.30 ± 9.06 cm, and 66.22 ± 9.99 kg). Twenty-five (37%) participants self-reported a previous injury. There was a statistically significant association between a previous injury and the SLHB for the right leg (Relative Risk (RR) = 0.93; 95% Confidence Interval (CI): 0.76-0.93), but not statistically significant association between previous injury and SLHB for the left leg (RR = 0.98; 95% CI: 0.86-1.05). There was no statistically significant association between the SLWS time on either the right (mean difference = 5.57 seconds; 95% CI: -14.17-3.04) or left (mean difference = 5.68 seconds; 95% CI: -13.37-2.02) with previous injury. **CONCLUSION:** These findings indicate that previous injury to the lower extremity may not affect SLWS time. The SLHB count could be affected depending on the side the injury was on, but additional research is warranted.

Reliability Estimates Of The Tuck Jump Assessment Following A Standardized Training Session

Monica Lininger¹, Kevin Racine¹, Craig Smith², Meghan Warren¹. ¹Northern Arizona University, Flagstaff, AZ. ²Smith Performance, Tucson, AZ.
Email: monica.lininger@nau.edu
(No relevant relationships reported)

The Tuck Jump Assessment (TJA), is a "clinician-friendly" test used to assess technique flaws during a 10-second, high intensity, jumping bout. Although the TJA has broad clinical applicability, there is no standardized training to maximize the measurement properties of the TJA. **PURPOSE:** To determine the reliability of the TJA using a variety of healthcare professionals following an online standardized training program. **METHODS:** A website was created by a physical therapist (PT) with videos and written descriptors of the 10 TJA technique flaws and examples of what constituted no flaw, minor flaw, or major flaw (0,1,2) using published standards. The website content was then validated (both face and content) by 4 experts (2 athletic trainers (AT) and 2 PTs). Three raters of different professions: a PT, an AT, and a Strength and Conditioning Coach Certified (SCCC), were selected due to their expertise with injury and athletic performance. The raters scored 41 videos of participants' TJAs after reviewing online standardized training scored the same 41 videos 2 weeks later. Reliability estimates were determined using intraclass correlation coefficients (ICCs) for summative scores of the 10 flaws and Krippendorff α (K α) for the individual technique flaws (ordinal). **RESULTS:** Of all individual technique flaw reliability estimates, only 11 (50 total) were above the acceptable level (K α = 0.80). The summative score had moderate interrater reliability in both sessions (Session 1: ICC_{2,2} = 0.64; 95% CI (Confidence Interval) (0.34-0.81); Standard Error Measurement (SEM) = 0.66 flaws and Session 2: ICC_{2,2} = 0.56; 95% CI (0.04-0.79); SEM = 1.30). Rater 1 (PT) had a good reliability (ICC_{2,2} = 0.76; 95% CI (0.54-0.87); SEM = 0.26),

rater 2 (SCCC) had a moderate reliability (ICC_{2,2} = 0.62; 95% CI (0.24-0.80); SEM = 0.41) and rater 3 (AT) had excellent reliability (ICC_{2,2} = 0.98; 95% CI (0.97-0.99); SEM = 0.01). **CONCLUSION:** All raters, across professions, had at least good reliability estimates for the summative score; yet the same level of consistency was not seen when evaluating each technique flaw. These findings suggest that the summative score may not be as accurate when compared to individual technique flaws, and should be used with caution.

396 Board #212 May 27 9:30 AM - 11:00 AM

Serial 7'S Do Not Discriminate Between Sports-related Concussion And Controls: Alternative Dual-task Paradigms

Tori Humiston, Sushma Alphonsa, Cameron Kissick, Madison R. Taylor, Philip Pavilonis, Brian Szekeley, Nora Constantino, Nicholas G. Murray. *University of Nevada, Reno, Reno, NV.*
Email: thumiston@nevada.unr.edu
(No relevant relationships reported)

Dual-task (DT) tandem gait has been used as a viable, functional task of postural stability and cognitive changes following a sports-related concussion (SRC). Additionally, completing tasks that test cognitive abilities during DT, such as serial 7's, is thought to capture cognitive changes. However, current methods of collecting DT information may not have sensitive psychometric properties. **PURPOSE:** The purpose of this study was to examine differences in time and errors in DT tandem gait testing between NCAA Division I athletes with and without SRC. **METHODS:** 13 Division I athletes with sports-related concussion (SRC: 6 males and 7 females, age=20±1) and 13 nearly-matched controls (CON: age=19±1) completed three trials of DT tandem gait using the Tekscan Strideway (100Hz, Boston, MA). All SRC participants had a medically-verified SRC and were assessed within 24-48 hours post-injury. All CON assessments were collected during pre-season. In the DT condition, all participants completed serial 7's subtraction with random numbers between 50-100. Data collected for tandem gait trials included time to complete the walking task and number of errors emitted. **RESULTS:** Paired t-tests were used to assess the differences across the average time and errors across trials. Results indicate that the SRC group (M time=23.7±7.5s) took significantly longer to complete DT compared to the CON group (M time=17.2±5.1s, p=0.03, d=1.0). Total amount of errors emitted during the DT were not significantly different (SRC: M errors=1.3±1.6, CON: M errors =0.7±0.6, p=0.18, d=0.49). **CONCLUSIONS:** Only time in DT trials appears to be a viable method of discriminating between participants who experienced an SRC compared to those without SRC. This indicates that errors emitted during a serial 7's task may not provide meaningful information regarding cognitive changes following SRC. Extant literature indicates that serial 7's may be a favored task among researchers, however, alternative tasks may provide a more sensitive measure of cognitive changes. Future research should examine the use of alternative tasks, such as an auditory Stroop task, which may provide more clinically meaningful data.

Objectively Measured Physical Activity During The First Trimester And Glucose Tolerance At 24-28 Weeks Gestation

Samantha F. Ehrlich¹, Monique M. Hedderson², Susan D. Brown², Scott E. Crouter, FACSM¹, Paul R. Hibbing¹, Juanran Feng², Ai Lin Tsai², Assiamira Ferrara². ¹UTK, Knoxville, TN. ²Kaiser Permanente Northern California, Oakland, CA.
Email: sehrlic1@utk.edu
(No relevant relationships reported)

Physical activity (PA) during pregnancy may improve glucose tolerance and reduce the risks of adverse outcomes associated with pregnancy hyperglycemia (e.g., pregnancy and delivery complications, delivering a large infant, and developing diabetes later in life), yet the evidence to date has primarily relied on self-reported PA via questionnaire. **PURPOSE:** To examine whether objectively measured PA during the first trimester of pregnancy is associated with glucose tolerance at 24-28 weeks' gestation. **METHODS:** Study participants (n=261) were a subsample of the Gestational Weight Gain and Optimal Wellness (GLOW) trial conducted at Kaiser Permanente Northern California in 2014-2016 to test whether a lifestyle intervention prevents excess gestational weight gain in women with overweight/obesity, as compared to usual medical care. Participants wore an ActiGraph wGT3X-BT for 7 days on the non-

dominant wrist during the first trimester. Valid measurements were defined as having ≥ 600 minutes of wear time [by the algorithm of Choi et al. (MSSE, 2012)] on 4 days, including 1 weekend day. Wrist-specific two-regression algorithms [Hibbing et al. (MSSE, 2018)] were used to estimate daily minutes of moderate to vigorous intensity PA (MVPA), light PA (LPA), and sedentary behavior (SB). Minutes per day of MVPA, LPA, and SB were then combined into weighted (i.e., weekend day vs. weekday) averages. Plasma glucose values from a random, 50-g 1-hour glucose challenge test (GCT) performed at 24-28 weeks' gestation were obtained from the Kaiser Permanente Northern California electronic health records. Associations of MVPA, LPA and SB (i.e., log transformed) with glucose were estimated by linear regression and adjusted for age, race-ethnicity, BMI category, and GLOW trial randomization (i.e., intervention vs. usual care). **RESULTS:** The cohort had a median 38 (IQR= 37) minutes per day of MVPA, 248 (81) minutes per day of LPA, and 389 (97) minutes per day of SB. The median plasma glucose value on the GCT was 112 mg/dl (35). None of the PA variables were statistically significantly associated with plasma glucose ($p > .05$ for MVPA, LPA, and SB). **CONCLUSION:** Objectively measured PA, assessed over 7 days during the first trimester of pregnancy, does not appear to impact glucose tolerance at 24-28 weeks gestation in women with overweight/obesity.

398 Board #214 May 27 10:30 AM - 12:00 PM
Patterns Of Sedentary Behavior In Pregnant Women During The Third Trimester

Meghan Baruth, Rebecca A. Schlaff, FACSM. *Saginaw Valley State University, University Center, MI.* (Sponsor: Rebecca A Schlaff, FACSM)
 Email: mbaruth@svsu.edu
 (No relevant relationships reported)

The amount of time spent in sedentary behaviors is higher in pregnant populations compared to non-pregnant populations. Time spent in sedentary behaviors has also been shown to increase across trimesters. **PURPOSE:** To describe patterns of sedentary behavior in a sample of pregnant women in their third trimester. **METHODS:** Participants were enrolled in a behavioral physical activity and dietary intervention. Participants wore an accelerometer on their right hip for all waking hours for seven consecutive days during the third trimester (~35 weeks gestation). Participants had to wear the monitor for a minimum of 10 hours/day, on at least 3 days to be included analyses. Sedentary time was defined as any count <100 counts/minute. Sedentary behaviors were quantified (mean \pm SD, or %) as total volume (% of day), % of morning (6am-12pm), afternoon (12pm-6pm), and evening (6pm-12am); % of weekday and weekend; number and length of bouts; and total number and length of breaks from sedentary behavior. **RESULTS:** Participants (n=29) were on average 29.0 \pm 4.4 years of age and had a pre-pregnancy BMI of 26.6 \pm 7.2 kg/m². A majority of participants were White (75.0%), married (86.2%) and had a college degree (58.6%). Women spent 63.8% of waking hours sedentary (549.5 \pm 153.5 minutes), engaging in 77.2 \pm 17.7 total bouts per day, with each lasting on average, 7.7 \pm 2.4 minutes. Time spent sedentary was similar across (1) time of day: 62.8% of morning, 62.5% of afternoon, and 63.2% of evening and (2) type of day: 64.2% weekdays and 62.9% of weekend days. Women took 76.8 \pm 17.6 breaks from sedentary behavior per day, each lasting 4.0 \pm 0.9 minutes. **CONCLUSION:** Emerging evidence suggests that sedentary behavior during pregnancy can have a negative impact on maternal and child outcomes. Our findings suggest that women in their third trimester, even while participating in a behavioral physical activity intervention, spent a majority of their waking hours engaged in sedentary behaviors. Interventions that address challenges commonly seen during the latter part of pregnancy (e.g. fatigue, body size, swelling, etc.) are needed to help reduce time spent sedentary. Increasing light intensity activity (vs. moderate intensity) may be an appropriate place to start.

399 Board #215 May 27 10:30 AM - 12:00 PM
Heart Rate Response Is Influenced By Antenatal Physical Activity On The Third Trimester.

Olga Roldan-Reoyo¹, Melitta McNarry¹, Kelly Mackintosh¹, Lidia Romero-Gallardo², Laura Baena-Garcia², Michael J. Lewis¹. ¹SWANSEA UNIVERSITY, SWANSEA, United Kingdom. ²GRANADA UNIVERSITY, GRANADA, Spain.
 Email: olga.roldanreoyo@swansea.ac.uk
 (No relevant relationships reported)

Pregnancy represents a potent stimulus to the cardiovascular system, eliciting significant hemodynamic adaptations. The factors that mediate these adaptations are largely unknown; whilst habitual PA does not influence resting cardiac function during pregnancy, whether it influences the hemodynamic adaptations observed during exercise is unclear. **PURPOSE:** This study sought to determine whether PA during pregnancy influences the antenatal cardiac response to acute exercise, assessed via heart rate (HR) and stroke volume (SV). **METHODS:** Twenty-three pregnant women participating in the 'PE-CAMP' randomized controlled trial underwent physiological assessment at 34-36 weeks gestation. HR and SV were continuously recorded using the Task Force Hemodynamic

Monitor during rest (5-min), during exercise on a cycle-ergometer at a workload equivalent to 40-60% HR reserve (15-min), and during post-exercise recovery (20-min). Antenatal PA levels were measured for seven consecutive days during T2 (18-22 weeks gestation) and T3 (34-36 weeks gestation), using a wrist-worn accelerometer. A two-step bootstrapped hierarchical regression model examined the influence of four predictor variables (age, Body Mass Index (BMI), and total PA volume (light, moderate and vigorous) in 2T and 3T on HR and SV.

RESULTS: Regression analysis revealed significant influences on mean HR at exercise ($R=.907$; $R^2=.823$; $F(3, 17)=8.147$; $p=.009$) with PA-3T as strongest predictor ($b=.133$; $p=.005$); and on mean HR at recovery ($R=.839$; $R^2=.704$; $F(3, 17)=4.154$; $p=.049$) where PA-3T and BMI were significant predictors ($b=.196$; $p=.007$) and ($b=1.887$; $p=.049$) respectively. PA-3T was predictive of minimum HR at rest ($b=.128$; $p=.041$), as well as BMI was for minimum HR at recovery ($b=1.739$; $p=.033$). **CONCLUSIONS:** Higher levels of PA in 3T increase HR values in the different stages of an exercise protocol. Whether this is a cardiac adaptation due to the pregnancy to higher PA levels needs further investigation; as generally a lower HR would have been expected as a result of an active lifestyle. **Acknowledgement:** This project is funded by the European Union's Horizon 2020 Research and Innovation programme under the Marie Skłodowska-Curie grant agreement No 663830.

"Optimal Physical Activity Cut-off Value" For Preventing Gdm Among Pregnant Women In Beijing

Liuwei Zhang, Hong Ren, Hongjuan Li, Cailiang Zhou, Xiaotong Dai. *Beijing Sport University, Beijing, China.*
 Email: zhangliuwei1988@163.com
 (No relevant relationships reported)

The prevalence of gestational diabetes mellitus (GDM) has rapidly risen during the past decade, and it is considered that GDM contributes to the increasing risk of adverse perinatal outcomes. Physical activity has been reported to be beneficial in improving pregnancy outcomes in pregnant women with GDM, however, there is a lack of evidence-based recommended amounts of physical activity specific for preventing GDM among Chinese pregnant women.

PURPOSE: The study aims to explore the "optimal physical activity cut-off value" for preventing GDM among pregnant women in Beijing, preparing to provide scientific basis for future research of personalized exercise prescription. **METHODS:** A total of 321 pregnant women who took regular prenatal examination in outpatient clinics were finally chosen into the study, including 59 patients with GDM and 262 controls. General information and clinical data of each participant was collected through electronic medical record system, physical activity data was investigated using the short form of International Physical Activity Questionnaires (IPAQ), and physical activity level was calculated based on the standard methods. Difference in means for continuous variables were compared using t-test, and differences in proportions were tested by chi-square test, ROC curve analysis was conducted to screen the "optimal physical activity cut-off value."

RESULTS: Compared with control group, average age (31.62 ± 2.95 vs 29.90 ± 3.34 yrs, $t=3.63$, $P<0.05$), the proportion of participants with low education level (25.42% vs 8.78%, $\chi^2=19.31$, $P<0.05$) and overweight or obese before pregnancy (38.98% vs 24.05%, $\chi^2=7.19$, $P<0.05$) in GDM group are significantly higher. The area under the ROC curve is 0.82(0.77-0.86)($P<0.05$), and the "optimal physical activity cut-off value" is 834 MET*min per week.

CONCLUSIONS: Older age, lower education level and overweight or obese before pregnancy contributes to the risk of GDM. It is recommended that physical activity level of more than 834 MET*min per week, accordingly walking no less than 36 minutes per day is beneficial to reduce the risk of GDM.

 (No relevant relationships reported)

After pregnancy and delivery, dysfunctions, such as alterations in pelvic floor function (PFF), core stability (CS), and aerobic capacity (AC), are common in postpartum women. **PURPOSE:** To observe the differences in PFF, CS, and AC in postpartum women before and after an 8-week functional training program.

METHODS: Sixteen postpartum women (age: 32 \pm 3.0years, ≤ 1 year post-delivery) completed an 8-week functional training intervention (60 minutes each time, 4 times per week). The functional training including pelvic floor muscle bio-feedback training,

T-spine mobility exercise, breathing exercises and inner core activation. Before and after the intervention, a pelvic floor bio-feedback test (PFBFT) was used to assess PFF, a Y-balance test (YBT) and an abdomen muscle endurance test (AMET) were used to assess the CS, and a 3-minute step test (ST) were used to assess the AC. During the YBT, values on three directions (A-anterior, PM-posteromedial, and PL-posterolateral) bilaterally were measured. And, during the AME, three muscle groups (F-Flexor, E-Extensor and bilateral lateral flexor-LFL&LFR) were recorded. Paired t-tests were used to compare the pre- and post-intervention values of all variables.

RESULTS: There were significant differences in pre- and post-intervention values of all variables in these postpartum women following 8-week functional training. Specifically, the PFBFT composite score was improved by 33.8% ($p<0.01$), the YBT scores for the directions of AL, PL, PMR, PLL and PLR were improved by 13.4%, 13.2%, 7.1%, 13.5%, and 8.5%, respectively (all $p<0.01$), the AMET scores for abdomen E, F, LFL and LFR were improved by 56.6%, 30%, 26.5% and 30.1%, respectively (all $p<0.01$), and the ST score was improved by 19.9% ($p<0.05$).

CONCLUSIONS: An 8-week functional training program, improved PFF, AC and CS in postpartum women. Future randomized, controlled studies are needed to confirm these findings.

Examining Barriers To Physical Activity For Breastfeeding Mothers Through A Socioecological Lens

Kailey Snyder¹, Darbi Klinkhammer², ¹Creighton University, Omaha, NE. ²University of Nebraska at Omaha, Omaha, NE.
 Email: KaileySnyder@creighton.edu
 (No relevant relationships reported)

Background: Mothers who are physically active after the birth of a child can experience a range of mental and physical health benefits. However, only 1 in 5 women in the postpartum period are currently meeting physical activity recommendations of 150 minutes of moderate-intensity physical activity per week. Further, breastfeeding women experience additional barriers to physical activity. A multi-system approach is needed to better support breastfeeding women's ability to engage in physical activity. The use of a framework like the socio-ecological model (SEM) provides a unique opportunity to understand barriers to physical activity from perspectives at varying levels (i.e., individual, interpersonal, community, organization and policy). **PURPOSE:** The present study was conducted to examine barriers to physical activity among breastfeeding women from SEM representatives. **METHODS:** A total of 49 representatives were identified at various levels of the SEM based on their occupation or if they were a currently breastfeeding mother. All individuals participated in a telephonic interview between May and August of 2019. A direct content analysis was performed as well as a cross-case analytic strategy to determine differences between level representatives. **RESULTS:** General themes found included a lack of time and lack of ability for self-care. In addition, key differences were seen across SEM levels. For example, representatives of the individual level (breastfeeding mothers) reported lack of time as their critical barrier however those at the interpersonal (significant others) and community level (community lactation counselors) saw the greatest barrier to be associated with an inability to provide self-care due to prioritizing the baby. At the organizational level (healthcare administrators) and policy level (state coordinator; breastfeeding medicine experts) a lack of knowledge or misinformation was more frequently cited. **Conclusion:** Future interventions to increase physical activity among breastfeeding women should recognize the differences seen across SEM levels. Further, interventions should focus on enhancing maternal desire for self-care, opportunities to engage in activity with baby and increasing education on how to be active while breastfeeding.

Impact Of Postpartum Exercise On Maternal Health And Infant Physical Activity And Sleep Behaviours

Stephanie A. Paplinskie¹, Rachel Filler¹, Taniya S. Nagpal², Karishma Hosein¹, Roberta Bgeginski¹, Mollie Manley¹, Chiara Marra³, Giorgia Spigolon³, Silvia Pogliaghi³, Michelle F. Mottola, FACSM¹. ¹Western University, London, ON, Canada. ²University of Ottawa, Ottawa, ON, Canada. ³University of Verona, Verona, Italy. (Sponsor: Michelle F. Mottola, FACSM)
 Email: spaplins@uwo.ca
 (No relevant relationships reported)

Physical activity (PA) has many implications for health, including effects on weight loss, body mass index (BMI), and sleep behaviours. The literature has established a relationship between mother-child physical activity, however, the impact of this interaction is unknown during the postpartum period. **PURPOSE:** To determine if a structured postpartum resistance training intervention with strollers and babies (60 minutes/session, twice/week for 10 weeks) improves maternal health outcomes and if infant physical activity (IPA) levels and infant sleep behaviours (ISB) are impacted. **METHODS:** Forty-six women voluntarily enrolled in the Active Mom, Active Baby

Intervention. Measures were taken at baseline (t1), 5-weeks (t2; mid-intervention), and 10-weeks (t3; post-intervention). At each time point, maternal weight (kg) was used to calculate BMI (kg/m²), and maternal physical activity (MPA) levels were measured using the self-reported International Physical Activity Questionnaire-long form (IPAQ-L). Infants were assessed using the Rothbart Infant Behaviour Questionnaire-Revised (IBQ-R) for PA and sleep behaviours. A nonparametric test was conducted to determine if there was a significant change in maternal weight, BMI, and PA levels (light, moderate, and vigorous) across the intervention. Comparisons in IPA and ISB were made using a one-way ANOVA with repeated-measures. A post hoc comparison was completed using the Bonferroni test through the three time points. **RESULTS:** Maternal age of participants (n=46) was 32.0±3.5 years at 16.6±7.5 weeks postpartum. The results showed a significant ($p<0.001$) decrease in maternal weight (-1.4±0.04kg) and BMI (-0.5±0.005kg/m²) across the intervention. There was no significant difference in light- or moderate- PA in the mother, however, vigorous-intensity PA increased from t1 (214.2±331.3MET-mins/week) to t2 (837.3±516.7MET-mins/week; $p<0.001$) and was maintained until t3 (736.0±582.6MET-mins/week; $p>0.001$). There was a significant increase in scores for IPA from t1 (3.89±0.85) to t2 (4.47±0.83; $p<0.001$) to t3 (4.80±0.93; $p<0.001$). No change in infant sleep behaviour was found between time points. **CONCLUSION:** A postpartum exercise intervention with babies can increase physical activity in both mother and infant, resulting in maternal weight loss.

Prescribed Physical Activity In Postpartum Period Helps Women Increase Physical Activity And Decrease Body Weight

Nicolas D. Knuth, Jaime R. DeLuca. Towson University, Towson, MD.
 Email: nknuth@towson.edu
 (No relevant relationships reported)

New mothers frequently report a lack of adequate physical activity (PA) due to a variety of constraints. PA is an important factor in developing and maintaining a healthy lifestyle and may assist new mothers in returning to pre-pregnancy weight. Despite the potential positive impact of PA on new mothers, PA level during the postpartum period is unknown. **PURPOSE:** To evaluate the impact of a PA intervention in increasing postpartum PA level and weight loss. **METHODS:** Thirty-two postpartum women (mean age=33±3, mean BMI=27.8±5.6 kg/m²) were randomized into control (n=16) and intervention (n=16) groups. The intervention group was instructed to engage in 150 minutes of MVPA each week and take 10,000 steps per day, the control group was given no physical activity prescription. Measures of body weight and PA (by wrist-worn ActiGraph Link accelerometers worn continuously over 7 days) were made at 3, 6, 9, and 12 months postpartum. PA data was expressed as the vector magnitude of counts (VMC) across the three axes. Differences in PA and body weight between groups over time were examined using two-way ANOVA with repeated measures and Tukey post hoc analysis. **RESULTS:** The intervention protocol was successful at increasing women's overall PA during the postpartum period (main effect: $2.9 \times 10^6 \pm 0.4 \times 10^6$ vs. $2.6 \times 10^6 \pm 0.4 \times 10^6$ counts, $p<0.05$) but the only significant differences in PA by time between groups was at the initial 3 month postpartum visit ($2.7 \times 10^6 \pm 0.3 \times 10^6$ vs. $2.4 \times 10^6 \pm 0.4 \times 10^6$ counts, $p<0.05$) as the intervention did not lead to a further significant increases in PA throughout the remainder of the postpartum period. The control group showed a significant increase in PA from the 3 month to the 12 month visit ($2.4 \times 10^6 \pm 0.4 \times 10^6$ vs. $2.8 \times 10^6 \pm 0.4 \times 10^6$ counts, $p<0.05$), ultimately reaching similar PA to that of the intervention group. Body weight was similar at the initial 3 month visit and decreased significantly in both groups during the postpartum period, however the intervention group had a significantly lower body mass by the end of the postpartum period compared to the control group (70.2±14.8 vs. 72.6±16.8 kg, $p<0.05$). **CONCLUSION:** Increased PA habits during the postpartum period may help women more successfully return to pre-pregnancy body weight and reduce the risk for overweight or obesity following childbirth.

Exercise And Nutrition Patterns Of Pregnant Women Self-Selecting For Participation In A Lifestyle Intervention

Karishma Hosein¹, Taniya S. Nagpal², Roberta Bgeginski¹, Harry Prapavessis¹, Barbra de Vrijer¹, Christina G. Campbell³, Stephanie A. Paplinskie¹, Mollie Manley¹, Michelle F. Mottola, FACSM¹. ¹Western University, London, ON, Canada. ²University of Ottawa, Ottawa, ON, Canada. ³Iowa State University, Ames, IA. (Sponsor: Michelle F. Mottola, FACSM)
 Email: khosein2@uwo.ca
 (No relevant relationships reported)

Exercise and healthy eating are integral parts of a comprehensive healthy lifestyle intervention during pregnancy. Women who volunteer to participate in such an intervention in early to mid-pregnancy may already be practicing healthy lifestyle

habits such as walking 10,000 steps/day (active), and consuming 1800-2252 kilocalories/day (kcal), whereas most pregnant woman walk on average 3000-7000 steps/day (sedentary to low active) and consume 1882-2789 kcal/day. As such, intervention participants may not be representative of the general population of pregnant women, especially relating to exercise. **PURPOSE:** To assess the baseline exercise and nutrition patterns of pregnant women who enrol in a healthy lifestyle intervention in London, Canada. **METHODS:** Pregnant women who had self-selected to participate in a nutrition and exercise intervention completed a baseline (12-18 weeks gestation) 3-day step count log and 3-day food intake record (3dFR). Step counts were recorded over 3 consecutive days using a hip-worn pedometer or a wrist-worn activity tracker, and an average was calculated. The 3dFR was completed over the same 3 consecutive days and was analyzed for average energy intake (kcal) using Nutritionist Pro (NP; Axxya Systems). Measured height and self-reported pre-pregnancy weight were used to calculate pre-pregnancy body mass index (BMI). Gestational age at study entry and maternal age were also collected. **RESULTS:** Ninety-seven pregnant women chose to participate in a healthy lifestyle intervention study and completed both the 3-day step count log and 3dFR at baseline. At study entry, mean daily steps were 7399±2741 (low to above normal range) and energy intake was 2305±634 kcal/day (within to above normal range). Pre-pregnancy BMI was 26.2±5 kg/m² (overweight), gestational age was 15±3 weeks, and maternal age was 32±4 years. **CONCLUSION:** Many pregnant women who self-select to participate in a lifestyle intervention in early to mid-pregnancy may already have healthy patterns of exercise and to a lesser extent nutrition. To achieve a more representative sample of pregnant women, interventions could be performed in a clinical setting, which may allow for better identification of effective behaviour change strategies to promote and maintain healthy exercise and nutrition patterns during pregnancy.

A-50 Free Communication/Poster - Protein Metabolism

(No relevant relationships reported)

Purpose: Elevated levels of circulating branched-chain amino acid (BCAA) and ketone bodies are recognized as biomarkers for cardiovascular disease (CVD) and other pathological conditions in type-2 diabetes mellitus (T2DM). Aerobic exercise interventions have previously shown decreases in levels of these markers, suggesting improved metabolic status and reduced risk of CVD. However, the efficacy of resistance training and concurrent programs in reducing BCAA and ketone body levels has not been well researched.

Methods: The current study was performed as a secondary analysis of the HART-D trial, a 9-month randomized, controlled exercise-training trial of 262 participants with T2DM. Participants were randomized to one of four groups; non-exercise control, aerobic training (AT), resistance training (RT), or a combined aerobic-resistance training (ATRT). The effects of the 9-month intervention on BCAAs (leucine, valine, and isoleucine) and ketone bodies (β -hydroxy-butyrate, BHB; acetoacetate, AcAc; and acetone) were examined across groups using generalized linear models adjusting for age, race, sex, and baseline BMI. We performed per-protocol analyses limited to all control participants (n=33) and only the exercise group participants who met the criteria of at least 70% adherence to their exercise prescription for 6 months (AT, n=62; RT, n=55; ATRT, n=64).

Results: AcAc (-17.6 ± 6.4, p=0.006), acetone (-10.6 ± 3.6, p=0.003), and total ketone body (-51.4 ± 20.0, p=0.01) concentrations (shown as mean ± SE in μ mol/L) decreased in the RT group compared to the control group. Acetone also decreased in ATRT compared to the control group (-10.2 ± 3.5 μ mol/L, p=0.004).

Conclusions: Our results suggest that RT and ATRT programs could improve ketone body metabolism in those with T2DM.

407 Board #223 May 27 9:30 AM - 11:00 AM

Does Exercise Intensity Influence Dietary Protein Requirements Of Male Endurance Athletes?

Carolyn P. Adams, Jenna B. Gillen, Daniel W.D. West, Daniel R. Moore. University of Toronto, Toronto, ON, Canada.
(No relevant relationships reported)

Adequate protein intake is important for endurance athletes to replenish exercise-induced amino acid (AA) oxidation and support post-exercise muscle and whole body protein synthesis. High-intensity endurance exercise is associated with increased carbohydrate oxidation during exercise and greater protein turnover (synthesis and breakdown) after exercise relative to lower intensity exercise. Muscle glycogen depletion can increase AA oxidation during exercise and increase daily protein requirements.

PURPOSE: To determine the impact of exercise intensity during prolonged endurance exercise on estimates of dietary protein requirements in endurance athletes. **METHODS:** Eight males (26±3y, 76±16kg; 62±6 ml O₂·kg⁻¹·min⁻¹; mean±SD) completed two trials in a randomized order with exercise (20-km run) performed at a low (LOW; 72±1% HRmax, 55±5% VO_{2,peak}) or high (HIGH; 88±1%HRmax, 75±7% VO_{2,peak}) intensity. After 2 days of exercise and dietary (1.4g·kg⁻¹·d⁻¹ protein) control, participants consumed 0.6g·kg⁻¹ CHO before a 20-km treadmill run with continuous HR monitoring and periodic measurement of gas exchange (indirect calorimetry). During the 8h post-exercise recovery period, participants consumed 8.6g·kg⁻¹·d⁻¹ CHO and hourly meals providing 0.93g·kg⁻¹·d⁻¹ protein as crystalline AA modeled after egg protein, which was enriched with [¹³C]phenylalanine as an indicator AA. Breath and urine were collected at isotopic and metabolic steady state to determine phenylalanine excretion (F¹³CO₂), flux (Q; estimate of protein breakdown), and oxidation (OX; reciprocal of protein synthesis). **RESULTS:** Preliminary analysis (n=6) showed that respiratory exchange ratio during exercise was higher in HIGH vs. LOW (0.92±0.03 vs. 0.88±0.03, p<0.05), which corresponded to a 37% greater CHO oxidation rate in HIGH (3.12±0.76 vs. 1.96±0.52 g·min⁻¹, p<0.01). Exercise duration was shorter in HIGH vs LOW (86±18 vs. 112±23 min, p<0.01). F¹³CO₂ was not different between trials (HIGH: 0.94±0.25 vs. LOW: 0.89±0.14 umol·kg⁻¹·h⁻¹, p>0.05). Urinary analysis is ongoing to determine Q and OX. **CONCLUSION:** Preliminary findings suggest that prolonged, high-intensity endurance exercise increases CHO oxidation during exercise but has little impact on estimates of protein requirements of male endurance athletes.

High And Standard Free-form EAA Intake Equally Stimulate Muscle Protein Synthesis During Moderate Energy Deficit

Jess A. Gwin¹, David D. Church², Adrienne Hatch-McChesney¹, Emily E. Howard¹, Chris T. Carrigan¹, Nancy E. Murphy¹, Marques A. Wilson¹, Lee M. Margolis¹, John W. Carbone³, Robert R. Wolfe², Army A. Ferrando², Stefan M. Pasiakos, FACSM¹. ¹U.S. Army Research Institute of Environmental Medicine, Natick, MA. ²Donald W. Reynolds Institute on Aging, University of Arkansas for Medical Sciences, Little Rock, AR. ³Eastern Michigan University, Ypsilanti, MI. (Sponsor: Stefan M. Pasiakos, FACSM)
(No relevant relationships reported)

BACKGROUND: Muscle protein synthesis (MPS) is regulated by essential amino acid (EAA) intake, postprandial extracellular EAA concentrations, and exercise. During energy balance, consuming approximately 0.10-0.14 g EAA/kg/meal (0.25-0.30 g protein/kg/meal) optimally stimulates MPS after exercise. However, EAA requirements are increased during energy deficit, and whether consuming EAA beyond 0.10-0.14 g/kg/meal further stimulates MPS during energy deficit is unknown.

PURPOSE: Determine the effects of standard and high EAA intake on resting and post-resistance exercise MPS during moderate energy deficit.

METHODS: Nineteen males (mean±SD; age: 22.9±5y; BMI: 25.4±2.7kg/m²) completed a randomized, double-blind crossover study consisting of two, 5d periods of controlled energy deficit (30±4%), separated by a 14d washout. At the end of each energy deficit period, MPS was determined at rest (postabsorptive and postprandial) and post-resistance exercise (postprandial) using a unilateral resistance exercise model and primed, constant ²H₅-phenylalanine infusions. Drinks providing standard (0.10g/kg/meal, 7.87±0.87g) and high (0.30g/kg/meal, 23.5±2.54g) EAA amounts were consumed post-exercise. Circulating EAA concentrations were measured throughout each infusion.

RESULTS: Postabsorptive MPS at rest was not different (p=0.71) between standard (0.047±0.3%/h) and high (0.045±0.02%/h). In the postprandial state, and independent of EAA, MPS at rest (standard, 0.055±0.01%/h; high, 0.061±0.02%/h) and post-exercise (standard, 0.055±0.01%/h; high, 0.065±0.02%/h) was greater than postabsorptive MPS at rest (fed state main effect, p=0.019 and p=0.005). Postprandial MPS at rest and post-exercise did not differ (p=1.0). EAA concentrations were greater in high (peak: 2915±569 μ mol/L; AUC: 228485±54783 μ mol/L/240min) than standard (peak: 1843±497 μ mol/L; AUC: 75727±32254 μ mol/L/240min; both, p=0.001).

CONCLUSION: Despite greater increases in extracellular EAA concentrations for high versus standard EAA intakes and the mechanical stimulus exerted by exercise, the stimulatory effect of varying doses of free-form EAA on MPS are equivalent during moderate energy deficit.

Correlation Between Plasma Creatinine, Lean Body Mass, And Grip Strength In Inactive Vegetarians And Vegans

Eric Bartholomae, April Incollingo, Maricarmen Vizcaino, Christopher Wharton, Carol Johnston. *Arizona State University, Phoenix, AZ.*

(No relevant relationships reported)

In recent years vegetarian diets have increased in popularity. While they have been associated with decreased risk for cardiometabolic diseases, concern remains over the potential of low protein intake, which can lead to reduced muscle mass and strength. Plasma creatinine has been shown to be a reliable marker of muscle mass. **PURPOSE** Examine the relationship between plasma creatinine, lean body mass (LBM), and strength in underactive vegetarian and vegan adults. Additionally, to determine any change in creatinine levels following an 8 week protein supplementation intervention. **METHODS** Twenty-six inactive (<150min exercise/wk) vegetarians and vegans (34y±8.9; n=19 vegan) of at least 1 year participated in this study. This study examined relationships between creatinine, strength, and LBM before and after 8 weeks of supplementation with 18 g/day of mung bean protein. Additionally, change in creatinine levels before and after supplementation was determined between control and experimental groups. Handgrip strength was measured at baseline and week eight. LBM was determined via DEXA. Creatinine was determined via standard assay technique. An *a priori* α of 0.05 was used, and Pearson Product Moment correlation assessed relationships between creatinine, LBM and grip strength. A repeated measures ANOVA was used to determine changes in creatinine between groups over time. **RESULTS** There was a positive correlation between baseline creatinine (0.77±0.11 mg/dL) and LBM (40.1±8.8 kg) ($r=0.513$, $n=26$, $p<0.008$) as well as grip (25.5±7.8 kg) ($r=0.445$, $n=26$, $p<0.024$). There was a positive correlation between follow-up creatinine and (0.78±0.12 mg/dL) and LBM (40.2±8.7 kg) ($r=0.480$, $n=26$, $p<0.014$) but not grip (25.5±7.6 kg) ($r=0.390$, $n=26$, $p=0.054$). The change in creatinine (0.004±0.060 mg/dL) was not correlated to change in LBM (0.08±0.76 kg) ($r=-0.015$, $n=26$, $p=0.943$) or change in grip strength (0.18±1.90 kg) ($r=0.081$, $n=26$, $p=0.699$). There was no significant change in creatinine between groups following 8 weeks of protein supplementation $F(1,24) = 0.983$, $p=0.331$. **CONCLUSION** While there was no significant change in creatinine following 8 weeks of protein supplementation, this study shows positive associations between creatinine and lean mass as well as grip strength in underactive vegetarians and vegans.

Does Muscle Hypertrophy Relate To Resistance Training-Induced Changes In Myofibrillar Protein Synthesis In Women?

Julia M. Malowany¹, Sidney Abou Sawan¹, Cassidy Tinline-Goodfellow¹, Nathan Hodson¹, Daniel W. D. West¹, Jenna B. Gillen¹, Dinesh Kumbhare², Daniel R. Moore¹. ¹University of Toronto, Toronto, ON, Canada. ²Toronto Rehabilitation Institute, Toronto, ON, Canada.

(No relevant relationships reported)

Resistance exercise (RE) elevates skeletal muscle myofibrillar protein synthesis (MyoPS) for up to 48h, which can be measured under 'free-living' conditions using deuterium oxide (D₂O). The accumulation of repeated bouts of RE (resistance training—RT) results in skeletal muscle hypertrophy, which in men has been reported to correlate with post-RE 'free-living' MyoPS only in the trained state. However, the impact of training status on acute responses to RE and their relationship to hypertrophic adaptations has yet to be investigated in women. **PURPOSE:** The present study examined the MyoPS response over 48h of recovery from an acute bout of RE in the untrained (UT) and trained (T) state to determine its association with hypertrophic adaptations in women. **METHODS:** Ten recreationally active young women (23±5 yr, 62.3±12.0 kg, 23.7±7.4 % body fat; mean±SD) underwent ~8 wk of supervised whole-body RT (4 x 10 repetitions, 75% 1 repetition maximum (1RM), 3x/wk). Whole-body fat free mass (FFM; BODPOD), vastus lateralis muscle thickness (MT; B-mode ultrasound) and 1RM for each completed exercise were measured in the UT and T state to quantify training responses. MyoPS was measured during the mid-follicular phase (day 3-9 of the menstrual cycle) at rest pre-training and for 48h following the first and final bout of RE using orally administered D₂O. Muscle biopsies were obtained at pre-RE (0h), 24h and 48h post-RE to determine MyoPS in both the UT and T state. **RESULTS:** Following RT, there was a ~3.4% increase in FFM (49.3±6.4 vs. 51.0±6.9 kg; $P < 0.001$) and ~8.8% increase in MT (2.31±0.39 vs. 2.50±0.38 cm; $P < 0.05$). Representative 1RM strength increased for bench press and leg press

exercise (28.5±5.8 kg vs. 38.7±9.8 kg and 151.6±63.5 vs. 259.3±92.7 kg, respectively; $P < 0.01$). Forthcoming analysis will determine if: i) training alters the post-exercise MyoPS response, and; ii) whether muscle hypertrophy correlates with acute MyoPS in the UT and/or T state. **CONCLUSIONS:** Women responded favourably to ~8 wk of RT with significant gains in FFM, MT and 1RM strength. Ongoing analysis will provide insight into the potential relationship between acute muscle protein synthesis and training-induced hypertrophy in the understudied female population. Supported by the Natural Sciences and Engineering Research Council of Canada.

High Protein Supplementation Facilitates Weight Training Induced Bone Mineralization In Baseball Players

Chia-Hua Kuo, FACSM. *University of Taipei, Taipei, Taiwan.*
 Email: kuochiahua@gmail.com

(No relevant relationships reported)

PURPOSE: To determine whether weight training combined with high protein intake enhances total and regional bone mineral density (BMD) in athletes. **METHODS:** BMD of 27 Division-1 collegiate baseball players aged 18-22 y (N=13, 2 dropouts), received either 14% protein or isocaloric 44% protein supplements, were assessed by dual-energy x-ray absorptiometry (DEXA) before and following a 12-week weight training (challenging upper and lower body). **RESULTS:** Baseline data show unequivocally greater humerus BMD in the dominant arm than their contralateral non-dominant arm (~20 %) among all baseball players. Humerus BMD of non-dominant arm was enhanced by 2.7 % after weight training for both low and high protein groups (main effect, $P = 0.008$), concurrent with an unexpected, small decrease in total body BMD (main effect, $P = 0.014$). Humerus BMD of dominant arm with greater baseline value than non-dominant arm was not increased unless high protein was supplemented (+2.7 %) ($P < 0.05$). **CONCLUSION:** Bones with relatively higher BMD show inert adaptation against training, which can be delimited by high protein supplementation. Total BMD of athletes cannot be further elevated by weight training.

(No relevant relationships reported)

Potato protein stimulates muscle protein synthesis at rest and with resistance exercise Sara Y. Oikawa¹, Ravinder Bahniwal¹, Chris McGlory², Steven K. Baker¹, Stuart M. Phillips¹

¹McMaster University, Hamilton, Ontario, Canada

²Queens University, Kingston, Ontario, Canada

Skeletal muscle protein synthesis (MPS) is increased in response to amino acid feeding and to resistance exercise (RE) where RE enhances MPS above feeding alone. The use of vegetable based proteins have increased in popularity, however many vegetable based protein sources are of lower protein quality. Potato protein (PP) is a complete protein and has the highest protein quality score of any vegetable protein, however, its efficacy in stimulating MPS beyond the acute setting has yet to be determined.

PURPOSE

To determine the effects of PP on MPS with and without RE in healthy young women.

METHODS

In a single blind, parallel-group design, twenty-four healthy younger women (21 ± 3 years, n = 12/group) were assigned to consume either 25 g of PP twice daily or a non-protein-containing control (CON). Participants consumed a fully controlled diet for 3 weeks (0.8 g/kg/day CON, 1.6 g/kg/day PP), with non-supplemental protein comprising 51 ± 3% of total protein intake in the PP group. One leg of each participant was randomly allocated to perform RE (Exercise) while the other leg served as a rested control (Rest). RE was performed thrice weekly at ~30% of 1RM (20-25 reps) for 3 sets until volitional fatigue on the leg extension and leg press machines. Myofibrillar MPS was measured at baseline, following supplementation, and at supplementation+RE via the deuterated water method.

RESULTS

PP ingestion increased MPS by 0.14 ± 0.09 %/d at Rest and by 0.32 ± 0.14 %/d in Exercise ($p = 0.008$) while MPS was elevated only in Exercise with CON 0.20 ± 0.11 %/d but was not different from Baseline 0.01 ± 0.04.

CONCLUSIONS

Consuming PP in addition to a habitual diet increased rates of MPS at rest and there was a further increase with RE. PP may serve as a high quality, vegetable-based protein supplement to augment muscle protein anabolism in healthy young women.

Leucine-Enriched Essential Amino Acids Enhance Post-Exercise Muscle Recovery Independent Of 'Free-Living' Myofibrillar Protein SynthesisMarcus Waskiw-Ford. *University of Toronto, Toronto, ON, Canada.*

Email: marcus.waskiwford@mail.utoronto.ca

Reported Relationships: M. Waskiw-Ford: Industry contracted research; Ajinomoto Co. Inc.

Leucine-enriched essential amino acids (LEAA) can acutely enhance post-exercise muscle protein synthesis and may facilitate muscle damage recovery, although the relationship between these outcomes during the prolonged post-exercise recovery period is unclear. **PURPOSE:** We aimed to determine the effect of LEAA on 'free-living' rates of myofibrillar protein synthesis (MyoPS) and its relationship to markers of muscle damage after an unaccustomed bout of resistance exercise (RE) in recreationally-active men. **METHODS:** Twenty healthy males (24.1 ± 4.3 yrs) consuming a controlled diet (1.2g/kg/day of protein) were randomized to consume 4.0g of LEAA (containing 1.6g leucine) or isocaloric placebo (PLA) thrice daily for four days following an acute bout of lower-body RE (5x12 repetitions at 75% maximum of leg press and knee extension). MyoPS at rest and over 96h of recovery was measured by D₂O (150ml, 70% APE) with body water enrichment as the precursor. Total muscle torque (sum of isometric and 60 and 270°/s isokinetic torques; SUM) of the knee extensors, thigh muscle soreness (SOR), Z-band streaming, and muscle heat shock protein (HSP) 25 and 70 expression were measured at rest and during recovery. **RESULTS:** MyoPS increased ~72% after RE ($P < 0.01$) with no differences between groups ($P > 0.05$). By 48h, SUM decreased ~21% and SOR increased (all $P < 0.01$) with both variables generally returning to baseline by 96h. Compared to PLA, LEAA consumption significantly attenuated the decrease in SUM ($P < 0.05$) and had small-to-moderate effects on decreasing SOR. HSP25 increased ~16% post-RE ($P < 0.05$) with no difference between groups ($P > 0.05$). Consistent with a trend toward increased Z-band streaming in PLA ($P = 0.07$), HSP70 expression increased ~32% more ($P < 0.05$) during recovery in PLA as compared to LEAA. SUM correlated with SOR ($r = -0.64$, $P < 0.05$) whereas there were no correlations between MyoPS and any other outcomes ($P > 0.05$). **CONCLUSION:** Daily consumption of LEAA mitigates muscle strength loss and may moderately alleviate muscle damage during recovery from an unaccustomed bout of resistance exercise in recreationally-active men, but this does not appear to be related to the extent of myofibrillar protein synthesis.

IMPACT OF CASEIN PROTEIN CONTAINING L-TRYPTOPHAN AND MELATONIN ON SLEEP QUALITY AND ENERGY EXPENDITURESILVIO VALLADAO¹, Thomas Andre¹, Robert Sanders¹, Hannah Nelson¹, Neil Schwarz², Melinda Valliant¹, Josh Hogg¹. ¹University of Mississippi, OXFORD, MS. ²University of South Alabama, Mobile, AL.

(No relevant relationships reported)

Increases in morning resting energy expenditure (REE) have been observed following late evening ingestion of protein. However, the impact of late night protein supplementation containing melatonin and L-Tryptophan has yet to be examined. **PURPOSE:** The purpose of this study is to determine the impact of the ingestion of pre-sleep casein protein supplement that contains L-Tryptophan and melatonin (PRO) on sleep quality, energy expenditure prior, during, and post exercise. **METHODS:** Aerobically active females ($n = 13$; age = 22.6 ± 1.9 yrs; ht = 1.65 ± 0.06 m; wt = 60.5 ± 9.6 kg; % bf = 22.5 ± 4.3 ; $VO_{2max} = 44.1 \pm 5.3$ ml/kg/min) participated in the study. In a cross-over design, PRO (Casein; 34.3g; 140 kcal; 289mg L-Tryptophan; 1mg Melatonin) or placebo (PLA) (cocoa powder; 10g; 20 kcal) were ingested 30 min prior to sleep. Sleep quality and perceived satiety were assessed using 10cm sliding scale the following morning. REE was measured for 30 minutes with at least 5 min of steady state before and after exercise. The exercise protocol consisted of 20 min of aerobic exercise on a treadmill at 40-50% of VO_{2max} . Total calories during exercise were used to compare exercise energy expenditure (EEE). For the statistical analyses, Paired-samples t-tests and two-way repeated measures ANOVA. Results were considered significant at ≤ 0.05 . **RESULTS:** Sleep quality during PRO was not significantly different than the PLA trial (61.6 ± 21.5 mm vs 68.4 ± 20.5 mm; $p = 0.39$). Perceived satiety during PRO was not significantly different than PLA (29.6 ± 8.2 mm vs 23.9 ± 6.6 mm; $p = 0.43$). EEE during PRO was not significantly different than PLA (112.1 ± 20.4 kcal vs 112.2 ± 21.8 kcal; $p = 0.91$). The main effects (supplement: $p = 0.93$; time: $p = 0.15$) and the interaction (Supplement x Time: $p = 0.75$) for REE pre and post exercise in PRO and PLA were not significantly different. **CONCLUSIONS:** No changes were observed ingesting PRO prior to sleep on next morning EEE and REE

before and after exercise. Future investigations should examine the effects of relative (g/kg bw) pre-sleep protein containing tryptophan and melatonin ingestion on next morning EEE.

Pre-sleep Or Post-exercise Protein Intake Does Not Augment Resistance Training Adaptations In Older AdultsAlex Klemp, Mingchia Yeh, Chester Sokolowski, Do-Houn Kim, Michael J. Ormsbee, FACSM, Lynn B. Panton, FACSM, Jeong-Su Kim, FACSM. *Florida State University, Tallahassee, FL.* Email: Aok09@fsu.edu

(No relevant relationships reported)

Resistance training (RT) and protein consumption are recommended to attenuate decreases in muscle mass and strength with age. Immediate post-exercise (Post-ex) protein intake has been regarded as optimal for augmenting RT adaptations. However, nocturnal sleep is the longest post-absorptive period with muscle protein synthesis lower than basal rates. Thus, pre-sleep (Pre-sleep) protein intake may be more advantageous for older adults, who display blunted muscle anabolism, than Post-ex protein intake. **PURPOSE:** To examine the effects of pre-sleep versus post-exercise protein intake during 12 weeks of RT on muscle thickness (MT) and one-repetition maximum (1RM) strength in older adults. **METHODS:** 30 healthy, sedentary older males (age: 65.7 ± 4.0 yrs, body mass: 85.9 ± 13.1 kg) underwent the same 12-week whole-body RT program (2x/wk) and were randomly assigned to 1 of 3 groups, 1) consumed 40 g of protein immediately Post-ex ($n=9$), 2) consumed 40 g of protein 30 minutes Pre-sleep ($n=11$), or 3) did not consume additional protein supplementation (Ex only, $n=10$). MT was measured via ultrasound as the added values of the right rectus femoris, vastus intermedius, and vastus lateralis muscles. 1RM strength was assessed on the leg press machine. A 3x3 mixed-model ANOVA was used to analyze outcomes at pre-, mid-, and post-testing with significance at $p \leq 0.05$. **RESULTS:** There were significant main time effects for both MT (Pre: 6.29 ± 0.98 ; Mid: 6.63 ± 0.86 ; Post: 6.75 ± 0.94 cm) and 1RM strength (Pre: 155.9 ± 30.0 ; Mid: 170.1 ± 36.0 ; Post: 184.2 ± 47.1 kg). There were no group x time interactions or main group effects. Interestingly, only Post-ex significantly increased MT from pre to mid (Pre: 6.14 ± 0.91 ; Mid: 6.67 ± 0.88 ; Post: 6.70 ± 1.16 cm). **CONCLUSION:** During 12 weeks of RT in older adults, Post-ex protein intake increased MT in the first 6 weeks; however, after 12 weeks, improvements were similar to Pre-sleep protein intake and Ex only groups. Further, neither Post-ex nor Pre-sleep protein intake augmented RT-induced improvements in 1RM strength.

Effect Of Whey Protein Isolate On Cortisol Awakening Response In Recreationally Active WomenMICHAEL D. OLDHAM, Vic Ben-Ezra, Anthony A. Duplanty, Kyle D. Biggerstaff. *Texas Woman's University, Denton, TX.* (Sponsor: David L. Nichols, FACSM)

(No relevant relationships reported)

Introduction: The hypothalamus-pituitary-adrenal (HPA) axis plays a major role during stress responses and is associated with the secretion of cortisol. Serum cortisol concentration peaks between 30 and 45min after awakening, and is known as the cortisol awakening response (CAR). Disruptions in CAR have been associated with repetitive strenuous physical exercise. Whey protein branched chain amino acids (BCAA) compete for tryptophan transporters in the brain, subsequently reducing fatigue associated with exercise. **PURPOSE:** To determine the effects of whey protein on CAR after strenuous exercise, in recreationally active women, on post-exercise days. **METHODS:** Eleven recreationally active women (19 ± 2 yrs; $VO_{2max} = 31.6 \pm 4.5$ ml/kg/min) completed a double blinded, randomized, cross-over placebo trial, with a 7 day washout between trials. The supplement regimen (25g of maltodextrin (PL) or 25g of maltodextrin plus 25g of whey protein isolate (WH)) was given between 8am - 9am and 30min prior to exercise on 3 consecutive days of each trial. On Day 2 and 3 of each trial participants walked 30 min on a treadmill at 70-75% VO_{2max} (21.7 ± 0.1 ml/kg/min), rested 5 min, and completed a 30s Wingate anaerobic threshold test (WAnT). Saliva (2ml) was collected on days 1-4 of PL and WH, between 6am and 8am, immediately upon waking and every 15 min for the next hour. Saliva samples were analyzed for cortisol concentration using an enzyme linked immunosorbent assay (ELISA) and the area under the curve (total AUC) was calculated for cortisol. A repeated measures ANOVA (2 trial x 4 days) was used to determine significant differences ($p < .05$) in cortisol AUC. A repeated measures ANOVA (2 trial x 2 day) was used to determine significant differences ($p < .05$) in WAnT fatigue index. **RESULTS:** Main effect means for AUC were significantly different ($p = 0.033$) between PL (33.36 ± 2.0 $\mu\text{g} \cdot \text{hr}/\text{dL}$) and WH (30.88 ± 0.8 $\mu\text{g} \cdot \text{hr}/\text{dL}$). No significant difference ($p = 0.149$) in WAnT fatigue index means occurred between PL ($20.79 \pm 6.1\%$ Day 2 & $21.97 \pm 6.4\%$ Day 3) and WH trials ($22.52 \pm 6.2\%$ Day 2 & $22.78 \pm 6.4\%$ Day 3).

CONCLUSIONS: Whey protein isolate may decrease CAR on post-exercise days, in recreationally active women, indicating a possible reduction in central fatigue associated with strenuous exercise, but may not alter the ability to perform short-duration sprint cycling.

The Influence Of A Whey Protein Preload Prior To Carbohydrate Consumption On Cycling Performance

Chris Irvine¹, Matt Sokoloski², Isaac Rowland³, Ryan Gordon², Vic Ben-Ezra². ¹Rocky Mountain College, Billings, MT. ²Texas Woman's University, Denton, TX. ³Montana State University, Bozeman, MT.

(No relevant relationships reported)

INTRODUCTION: The consumption of carbohydrates during a bout of endurance exercise has been shown to promote a glycogen sparing effect and lead to an improvement in exercise performance. The consumption of whey protein prior to a prolonged bout of endurance exercise may augment insulin secretion and further spare muscle glycogen.

PURPOSE: To examine if a whey protein solution consumed as a preload prior to a glucose bolus influenced performance and metabolic responses during a cycling performance trial.

METHODS: Ten recreationally trained cyclists and triathletes completed two experimental trials. Each participant was required to perform two separate cycling performance tests, which consisted of cycling for 30 min at 90% lactate threshold, followed by a 30 min time trial. Participants consumed a whey protein isolate preload (0.7 g/kg/LBM) or a placebo 20 min prior to the consumption of a glucose beverage (0.9 g/kg/LBM). The glucose beverage was consumed 10 min prior to the cycling performance test. During both trials, plasma glucose, c-peptide, insulin, glucagon, and NEFA concentrations were measured.

RESULTS: There were no significant differences in overall time trial performance (WP 16.8 ± 0.34 km; PL 17 ± 0.4 km; $p = .346$). WP stimulated a significant increase in plasma insulin concentrations at time point 0 (WP = 222.88 ± 45.1 pg/ml; PL = 85.95 ± 45.1 pg/ml; $p = .047$) compared to the placebo trial. Despite an increase in plasma insulin, there were no significant timepoint differences for plasma glucose. WP stimulated a significant increase in plasma glucagon concentrations for timepoint -10, 0, 15, 30, 45, and 60 when compared to the PL trial (all values $p < .05$).

CONCLUSION: Although there were significant alterations in plasma insulin concentration due to the consumption of the whey protein isolate preload, this did not influence overall cycling performance or substrate utilization.

The Effects Of A Relative Dose Of Pre-sleep Protein On Recovery Following Evening Resistance Exercise

Juliana V. Costa, Takudzwa A. Madzima. *Elon University, Elon, NC.* (Sponsor: Paul C. Miller, FACSM)

(No relevant relationships reported)

Pre-sleep consumption of protein has been shown to enhance recovery of muscle function after evening exercise. Previous studies have primarily compared casein protein (CP) to carbohydrate (CHO), however, less data exists examining the effects of a blend of CP and whey protein (WP; (CP+WP)) or a dose relative to an individual's lean body mass (LBM). **PURPOSE:** To assess the acute effects of pre-sleep consumption of isocaloric CP, CP+WP, or CHO at a dose relative to LBM on recovery following an evening lower-body resistance exercise (RE) bout. **METHODS:** Fifteen active males (age: 21±1yrs, body fat:14.2±2.7%) participated in this randomized, double-blind, crossover study. One-repetition maximums were performed on the leg press and extension machines to determine RE intensity. Participants performed an evening (1600-1900) lower-body RE bout and were provided with 0.4g/kg/LBM WP supplement post RE. A single dose of 0.6g/kg/LBM of CP, 0.4g/kg/LBM CP and 0.2g/kg/LBM WP (CP+WP), or CHO was consumed 30 minutes prior to sleep and each trial was separated by 72 hours. Measurements of perceived recovery (visual analogue scales (VAS) for recovery, soreness and fatigue), appetite (VAS for hunger, satiety and desire to eat), as well as pressure-pain threshold (dolorimeter) and average power (Biodex™) of the right thigh muscles were assessed the following morning. ANOVAs were used for analyses and significance was accepted at $p < 0.05$. **RESULTS:** There was no significant difference in perceived morning recovery, soreness and fatigue between pre-sleep supplements. There was a significant difference in pressure-pain threshold at the rectus femoris ($p=0.001$), vastus medialis ($p=0.001$) and vastus lateralis ($p<0.001$). Both CP (98.0±17.3N), and CP+WP (98.2±21.7N) had a greater pressure-pain threshold (i.e. less soreness) than the PLA (80.6±21.7N) at the rectus femoris. Average power was similar between supplements. Hunger was significantly greater after CP than CP+WP (52.2±17.2 vs. 39.9±15.9 mm; $p=0.048$). There was no difference for satiety and desire to eat. **CONCLUSIONS:** Pre-sleep consumption of

CP and CP+WP at a dose relative to LBM may enhance overnight recovery to a greater extent than CHO as a result of less muscle soreness the following morning after an acute evening RE bout.

Effects Of Vespa Amino Acid Mixture On Submaximal And Maximal Cycling Performance

Brian Trieu, David Cansino. *CSU East Bay, Hayward, CA.*

(No relevant relationships reported)

Introduction: The ability to increase fat utilization during exercise and VO₂max could dramatically improve exercise performance, especially among endurance athletes. Prior research suggests that the chronic use of a Vespa Amino Acid Mixture (VAAM) may increase fat metabolism and VO₂max among elderly women (Sasai 2011). VAAM consumption provides a unique combination of amino acids (tyrine, phenylalanine, proline, and alanine) that are effective at increasing Krebs's Cycle activity, thereby facilitating increased aerobic metabolism. **Purpose:** The purpose of this study was to determine if a single pre-exercise dose of VAAM increased fat metabolism, VO₂max, or ventilatory threshold during cycling exercise. **Methods:** In this single-blind pilot study, three highly active male cyclists (age 37.3 + 10.1 years) completed two exercise tests separated by one week. Prior to each exercise test, in random order, subjects consumed either an 8 ounce drink containing 100mg of VAAM (Vespa CV-25, Vespa Power Products LLC, Davis CA) or an 8 ounce isocaloric placebo. On a cycle ergometer subjects completed four 5-minute submaximal exercise stages, followed immediately by a VO₂max test. Fat metabolism (FM, kcal/min), maximal oxygen uptake (VO₂max, ml/kg/min), and ventilatory threshold intensity (VT, Watts) were measured. **Results:** The results of these tests demonstrated an increase in submaximal FM, VO₂max, and VT following the consumption of VAAM. **Discussion:** The findings of this study indicate a potential improvement in aerobic exercise performance through increased fat metabolism, VO₂max, and VT intensity when consuming a single 100mg dose of VAAM prior to exercise compared to a placebo.

Effect Of Protein Supplementation On Running Exercise-induced Muscle Damage And Soreness: A Randomized Controlled Trial

Maria Hopman, FACSM¹, Dominique ten Haaf¹, Martin Flipsen¹, Hans Timmerman², Monique Steegers³, Lisette de Groot⁴, Thijs Eijvogels¹. ¹Radboudumc, Nijmegen, Netherlands. ²University Medical Center Groningen, Groningen, Netherlands. ³Amsterdam University Medical Center VU, Amsterdam, Netherlands. ⁴Wageningen University, Wageningen, Netherlands. Email: Maria.Hopman@radboudumc.nl

(No relevant relationships reported)

Purpose: The benefits of protein supplementation on endurance exercise-induced muscle damage and soreness remain inconclusive. Therefore, we assessed whether a protein supplementation protocol with optimized timing and amounts could attenuate running-induced muscle soreness and muscle damage compared to iso-caloric placebo supplementation.

Methods: A double-blind randomized controlled trial was performed among 323 recreational runners (age 44±11 years, 56% male) participating in a 15-km road race. Participants received 2 supplements per day containing 80% caseinate and 20% whey protein (intervention) or carbohydrate (placebo). Supplements were consumed post-race (at the finish line and prior to sleep) and during 3 consecutive days (at breakfast and prior to sleep). Habitual protein intake was assessed using 24hr recalls at baseline, on the day of the race and 1, 2 and 3 days post-race. Race characteristics were determined and muscle soreness was assessed with the Short-Form Brief Pain Inventory at baseline and 1 day, 2 days and 3 days post-race. In a subgroup ($n = 149$), muscle soreness was measured with a strain gauge algometer and concentrations of the muscle damage markers creatine kinase (CK) and lactate dehydrogenase (LDH) were measured 25 to 48hr post-race.

Results: At baseline, no group-differences were observed for habitual protein intake (79.9±26.5 g/d versus 82.0±26.8 g/d, $P=0.49$) and Numeric Pain Rating Scale muscle soreness (0.45±1.08 versus 0.44±1.14, $P=0.96$) in the protein group compared to the placebo group. Subjects completed the race at an exercise intensity of 94±6% of HRmax and a running speed of 12±2 km/h. The protein group reported higher muscle soreness 24hr post-race compared to the placebo group (2.96±2.27 versus 2.46±2.38, $P=0.039$), but no differences were observed on day 2 and 3 post-race. Similarly, we found a lower pressure pain threshold for the quadriceps muscle in the protein group compared to the placebo group (71.8±30.0 N versus 83.9±27.9 N, $P=0.019$). Similar concentrations of CK and LDH were found post-race in both groups.

Conclusion: Post-exercise protein supplementation is not more preferable than carbohydrate supplementation to reduce muscle soreness or damage in recreational athletes with a protein intake of 1.14 ± 0.35 g/kg/d running a 15-km road race.

Protein ingestion is recommended to maximize muscular adaptations post resistance training (RT). Eggs are a rich food source commonly consumed post-workout to meet protein requirements. Although removing egg yolk is often promoted for the improvement of body composition (BC), whole-egg (WE) consumption has been shown to cause a greater stimulation of post-exercise muscle protein synthesis than egg-white (EW). However, changes in BC and skeletal muscle regulatory markers to chronic RT coupled with WE or EW consumption have not been evaluated.

PURPOSE: To compare the effects of WE vs. EW ingestion after 12 wks of RT on BC and skeletal muscle regulatory markers in RT men. **METHODS:** Thirty RT men [age (24 ± 2 yrs), were randomized to either a WE (n=15) or EW (n=15) consumption group for 12 wks. The WE group ingested three WE while the EW group ingested six EW immediately post-workout and at the same time on non-training days. RT consisted of 10 exercises/session, 3x wk. Three sets of 3-14 reps (load was progressed) were performed for each exercise. Body weight, fat mass (FM), skeletal muscle mass (SMM) as well as serum follistatin (FOL), myostatin (MYO) and basic fibroblast growth factor (FGF-2) levels were measured at baseline and after 12 wks. **RESULTS:** Significant main effects of time were observed for body weight, SMM, FOL and FGF-2 which significantly (P < 0.05) increased, and for FM and MYO which significantly (P < 0.05) decreased. However, no significant group × time interactions were noted for any markers. Although non-significant, the WE group had ~1 Kg of extra FM loss than EW group. **CONCLUSIONS:** There are no differences in the changes achieved in BC and skeletal muscle regulatory factors after 12 wks of RT between WE and EW consumption. Although BC did not differ between groups, the ~1 Kg of extra FM loss seen after WE consumption may be an advantage for fitness enthusiasts with aesthetic goals.

Proteins Or Carbohydrates Influence On Strength And Functionality After Exercising In Elderly Type II Diabetics.

Andre Luiz de Seixas Soares¹, Adriana L. Machado-Lima², Julia M. Greve¹, Ricardo A. Becker¹, Thiago R. Inojosa¹, Grazyelle S. Araujo¹, Bruna A. Marcolino¹, Daiane A. Matos¹, Joselma Rodrigues¹, Keren R. da Silva¹, Angelica C. Alonso². ¹Faculdade de Medicina da Universidade de São Paulo, São Paulo, Brazil. ²São Judas Tadeu University, São Paulo, Brazil.
 Email: andre@winsaude.com
 (No relevant relationships reported)

In seniors with type 2 diabetes mellitus (SDM2), skeletal muscle LOSS is two to four times higher than in non-diabetics. In addition, SDM2 have a greater reduction in neuromuscular function and worse performance in functional tests. Hence, the recommendation of physical exercise is consensual for this population. Exercise-induced muscle damage is known to hinder motor learning and carbohydrate with protein intake reduces this damage, possibly improving the functional outcomes from exercises. **PURPOSE:** Verify the role of protein or glycemic intake on muscle strength and functionality of SDM2 undergoing resistance training. **METHODS:** This is an experimental, controlled, randomized, double-blind study. Twenty-six males SDM2 with a mean age of 68.5 (± 4.3) years randomly put into two groups: Protein Group (GP) (13) and Carbohydrate Group (GC) (13). The training sessions were held twice a week for 12 weeks. Eight exercises were performed for the main muscle groups, being 3 sets of 8 to 12 repetitions. The intensity was continuously adjusted

between 7 - 8, according to the Subjective Effort Perception (1 to 10). Ingestion of macronutrients was performed immediately after strength training, using 20 g of water-diluted whey protein for the GP group and 20 g of water-diluted maltodextrin for the GC group. Muscle strength was assessed by isokinetic dynamometry of knee extensors and flexors, upper limbs by the Hand Grip Strength Test (HGS) and functionality by the Short Physical Performance Battery Test (SPPB). **RESULTS:** No significant differences were found between the groups, nor before and after training in relation to the dominant side muscle strength (DS) - Extensors torque peak = (F = 1.51 = 0.247; p = 0.62; η = 0.005) and flexors (F = 1.51 = 0.345; p = 0.56; η = 0.007); non-dominant side (NDS) - Peak torque of extensors (F = 1.51 = 0.143; p = 0.70; η = 0.003) and flexors (F = 1.51 = 0.187; p = 0.66; η = 0.004); FPM (DS) (kg / f) (F = 1.51 = 0.455 p = 0.50; η = 0.009); HGS (NDS) (kg / f) (F = 1.51 = 0.020 p = 0.88; η = 0.000). In functionality there was a significant gain in the protein group in the interaction between groups * condition (pre and post) (F = 1.51 = 6.23; p = 0.01; η = 0.115). **CONCLUSION:** Ingestion of both macronutrients does not produce an increase in muscle strength alone, but protein supplementation shows improvements in functionality.

423 Board #239 May 27 9:30 AM - 11:00 AM
Effects Of Protein Intake On Gastrointestinal Symptoms In Runners - A Pilot Study

Vanessa R. Lee, Jill Parnell. Mount Royal University, Calgary, AB, Canada.
 (No relevant relationships reported)

PURPOSE: Gastrointestinal (GI) symptoms often hinder running performance and are responsive to nutrient intakes. Currently, the recommendation is to “limit” protein intakes to minimize symptoms, but a threshold has not been established. The purpose of this study was to examine the effect of a highprotein (HP) vs a low protein (LP) shake on running induced GI symptoms. **METHODS:** Five (n=2 male) endurance trained runners were administered a HP (0.4 g/kg body weight) or LP (0.15 g/kg/ body weight) shake one hour prior to a 10 km run at 85% of their race pace in a single-blind, randomized cross-over design. Carbohydrate and water intakes remained consistent across trials. Exercise induced GI symptoms were measured pre-shake, 60 minutes post-shake, and post-run. Symptoms were rated on a 10 point scale and included six upper abdominal problems, seven lower abdominal problems, and five systemic problems. **RESULTS:** Symptoms experienced during the LP run included belching (2), stomach cramps (2), intestinal cramps (3), flatulence (1), urge to defecate (1), stitch (1), dizziness (1), muscle cramp (1), urge to urinate (2), and fullness (1). Severity was consistently low with only urge to urinate rated as a 4. Symptoms experienced during the HP run included re-flux (1), belching (2), bloating (1), stomach cramps (2), intestinal cramps (1), flatulence (1), stitch (1), and fullness (1). Severity was consistently low with a maximum of 3. There was no significant difference in the severity of symptoms experienced between the two trials and no difference in the number of symptoms. **CONCLUSIONS:** A pilot trial indicates no difference in exercise-induced GI symptoms with a HP or LP shake pre-run and suggests intakes up to 0.4g/kg body weight can be well tolerated. Supported by a Mount Royal University Innovation Grant.

Preschool Children Consumption Of School Lunches Different From Menus That Meet Dietary Guidelines And To What Is Served

Stacie M. Kirk, Erik Kirk, FACSM. Southern Illinois University Edwardsville, Edwardsville, IL.
 Email: skirk@siue.edu
 (No relevant relationships reported)

Preschool menus must meet the Dietary Guidelines for Americans however, what is actually served and consumed by children is not restricted, potentially affecting consumption of a balanced diet. **PURPOSE:** Compare preschool lunch menus that meet dietary guidelines to what is actually served and consumed by children. **METHODS:** Fifty-two preschool children (mean ± SD, age 3y and 10m ± 8m) from a university early childhood center participated in the 10-week study. Each day, 15 children were randomly selected for nutritional analysis of their lunch. Prior to and immediately after consumption, a picture of the child's tray was taken using digital photography. If a child had additional food (second's), additional pictures were taken. Analysis of energy and nutrient content for menus, food served, and food consumed was completed using Food Processor Nutrition Analysis by ESHA. Food color (white, brown, orange, yellow, red, green, other) was determined by observation during analysis. A food preference survey was administered orally to children immediately after each meal. **RESULTS:** There was a significant (p<0.05) difference for total kilocalories (kcal) between menu (448 ± 130), served (523 ± 148) and consumed (361 ± 178). There was a significant (p>0.05) difference for grams of carbohydrate between menu (55.3 ± 18.9g) and served (56.5 ± 20.5g) compared to what was consumed (38.5 ± 21.7g). There was a significant (p<0.05) difference for grams of fat between menu (15.9 ± 8.7g), served (21.2 ± 9.7 g) and consumed (14.5 ± 10.0g). There was a

significant ($p < 0.05$) difference for protein between menu (21.7 ± 5.7 g), served (27.9 ± 10.6 g) and consumed (19.5 ± 11.8 g). The majority of food served was white (38.1%), brown (20.4%), or yellow (14.2%) with minimal from orange (10.2%), red (6.1%) or green (10.7) foods. Children described food as yummy (75.2%), okay (7.6%), and yucky (17.2%). Consumption of vegetables (46.9%) was significantly ($p < 0.05$) lower than dairy (88.9%), fruits (82.0%), grains (81.8%), and meats (72.8%). Children consumed a high percentage (77.9%) of fats/sweets. **CONCLUSION:** The amount of food consumed at lunch was significantly less than the menu and served amounts, indicating that children were not meeting the dietary recommendations as intended, potentially contributing to long-term health consequences.

425 Board #241 May 27 9:30 AM - 11:00 AM
The Effects Of Two Different Patterns Of Protein Ingestion On Muscle Growth In Trained Men.

André dos S. Costa, José Henrique C. Tavares Filho, Álvaro N. Madureira, Vitória F. Souto, Elizabeth Nascimento. *Federal University of Pernambuco, Recife, Brazil.*
 Email: andre.santoscosta@ufpe.br
 (No relevant relationships reported)

It is known that different patterns of protein ingestion might influence the muscle protein synthesis rate in different magnitudes. However, it is questionable whether this could be translated into differential muscle growth, when the total amount of protein ingested throughout the day is equal and optimal to induce muscle hypertrophy.

PURPOSE: To examine whether consuming the recommended amount of protein, for hypertrophy, in 3 or 5 meals results in different muscle growth on trained men submitted to 8 weeks of resistance training.

METHODS: 19 men (24.9 ± 5.6 years old), with more than 1 year of experience in resistance training, were randomly allocated in one of two groups: P3X ($n=10$) or P5X ($n=9$). All volunteers had a diet program prescribed by a registered dietitian. Men in the P3X group, were instructed to ingest the recommended amount of protein (1.6-2.2g/kg), mainly, in three meals; while, men in the P5X were instructed to ingest the total amount of protein in five meals. While dieting, both groups were submitted to an equal program of lower limbs resistance training, for 8 weeks, twice a week. Each session comprised 5 sets of unilateral horizontal leg press and 3 sets of unilateral knee extension, with a range of 8-12RM and 2 minutes of interval between sets. Before, and after, the intervention, the cross-sectional area (CSA) of muscles rectus femoris (RF) and vastus lateralis (VL) were measured by ultrasonography and then, data were analyzed. The normality and homogeneity of data were tested with Shapiro-wilk's and Levene's tests, respectively, and then a repeated measures GLM analysis was run to test the effects of intervention (P3X vs P5X) vs time (baseline vs 8 weeks) on muscle CSA.

RESULTS: Both groups showed an increase in the CSA of RF (P3X: 9.97 ± 0.58 to 10.76 ± 0.56 cm², P5X: 8.53 ± 0.61 to 9.64 ± 0.59 cm², $p=0.014$), VL (P3X: 30.19 ± 1.54 to 33.60 ± 1.49 cm², P5X: 31.95 ± 1.62 to 34.13 ± 1.57 cm², $p=0.003$), and in the sum of the CSA of both muscles (P3X: 40.16 ± 1.70 to 44.36 ± 1.72 cm², P5X: 40.48 ± 1.79 to 43.77 ± 1.81 cm², $p=0.002$). However, there was no statistically significant difference between groups for any of the variables.

CONCLUSIONS: The ingestion of the total amount of protein, recommended for induction of muscle hypertrophy, in three or five meals a day had no influence in rectus femoris and vastus lateralis muscles growth.

Protein-enriched Meals At Breakfast Increase Muscle Accretion In Healthy Young Men Undergoing 12-week Resistance Training

Jun Yasuda, Toshiki Tomita, Takuma Arimitsu, Satoshi Fujita. *Ritsumeikan University, Shiga, Japan.* (Sponsor: Takeshi Hashimoto, FACSM)
 Email: 55fhyanh@gmail.com
 (No relevant relationships reported)

While daily protein intake has been reported to be essential for muscle regulation, the breakdown of daily protein intake in individuals is typically the lowest at breakfast and skewed towards dinner. Skewed protein intake pattern and inadequate protein intake at breakfast was reported to be a negative factor for muscle regulation, and no study has examined the effects of protein intake pattern at each meal on anabolic response such as muscle hypertrophy.

PURPOSE: This study aimed to examine whether a protein-enriched meal at breakfast to achieve adequate protein intake at all 3 meals is more effective for muscle accretion compared to typical protein intake pattern, skewed protein intake towards dinner.

METHODS: This 12-week, parallel-group randomized clinical trial included 26 men (means \pm SEs; age, 20.8 ± 0.4 years; BMI, 21.8 ± 0.4 kg/m²). The participants were divided into 2 groups: HBR ($n = 12$), consuming a protein-enriched meal at breakfast to achieve adequate protein intake at all 3 meals; LBR ($n = 14$), consuming a provided meal at breakfast to achieve adequate protein intake at lunch and dinner. The

participants performed 12-week supervised resistance training (RT) program 3 times/week (3 sets of 8-12 repetitions at 75-80% of one repetition maximum for 5 exercises). We used dual-energy X-ray absorptiometer to measure total fat-free mass (TotalFFM). **RESULTS:** No significant difference in TotalFFM was observed between the 2 groups at baseline (HBR vs LBR: 52.4 ± 1.3 vs 53.4 ± 1.2 kg). After completing the 12-week diet plan and RT program, both the groups gained significant TotalFFM (2.1 ± 0.2 kg, 4.0 ± 0.4), with the HBR group having greater changes in TotalFFM than the LBR group [HBR vs LBR, 2.5 ± 0.3 vs 1.8 ± 0.3 kg; $P = 0.056$; cohen's $d = 0.795$ (Large effect size)].

CONCLUSIONS: Protein-enriched meal at breakfast to achieve adequate protein intake at all three meals is more effective than skewed protein intake at dinner for RT-induced muscle hypertrophy.

Effects Of Protein Pre-run On Glucose And Perceived Exertion - A Pilot Study

Brynn Lindstrom, Vanessa Lee, Jill Parnell. *Mount Royal University, Calgary, AB, Canada.*
 Email: blind831@mtroyal.ca
 (No relevant relationships reported)

Purpose: Protein recommendations pre-running have yet to be established and will need to consider performance responses as well as the potential for exercise-induced gastrointestinal symptoms. The purpose of this study was to examine the impact of a high protein (HP) shake consisting of 0.4 g/kg body weight (BW) protein vs. a low protein shake (LP) 0.15 g/kg BW protein pre-run on glucose, gut fullness, and perceived exertion. **Methods:** Five ($n=2$ male) endurance trained runners were administered a HP or LP shake one hour prior to a 10 km run in a randomized cross-over design. Carbohydrate and water intakes remained consistent across trials. Blood glucose was measured at fasting, 30, and 60 minutes post-shake and post-run using a glucose meter. Perceived exertion was measured using Borg's scale. Exercise induced gastrointestinal symptoms were measured at fasting, pre-run and post-run using a 10-point questionnaire. Gut fullness was measured using a visual analogue scale at fasting, 15, 30, 60 minutes post-shake and post-run. **Results:** Blood glucose peaked at 30 minutes post-shake and there was no difference between the HP and LP shakes. There was a significant interaction between time and shake ($p=0.044$), however no main effect of time or shake. There was no difference in perceived exertion between the two interventions. Gut fullness changed over time ($p=0.005$), however, was not affected by the composition of the shake. There was no difference in the number of exercise-induced gastrointestinal symptoms experienced on the HP and LP shakes. **Conclusion:** The results from this pilot study suggest that the inclusion protein in the pre-run meal is feasible and provides support for a fully powered trial.  (No relevant relationships reported)

Nutrient availability is known to influence the exercise response. However, there is a paucity of information regarding the role of post-exercise protein ingestion in modulating intra-muscular adaptation to treadmill-based endurance exercise training.

PURPOSE: To examine the influence of post-exercise protein ingestion on mRNA gene expression in response to six-weeks treadmill running. **METHODS:** In a randomized parallel group design, 15 individuals ($VO_{2max} 55 \pm 6$ ml·kg⁻¹·min⁻¹) completed six weeks of treadmill running (4 sessions per week), progressively increasing in both duration (30-60 min) and intensity (70-75 % VO_{2max}). Participants were randomly assigned to a group receiving a supplement containing carbohydrate (CHO; 1.6 g sucrose·kg⁻¹; $n=7$) or carbohydrate-protein (CHO-P; 0.8 g sucrose·kg⁻¹ and 0.8 g whey protein hydrolysate·kg⁻¹; $n=8$) ingested immediately post-exercise and then 1 h later. To determine mRNA expression of several mitochondrial, mitogenic signaling, protein synthesis and lipid/carbohydrate metabolism genes, muscle biopsy samples were collected at baseline and follow-up, with 48 h of lifestyle standardization to exclude any acute effects on transcriptional changes. **RESULTS:** An up-regulation in mammalian target of rapamycin (mTOR) gene expression was shown in CHO-P

(+46%; $p=0.025$) relative to CHO (+4%) following the intervention. Mitochondrial transcription factor A (TFAM) up-regulation was shown in CHO-P group (26%) when compared with CHO (13%), albeit this did not reach statistical significance ($p=0.07$). No changes in the expression of other mitochondrial, lipid/carbohydrate metabolism, mitogenic signaling genes were observed between groups ($p>0.05$). **CONCLUSION:** post-exercise protein supplementation up-regulates the expression of mTOR in skeletal muscle over six-weeks of treadmill-based endurance exercise training, indicating that post-exercise protein supplementation may have a potential role in accentuating skeletal muscle adaptations to endurance exercise training. Varying Postprandial, Postexercise Nutrient Timing: Effects On Substrate Oxidation And Protein Retention In Resistance-trained Men

Laura A. Mangone, William R. Lunn, FACSM. *Southern Connecticut State University, New Haven, CT.* (Sponsor: Dr. William R. Lunn, FACSM)
 Email: mangone1@southernct.edu
 (No relevant relationships reported)

Dietary protein and/or carbohydrate consumption augments postexercise recovery by facilitating the rebuilding of damaged contractile tissues and restoring energy reserves, particularly in a postabsorptive state. It is unclear how altering postexercise nutrient timing when in a postprandial state affects the shift towards fat utilization and changes in net protein retention after a resistance training bout. **PURPOSE:** To examine the effects of immediate versus delayed postexercise nutrient intake on substrate oxidation and protein retention during recovery. **METHODS:** In a single-blinded, crossover design, resistance trained (≥ 1 y) men ($n=10$, 22 ± 2 y, 83 ± 10 kg) consumed a mixed, eucaloric meal 2 hours before performing resistance exercise (3 sets of 6 whole body exercises, 2-3 minutes rest). Participants then consumed one of three postexercise beverages: immediate consumption of a whey protein concentrate (0.35 g/kg) and dextrose (1.0 g/kg) beverage (IMM), delayed consumption (2 h) of a whey and dextrose beverage (+2H), or placebo (flavoring with water) (PLA). Participants recovered (3 h) while expired carbon dioxide and oxygen were analyzed. Carbohydrate and fat oxidation was determined and body protein breakdown was investigated via analyses of salivary cortisol and urinary nitrogen excretion. **RESULTS:** Nitrogen balance in PLA (-0.02 ± 0.01 g) was significantly lower than +2H (5.21 ± 0.63 g, $p<0.001$, $ES=11.61$) and IMM (5.21 ± 0.64 g) ($p<0.001$, $ES=11.59$) during the three-hour recovery. There were no significant differences in nitrogen balance between IMM and +2H ($p=1.0$). Carbohydrate oxidation in IMM was significantly higher than +2H at 60 minutes postexercise (0.21 ± 0.13 g/min vs. 0.11 ± 0.12 g/min, respectively; $p=0.014$). Fat oxidation was higher in IMM at minute 90 ($p>0.05$, $ES=0.60$), minute 120 ($p>0.05$, $ES=0.40$), and minute 150 ($p>0.05$, $ES=0.50$). There were no significant differences in salivary cortisol among groups (all $p=1.0$). **CONCLUSION:** In the postprandial state, +2H promoted higher fat utilization than IMM, whereas IMM promoted greater carbohydrate oxidation earlier in the recovery period. Both interventions resulted in similar net protein retention. Thus, postponing postexercise nutrient intake when in a postprandial state may be implicated in body composition improvements.

Walking Or Body Weight Squats May Improve Muscle Dietary Amino Acid Sensitivity During Prolonged Sitting

Eric Williamson¹, Jenna B. Gillen¹, Stephanie Estafanos¹, Julia M. Malowany¹, Nathan Hodson¹, Dinesh Kumbhare², Daniel R. Moore¹. ¹University of Toronto, Toronto, ON, Canada. ²Toronto Rehabilitation Institute, Toronto, ON, Canada.
 Email: eric.williamson@mail.utoronto.ca
 (No relevant relationships reported)

Low physical activity (e.g. reduced daily steps) reduces the ability of dietary amino acids (AA) to support muscle protein synthesis, leading to eventual muscle loss. Interrupting prolonged sitting with short bouts of intermittent exercise can improve carbohydrate and lipid metabolism, however its ability to sensitize skeletal muscle to dietary AA has yet to be investigated. **PURPOSE:** To determine the ability of interrupting prolonged sitting with practical 'activity snacks' to enhance the postprandial incorporation of dietary AA into myofibrillar protein. **METHODS:** As a subset of a larger study, twelve participants (7 males and 5 females; ~ 23 y; ~ 40.0 mlO₂/kg/min; ~ 25.1 kg/m²; ~ 4676 steps/d) completed three 7.5 hr trials in a randomized order consisting of prolonged sitting (SIT), sitting with intermittent walking (WLK; 2 min at 3.1mph every 30 min) or sitting with intermittent squatting (SQT; 15 'chair stands with calf raise' every 30 min). Mixed-macronutrient meals ($\sim 55:30:15\%$ carbohydrate:fat:protein) were provided at 20% (breakfast) and 30% (lunch) of daily energy requirements to be consistent with Western feeding patterns. Meals were

enriched to 15% with ring-^{[2}H₂]phenylalanine or ring-^{[13}C₆]phenylalanine to model the metabolic fate of dietary AA. Muscle biopsies taken at the end of each trial as well as at the beginning of trial 2 were used to determine change in AA enrichment (LC/MS/MS) in the myofibrillar protein fraction (Δ Myo). **RESULTS:** Δ Myo was 0.032 ± 0.004 MPE in SIT and tended to be greater with SQT (0.038 ± 0.003 ; $P=0.10$) and WLK (0.047 ± 0.006 ; $P=0.06$) according to a *prior* comparisons (paired one-tail T-test). Relative to SIT, effect sizes were large for WLK ($ES=0.88$; 95% CI $-0.30 - 2.07$) and moderate for SQT ($ES=0.55$; 95% CI $-0.60 - 1.71$). **CONCLUSION:** Interrupting prolonged periods of sitting with intermittent bouts of body weight-dependent activity has the potential to improve the utilization of dietary AA for *de novo* muscle protein synthesis in young healthy adults. Our results add to the evidence that reducing sedentary time through 'activity snacks' may help maintain muscle mass and quality. Future research should determine whether at risk populations (e.g. aging, obese) may obtain a greater benefit from this simple lifestyle modification. Supported in part by an ACSM Research Endowment Grant.

 (No relevant relationships reported)

Abstract: The multiplicity of resting metabolic rate (RMR) prediction equations indicates that many variables affect RMR, making it difficult to adopt a single equation for all individuals who wish to lose, gain or maintain weight. **PURPOSE:** To improve the accuracy of RMR prediction equations for obese individuals and to construct a new formula to evaluate RMR after weight loss (WL). **METHODS:** This study examined the RMR gap in 21 men (M) and 18 women (W), 25-60 yrs, with $27 < BMI < 40$ kg/m² and 10-20% WL after at least three months in a structured weight reduction program with a customized diet and professionally tailored exercise prescription. At entry and at follow-up visits participants' RMR, weight, height, fat-free mass (FFM), fat mass (FM), were measured with reliable instruments to ascertain the RMR change relative to FFM and FM. Pre and post RMR measurements were compared to calculated RMR using existing Harris and Benedict (HB), Ravussin and Bogradus (RB) and Johanness et al. (J). T-test, ANOVA and χ^2 test comparisons were analyzed using SPSS 19.0, significance level $P>0.05$. To improve accuracy new prediction equations were constructed through stepwise linear regression based on before (RMR_b) and after (RMR_a) RMR measurements: M: $RMR_b = 132.82 + 28.37(W) - 250.595(H) + 9.464(FFM) - 2.871(A) - 25.932(FM)$ M: $RMR_a = 1862.68 - 7.779(W) + 1716.697(H) + 18.091(FFM) + 1.964(A) + 14.972(FM)$ W: $RMR_b = 553.971 + 16.601(W) + 1033.839(H) - 13.734(FFM) - 10.930(A) - 19.668(FM)$ W: $RMR_a = 552.850 + 7.288(W) + 340.730(H) + 8.932(FFM) - 5.064(A) - 5.015(FM)$. **RESULTS:** In M and W there was a significant difference in WL (M: 104 ± 13 vs. 87 ± 11 ; W: 88 ± 10 vs. 75 ± 8 , $P\leq 0.01$), BMI (M: 33 ± 3 vs. 28 ± 3 ; W: 32 ± 4 vs. 27 ± 3 , $P\leq 0.01$) and FM in kg (M: 37 ± 7 vs. 26 ± 9 ; W: 40 ± 9 vs. 27 ± 8 , $P\leq 0.01$); M only in FFM (65 ± 9 vs. 63 ± 9 , $P=0.02$); W only in RMR (1802 ± 176 vs. 1684 ± 176 , $P=0.04$). Calculated RMR before and after WL using the J equation was closest to measured RMR in M and W before and in W after WL (M: -337 ± 223 ; W: -57 ± 256 , vs. -69 ± 128); but only accurate was W before WL ($P=0.351$). RMR calculations with the new equations were more accurate and closest to measured RMR before and after WL in M (-0.05 ± 154 vs. 0.03 ± 197) but only after WL in W (-30 ± 116). **CONCLUSION:** The study illuminates the need to adopt different equations for assessment of individuals' RMR before and after weight loss.

Do Genetic Variations Predict Physical Activity Response To Lifestyle Intervention Among Obese Adults With Diabetes?**

Harold H. Lee¹, John E. McGeary², Shira Dunsiger³, Laura Baker⁴, Ashok Balasubramanyam⁵, William C. Knowler⁶, David M. Williams⁷, Jeanne McCaffery⁸. ¹Harvard TH Chan School of Public Health, Boston, MA. ²Providence Veterans Affairs Medical Center, Providence, RI. ³Miriam Hospital, Providence, RI. ⁴Wake Forest School of Medicine, Winston-Salem, NC. ⁵Baylor College of Medicine, Houston, TX. ⁶National Institute of Diabetes and Digestive and Kidney Diseases, Phoenix, AZ. ⁷Brown School of Public Health, Providence, RI. ⁸University of Connecticut, Storrs, CT.
Email: hhlee@hsph.harvard.edu
(No relevant relationships reported)

PURPOSE: Those who are prone to high physical activity (PA) in natural environments may respond better to a PA promotion intervention than those who are prone to low PA. A genome-wide association study (GWAS) and a candidate gene study identified 4 single nucleotide polymorphisms (SNPs) related to PA: rs978656 near *DNAPT6*, rs10887741 near *PAPSS2*, rs7279064 near *C18orf2*, and rs6265 near *BDNF*. We hypothesized that the 4 SNPs will predict greater change in PA phenotypes in response to a lifestyle intervention.

METHODS: This is a secondary analysis of Look AHEAD, a multi-center randomized controlled trial among participants who are overweight/obese and have type 2 diabetes (ages 45-76). Look AHEAD is designed to test the health benefits of an intensive lifestyle intervention (ILI), combining calorie restriction and PA promotion for weight loss, as compared to diabetes support and education alone. We examined the moderating effects of the 4 SNPs individually and in a weighted genetic score (GS). Of the 3649 participants who were successfully genotyped for all the 4 SNPs, we examined only those cases that also completed Paffenbarger PA questionnaire (PPAQ) and cardiorespiratory fitness (CRF) measures at baseline, year 1, and year 4 (n=2675). We used linear mixed effects models to regress PA phenotypes (PPAQ and CRF) on genetic variations, time, intervention, as well as interactions between the three. Models controlled for age, sex, body mass index, ancestry principal components (for population stratification), and study sites and included a Bonferroni correction for multiple testing. Additive, recessive, and dominant models were tested.

RESULTS: None of the individual SNPs or the GS were associated with baseline CRF or PPAQ. The rs978656 interacted with time (year1) and intervention (p=0.04), such that the main effect of the intervention on CRF was significant (p=0.04) only among A allele carriers (less-PA-prone) at year 1; however, this finding did not persist following Bonferroni correction (alpha<0.006). GS was not predictive of change in CRF or PPAQ. Individual SNPs were not predictive of change in PPAQ.

CONCLUSIONS: The ILI may have a more salient effect on CRF among A allele carriers of rs978656. Future intervention studies on the genetic basis of PA change are recommended to include more GWAS-identified SNPs.

Motives And Barriers To Initiation And Exercise Adherence In A Fitness Club Setting.**

Christina Gjestvang, Trine Stensrud, Frank Abrahamsen, Lene Anette Hagen Haakstad. *Norwegian School of Sports Sciences, Oslo, Norway.*
Email: christina.gjestvang@nih.no
(No relevant relationships reported)

PURPOSE: Worldwide, about 183 million adults are fitness club members and there is a need of more understanding why some individuals adhere to exercise, and others drop-out. The main aims of the present study were to examine proportions reporting regular exercise, non-regular exercise and drop-out, as well as identify motives and barriers to exercise throughout the first year of fitness club membership. In addition, we wanted to compare motives between those who reported regular exercise at three, six and 12 months, with those who did not (irregular exercise or drop-out).

METHODS: New fitness club members (<four weeks membership) were followed for one year. At onset (n = 250), and after three (n = 224), six (n = 213) and 12 (n = 187) months, participants completed an electronic questionnaire (including background variables, exercise involvement, motives and barriers to exercise), and 184 answered at

all time-points. According to exercise involvement, participants were categorized into: *Regular exercise:* ≥two sessions/week, and *non-regular exercise:* ≤one session/week, exercise relapse or drop-out. Cochran's Q test, independent t-tests or χ^2 were used as appropriate.

RESULTS: Of 184 participants, 37.0% reported regular exercise throughout the follow-up. At three, six and 12 months; 23.0%, 28.3% and 34.8% reported exercise drop-out. At all follow-up, positive health (79.1% to 85.5%), increase in mobility (59.4% to 70.7%), and strength/endurance (58.3% to 66.3%) were reported as most important exercise motives. Among exercise drop-out, priority (60.9% to 71.7%) was perceived as most important barrier throughout one-year follow-up. Other barriers were reported by <20.0%. The intrinsic motives enjoyment and challenge were perceived as more important among regularly exercisers compared with non-regular exercisers (p = ≤0.05) throughout the first year of fitness club membership.

CONCLUSIONS: A total of 63.0% reported non-regular exercise throughout the first year of fitness club membership. Extrinsic motives and internal barrier were perceived as most important. Regular exercisers rated the intrinsic motives enjoyment and challenge higher than non-regular exercisers.

Heart Rate Variability Mediates Fatigue And Motivation Throughout A High-intensity Exercise Program.**

Derek A. Crawford¹, Justin DeBlauw², Katie M. Heinrich², Brady Kurtz², Nicholas B. Drake³, Michael J. Carper³.
¹University of Central Missouri, Warrensburg, MO. ²Kansas State University, Manhattan, KS. ³Pittsburg State University, Pittsburg, KS.
(No relevant relationships reported)

PURPOSE: High-intensity exercise programs are often promoted as a time-efficient public health intervention to combat chronic disease. Increased physical effort, and subsequent fatigue, can be barriers to long-term maintenance of these exercise programs. The purpose of the present study was to determine if heart rate variability (HRV) mediates state traits related to exercise program adherence. We hypothesized that exercise-induced, temporary shifts in resting HRV would significantly affect daily fatigue and motivation. **METHODS:** Fifty-five healthy men and women (ages 19-35 years) used a commercially-available smartphone application to monitor daily HRV status throughout a six-week high-intensity exercise intervention. Participants were randomly assigned to either control (CON) (n = 29, 24.1 ± 4.1 years, 41.4% male) or treatment (TREAT) (n = 26, 23.7 ± 4.5 years, 53.8% male) groups. Within CON, exercise intensity was completed as prescribed while intensity within TREAT was modulated in response to observed shifts in daily HRV. Participants reported state motivation to exercise and global physical fatigue immediately prior to each exercise session. **RESULTS:** Prevalence of temporary shifts in resting HRV were 37.6 and 38.7% for the CON and TREAT conditions, respectively. Within CON, shifts in HRV resulted in less motivation (mean diff. = -4.00%; 95%CI = -7.56, -0.44; F = 4.86, p = 0.028) and more physical fatigue (mean diff. = 4.79%; 95%CI = 1.85, 7.74; F = 10.24, p < .001). Spectral domain metrics (i.e., LF:HR ratio) were significantly lower (mean diff. = -0.14 au; 95%CI = -0.27, -0.01; F = 4.715, p = .030) during HRV shifts. Within TREAT, shifts in HRV resulted in no change in motivation (mean diff. = 2.58%; 95%CI = -6.54, 1.38; F = 1.63, p = .202) with reduced physical fatigue (mean diff. = -5.94%; 95%CI = -9.56, -2.32; F = 10.40, p = .001). Within TREAT, LF:HF ratio was higher (mean diff. = 0.13 au; 95%CI = 0.23, 0.24; F = 5.59, p = .018) during HRV shifts. **CONCLUSIONS:** These data establish a link between expected shifts in heart rate variability throughout high-intensity exercise programs with motivation to participate and physical fatigue. Additionally, modulation of training volume, in response to these shifts, can optimize adherence-related behavioral responses during high-exercise programs.

**435 Board #251 May 27 10:30 AM - 12:00 PM
AUTONOMY AND VARIATION IN HIGH-INTENSITY INTERVAL TRAINING: IMPACTS ON POST-EXERCISE ENJOYMENT, SELF-EFFICACY, AND INTENTION**

Gianna F. Mastrofina, Robert P. Collins, Jorge A. Rosa, Katherine M. Sipos, Brian Waddell, Marcus W. Kilpatrick, FACSM.
University of South Florida, Tampa, FL. (Sponsor: Marcus Kilpatrick, FACSM)
Email: gfmastrofina@mail.usf.edu
(No relevant relationships reported)

Benefits associated with high-intensity interval training (HIIT) are established and research demonstrates that HIIT is well-tolerated in a variety of populations, protocols, and modalities. However, relatively little is known about the impact of variation and self-selection of work intervals on post-exercise perceptions. **PURPOSE:** The purpose of this study was to determine the impact of autonomy and variation on exercise enjoyment and both self-efficacy for and intention to repeat HIIT exercise. **METHODS:** Twenty-one physically active participants (12 male, 9 female; mean BMI = 27 ± 3; mean age = 28 ± 6) completed three, 20-minute HIIT trials after

completion of maximal testing. All experimental trials included a total of 10 minutes of work and 10 minutes of recovery. Work and recovery were conducted at 90% and 10% of peak work, respectively. Trials included: a standard interval bout with repeating 60-sec work and recovery segments (Traditional), an interval bout with a mix of predetermined 30-, 60-, 90-, & 120-second segments (Varied), and a bout with a self-selected number of 30-, 60-, 90-, & 120-second segments (Autonomous). In-task affective valence and enjoyment were measured four times during work and recovery. Data was analyzed using dependent t-tests. RESULTS: Enjoyment measured via questionnaire post-exercise revealed no significant differences between the three trials ($P > 0.05$) suggesting similar levels of enjoyment for all trials. All three trials were deemed to be enjoyable exercise sessions (scores ranging from 95-100 on the 18-126 scale). Self-efficacy for completing HIIT (measured on a 0-100 scale) was greater for the Autonomous trial compared to the Varied trial (77% vs. 70%; $P < 0.05$) and intention to exercise (measured on a 1-7 scale) was not different across trials, but there was a trend towards Autonomous HIIT producing stronger intentions than Varied HIIT (4.3 vs. 3.7; $P < 0.10$). CONCLUSIONS: Findings indicate that each trial of HIIT was enjoyable and produced relatively positive ratings for exercise self-efficacy and intention. These findings suggest that provision of autonomy during HIIT exercise sessions can produce more desirable psychological responses for self-efficacy and possibly exercise intention.

Perceived And Actual Motor Competence And Physical Activity In Children With And Without Asthma

Indica Sur, Katherine Q. Scott-Andrews, Lexie R. Beemer, Tiwaloluwa A. Ajibewa, Leah E. Robinson, FACSM, Toby C. Lewis, Rebecca E. Hasson, FACSM. *University of Michigan, Ann Arbor, MI.* (Sponsor: Rebecca Hasson, FACSM)
 (No relevant relationships reported)

Motor competence (MC) and perceived motor competence (PMC) are important determinants of physical activity participation and may contribute to the lower physical activity levels and fitness previously observed in children with asthma.

PURPOSE: The purpose of this study was to compare MC, PMC, and moderate-to-vigorous physical activity (MVPA) levels in children and adolescents with and without asthma, and to determine whether motor skills predict lower MVPA in children with asthma compared to their healthy peers.

METHODS: Eleven children with persistent asthma (age=11.1±0.7 years; 54.5% female; BMI percentile=53.4±9.8) and 20 children without asthma (age=11.1±0.6 years; 50.0% female; BMI percentile=60.3±6.2) participating in the Exercises for a Healthy Asthma Lifestyle and Enjoyment (EXHALE) study have been analyzed to date. Asthma diagnosis was verified by the child's physician. MC was measured using the Movement Assessment Battery for Children-2. PMC was measured using the Athletic Competence domain from the Self-Perceptions Profile for Children. MVPA was assessed via accelerometry.

RESULTS: Children with asthma reported lower PMC than children without asthma (2.5±0.1 vs. 2.9±0.1, $p=0.04$) with no significant differences in MC between groups (7.0±0.9 vs. 7.6±0.5, $p=0.55$). Children with asthma engaged in 16 fewer minutes of MVPA per day compared to their healthy peers (27.7±5.5 vs. 44.1±22.3, $p=0.06$), however, in preliminary analyses, this difference was not statistically significant. MC and PMC were not significant predictors of MVPA (MC: $\beta=0.95\pm 1.70$, PMC: $\beta=-14.6\pm 9.3$; $p>0.05$), and there were no differences by asthma status ($p>0.05$).

CONCLUSIONS: Children with asthma reported lower self-perceptions of motor competence and engaged in fewer minutes of health-enhancing physical activity compared to their healthy peers. Motor skills, however, were not significant predictors of physical activity engagement. Additional research is needed to better understand the factors contributing to lower physical activity levels and fitness previously observed in children with asthma. As the EXHALE study proceeds, we will be able to reexamine these relationships further and examine asthma characteristics that may influence these relationships.

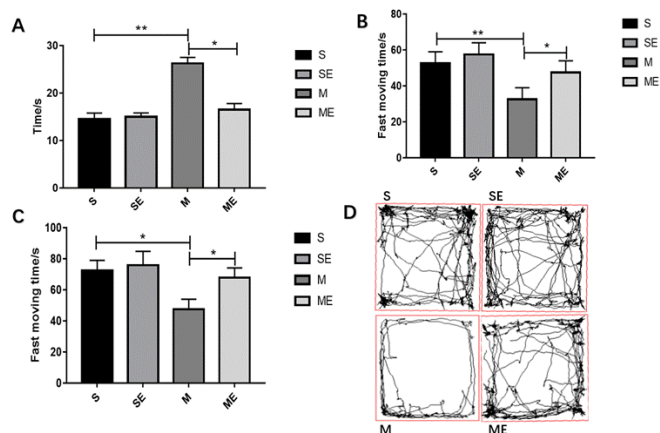

437 Board #253 May 27 10:30 AM - 12:00 PM
Aerobic Exercise Enhances Behavior Features In Model Of Parkinson'S Disease Mice Via Pink1/parkin Pathway

Jianshe Wei, Baozhu Fan, Riffat Jabeen, Chunlei Guo, Bright Anyomi, Solomon Agegnehu, Mengjie Han, Yuling Zhang, Yuling Zhang, Ke Wang, Hui Zhang, Juan Cen, Xinying Ji. *Institute for Brain Sciences Research, Henan University, Kaifeng, China.*
 Email: jswei@henu.edu.cn
 (No relevant relationships reported)

Oxidative stress in the brain of Parkinson's patients leads to impaired mitochondrial function, while exercise can improve mitochondrial function, but the mechanism is unclear. There are two mechanisms of mitochondrial function: autophagy and transport function. **PURPOSE:** To detect the expression of mitochondrial autophagy protein

PINK1/Parkin in MPTP-induced Parkinson's (PD) mice by treadmill exercise, and to explore the effect of aerobic exercise on mitochondrial function. **METHODS:** 32 C57BL/6J male mice were divided into 4 groups: Saline group (S), Saline+ Exercise group (SE), MPTP group (M), and MPTP + Exercise group (ME). M and ME mice were injected with MPTP to construct a PD model. SE and ME mice were subjected to 8 weeks treadmill training. Behavioral tests were performed after exercise; immunofluorescence and histochemistry, and Western Blot to detect molecular indicators. **RESULTS:** (1) The time of passing the balance beam, M group was longer than the S group ($P<0.01$), and the ME group was shorter than the M group ($P<0.05$) (Fig1A); In the forced swimming test (Fig1B) and the open field experiment (Fig1C&D) the mouse fast moving time, M group was shorter than the S group ($P<0.05$), while the ME group was longer than the M group ($P<0.05$). (2) The expression of α -Syn was up-regulated in the M group ($P<0.01$), but in the ME group was decreased after exercise ($P<0.05$) (Fig2). (3) The expression of Tyrosine hydroxylase (TH)(Fig3), TOM-40(Fig4) in group M was lower than that in group S ($P<0.05$), while ME group was higher than that M group ($P<0.05$). (4) The protein of Parkin and PINK1 were increased after exercise ($P<0.05$) (Fig5). **CONCLUSION:** Exercise can enhance the mitochondrial autophagy ability, improve the mitochondrial transport function, promotes behavior features in PD mice.

Key words: aerobic exercise; mitochondria; autophagy; Parkinson's disease

Age Differences For Relationships Between Perceived Health, Exercise Motivation And Self-efficacy Factors After HIFT

Katie M. Heinrich, Sarah J. Cosgrove, Blake Goodman, Victor C. Andrews. *Kansas State University, Manhattan, KS.*
 Email: kmhphd@ksu.edu

Reported Relationships: K.M. Heinrich: Consulting Fee; I received payment for consulting on two outside legal cases regarding the same exercise program as used in my abstract.

Health benefits are a frequent exercise motive, despite mental and fitness improvements occurring sooner. Key cross-sectional participation motives in high intensity functional training (HIFT) have included mental (e.g., enjoyment), social (e.g., affiliation), and fitness (e.g., nimbleness) factors, which vary by age and are related to self-efficacy (SE). However, no research has examined relationships between changes in these variables after HIFT participation. **PURPOSE:** To investigate how perceived changes in health and motivation related to SE changes by age. **METHODS:** Data were from an ongoing program evaluation study at a university HIFT gym. Participants ($n = 35$; 52% female, 97% white, 26.5 ± 26.6 months HIFT experience) were emailed two online surveys (2-6 months apart) including demographics, general health status, exercise motivation, and 12 SE mental, social, and fitness factors including HIFT adherence. Participant age ranged from 20-76 years; three age cohorts (C) were used for analysis: C1 (20-34 years, $n = 10$), C2 (35-64 years, $n = 13$), and C3 (65+ years, $n = 10$). Difference scores were compared using bi-variate correlations. **RESULTS:** No C1 participants reported changes in health; a slight decrease in motivation (-0.4 ± 1.0) was not correlated with changes in any SE factors. For C2 participants, the slight improvement in health (0.2 ± 0.4) was significantly correlated with SE for adherence ($r = 0.68$, $p = .011$), describing fitness goals/weaknesses ($r = 0.81$, $p = .001$), and recognizing strengths/weaknesses in different situations; a slight increase in motivation (0.3 ± 1.0) was not correlated with any changes in SE factors. Although C3 participants averaged a slight decrease in health (0.2 ± 0.4), improved health was correlated with SE for adherence ($r = 0.78$, $p = .008$); and a slight motivation increase (0.4 ± 1.5) was correlated with SE for adherence ($r = 0.65$, $p = .04$)

and agility ($r = 0.78, p = .006$). **CONCLUSIONS:** Perceived health improvements for participants ages 35+ increased SE for adherence, as well as mental factors for middle-age participants, while increased motivation was only related to increased SE for adherence among older adults. Age differences must be considered for HIFT program design and delivery, and future research might examine these relationships in comparison to other fitness programs.

439 Board #255 May 27 10:30 AM - 12:00 PM
Physical Activity, Sedentary Behavior, And Social Media Use In College Students

Sara J. Kovacs¹, Amanda L. Folk². ¹Temple University, Philadelphia, PA. ²University of Minnesota, Minneapolis, MN.
 (No relevant relationships reported)

There is currently a gap in the literature regarding the relationship between physical activity (PA), sedentary behavior, and social media use. It is unclear if hours per day of social media use is associated with activity patterns of college students. Additionally, it is unclear if type of social media accounts followed influence activity patterns. **Purpose:** To examine the relationship between PA, sedentary behavior, and social media use in college students. **Methods:** College students completed a one-time online questionnaire. PA and sedentary behavior were assessed using the International Physical Activity Questionnaire-Short Form. **Results:** Two-hundred ninety-two students provided informed consent and were eligible to participate in the study. Activity patterns were self-reported [median (25th, 75th percentile)]. Participants reported 120 (80, 240) min/wk of moderate intensity PA, 240 (120, 360) min/wk of vigorous intensity PA, and 250 (165, 360) min/wk of sedentary behavior. Only 30.8% of the sample engaged in a minimum of 150 of moderate intensity activity each week, and 61.4% in the recommended minimum of 75 minutes of vigorous intensity PA. Furthermore, 31.6% of participants did not report any engagement in moderate intensity PA, and 27.9% did not report any engagement in vigorous intensity PA. In this sample, 97.9% of students reported using social media daily, with 41.38% and 43.1% reporting 1-2 hours and 3-4 hours of social media use each day, respectively. Social media use was not associated with moderate or vigorous intensity physical activity ($p > 0.05$); however, hours per day of social media use was associated with sedentary behavior ($r = 0.156, p = 0.009$). Additionally, following health/fitness social media accounts was significantly associated with BMI ($r = -0.129, p = 0.029$), sedentary behavior ($r = 0.128, p = 0.031$), and reaching the vigorous intensity PA guidelines minimum recommendation ($r = -0.194, p = 0.001$). **Conclusion:** While there is an increased interest in utilizing social media as an intervention strategy to promote behavior change, results from this study indicate that social media may have a undesirable relationship with vigorous intensity PA and sedentary behavior. Future studies should examine the longitudinal influence of social media on PA and use objective PA monitoring.

440 Board #256 May 27 10:30 AM - 12:00 PM
Influence Of Resistance-exercise Training On Total Physical Activity In Gulf War Veterans With Chronic Pain

Aaron J. Stegner¹, Neda E. Almassi¹, Ryan J. Dougherty¹, Laura D. Ellingson, FACSM², Nicholas P. Gretzow¹, Jacob V. Ninneman¹, Stephanie M. Van Riper¹, Patrick J. O'Connor, FACSM³, Dane B. Cook, FACSM⁴. ¹Univ. of Wisconsin, Madison, WI. ²Western Oregon University, Monmouth, OR. ³Univ. of Georgia, Athens, GA. ⁴William S. Middleton Memorial Veterans Hospital, Madison, WI. (Sponsor: Dane B. Cook, FACSM)
 (No relevant relationships reported)

Nearly 30% of US military Veterans of the Persian Gulf War are currently suffering from debilitating multisymptom illnesses. A primary complaint among these individuals is chronic widespread musculoskeletal pain (CMP). Previously our lab has observed lower levels of total physical activity (PA) in civilian CMP patients compared to their healthy peers. In general, CMP patients with lower levels of PA are at risk for greater disability. While exercise-training interventions may have demonstrated benefits for fitness and health related outcomes, their influence on total PA, particularly in CMP patients, is an open question.

PURPOSE: To quantify the influence of a 16-week resistance exercise training (RET) trial on self-reported and actigraphy measures of total PA in Gulf War Veterans (GV) with CMP.

METHODS: Fifty-five GV with CMP were randomly assigned to 16 weeks of RET (n=28) or a wait-list control (n=27). The RET consisted of twice weekly sessions with a personal trainer, initiated at a low intensity (25-35% 1 RM) with progression as tolerated. At baseline, 6 weeks, 11 weeks, and 17 weeks, all participants completed the International Physical Activity Questionnaire (IPAQ) and wore a waist-mounted actigraphy monitor (ACTI) for 7 d during waking hours. Total PA was defined for the IPAQ as the summative total score (MET-min/week) and for the ACTI as total counts per day relative to wear time (counts/d/min). Analyses were limited to GV with valid

measures at baseline and at least one additional time point. Data were log transformed and extreme outliers (> 3 SD) were excluded. Separate linear mixed models with group and time point as fixed effects were computed for the IPAQ and ACTI measures, using baseline values as a covariate to control for initial differences.

RESULTS: GV assigned to RET completed 88% of training sessions and exhibited strength increases of $>20\%$ for 7 of 8 lifts. Estimates for the fixed effects and their interaction were not significant for either measure (IPAQ: $F_G = 0.17, F_{TP} = 0.02, F_{G \times TP} = 0.09, p < 0.05$; ACTI: $F_G = 0.47, F_{TP} = 0.09, F_{G \times TP} = 0.22, p < 0.05$).

CONCLUSION: Although 16 weeks of RET were well attended and resulted in improvements in fitness for GV with CMP, total PA level, outside of the exercise sessions, did not appear to be impacted.

Acute Effects Of Intermittent Physical Activity On Psychological Stress And Insecurity In Children And Adolescents With And Without Asthma

Tiwailoluwa A. Ajibewa, Lexie R. Beemer, Katherine Q. Scott-Andrews, Indica Sur, Leah E. Robinson, FACSM, Toby C. Lewis, Rebecca E. Hasson, FACSM. University of Michigan, Ann Arbor, MI. (Sponsor: Rebecca E. Hasson, FACSM)
 Email: tajib@umich.edu
 (No relevant relationships reported)

Intermittent physical activity (PA) may be a novel strategy to promote PA in children and adolescents with asthma, potentially averting the physiologic changes associated with exercise-induced bronchoconstriction that occurs during longer bouts of exercise. Yet, the psychological impact and acceptability of intermittent PA have not been rigorously evaluated in this clinical population. **PURPOSE:** To examine acute changes in psychological stress and insecurity in children and adolescents with and without asthma while performing five exercise conditions in a laboratory setting. **METHODS:** Thirty-one children and adolescents between the ages of 8-15 years (35% with asthma; 52% female; mean age: 11.1 ± 0.4 years; BMI_{50ile}: 57.8 ± 5.2) were recruited from Southeast Michigan to participate in the Exercises for a Healthy Asthma Lifestyle and Enjoyment (ExHALE) Study. Participants completed 5 exercise conditions in the following order: i) 6-minute walk test, ii) 5-minute resistance circuit, iii) 5-minute activity video, iv) 5-minute gamified obstacle course, and v) the YMCA Three-Minute Step Test. Heart rate (HR) and rating of perceived exertion (RPE) were measured to objectively and subjectively assess exercise intensity using HR monitoring and the children's OMNI Perceived Exertion Scale, respectively. Psychological stress and insecurity were self-reported using a Visual Analog Scale pre- and post-activity. **RESULTS:** Mean HR was significantly different across all conditions ($p < 0.01$), with the highest HRs observed during the obstacle course and the lowest HRs during the activity video (gamified obstacle course: 167.2 ± 2.4 bpm; step test: 146.0 ± 3.5 bpm; walk test: 122.4 ± 4.1 bpm; resistance circuit: 113.8 ± 2.9 bpm; activity video: 105.7 ± 2.5 bpm). There were no differences in HR by asthma status ($p > 0.05$). RPE followed the same trend as HR but there were no significant differences in RPE ($p = 0.05$), psychological stress or insecurity across conditions or by asthma status ($p > 0.05$). **CONCLUSIONS:** Intermittent PA of varying intensity and duration did not increase psychological stress or insecurity in children and adolescents with and without asthma. These findings provide preliminary evidence in support of using intermittent PA to promote PA participation among children and adolescents with asthma.

Psychological Responses To Intermittent Physical Activity In Children With And Without Asthma

Katherine Q. Scott-Andrews, Lexie R. Beemer, Tiwailoluwa A. Ajibewa, Indica Sur, Leah E. Robinson, FACSM, Toby Lewis, Rebecca E. Hasson, FACSM. University of Michigan, Ann Arbor, MI. (Sponsor: Rebecca Hasson, FACSM)
 Email: abeemer@umich.edu
 (No relevant relationships reported)

BACKGROUND: Knowing *how* children feel during physical activity and what *type* of activities they enjoy can provide insight regarding their motivation to participate in future activity. These factors may be especially important for children with asthma who experience many barriers to maintaining an active lifestyle. **PURPOSE:** To compare psychological responses (physical activity enjoyment and mood) during intermittent activities of varying intensity and durations in children with and without asthma. **METHODS:** Thirty-one children (asthma: n=11, 45% male, mean age: 11.1 ± 0.7 years, BMI_{50ile}: 53.4 ± 9.8 ; non-asthma: n=20, 50% male; mean age: 11.1 ± 0.6 years; BMI_{50ile}: 60.3 ± 6.2) participated in the Exercises for a Healthy Asthma Lifestyle and Enjoyment (ExHALE) Study. Participants completed 5 conditions in the following order: 1) Six-minute moderate-intensity walk test, 2) 5-minute moderate-intensity resistance circuit, 3) 5-minute moderate-intensity activity video, 4) 5-minute high-intensity gamified obstacle course, and 5) the YMCA three-minute high-intensity step test. Enjoyment was assessed via the Physical Activity Enjoyment Scale following

each condition. Mood was assessed via the Feeling Scale at the midpoint of each condition. **RESULTS:** There was a significant effect of condition on mood across activities ($p < 0.02$) with lower mood reported during the step test compared to the walk test, resistance circuit, and activity video (step test: 2.1 ± 0.3 vs. walk test: 3.6 ± 0.3 , resistance circuit: 3.2 ± 0.3 , activity video: 3.4 ± 0.3 , all p 's < 0.01). There was no effect of condition on enjoyment with children reporting high levels of enjoyment across activities (walk test: 3.6 ± 0.1 , resistance circuit: 3.9 ± 0.1 , activity video: 3.9 ± 0.1 , obstacle course: 3.9 ± 0.1 , step test: 3.7 ± 0.2 ; $p > 0.05$). There were no differences by asthma status on mood or enjoyment across activity conditions (all p 's ≥ 0.05). **CONCLUSIONS:** Participants reported lower mood during the higher intensity tempo-paced activity, but similar levels of enjoyment for all activities. These findings suggest intermittent activity of varying intensities and durations is an enjoyable form of exercise for both children with and without asthma.

Alcohol, Tobacco And Marijuana Use In A Population Of Ultramarathon Runners

Ankit Shah¹, Umar Khan², Rebecca Torguson³, Kezia Alexander⁴, Casey Fisher⁵, Matthew Sedgley, FACSM¹, Aaron Baggish⁶, Andrew Lincoln⁷. ¹MedStar Union Memorial Hospital, Baltimore, MD. ²Georgetown University School of Medicine, Washington, DC. ³MedStar Cardiovascular Research Network, Baltimore, MD. ⁴MedStar Sports Medicine, Baltimore, MD. ⁵MedStar Franklin Square Hospital, Baltimore, MD. ⁶Massachusetts General Hospital, Boston, MA. ⁷MedStar Health Research Institute, Baltimore, MD. (Sponsor: Matthew Sedgley, FACSM)
 Email: ankit.b.shah@medstar.net
 (No relevant relationships reported)

Purpose: It is well accepted that routine low to moderate intensity physical activity leads to decreased cardiovascular (CV) morbidity and mortality. However, recent observational studies suggest that athletes who exercise at the highest doses (frequency x duration x intensity) may exhibit a reverse J-shaped dose-response with respect to mortality and development of CV disease. Our objective was to determine the prevalence of alcohol and marijuana use in ultramarathon runners and whether these behaviors were associated with CV risk factors.

Methods: This was a pilot survey involving 2018 John F. Kennedy 50 Mile ultramarathon race participants held in Hagerstown, MD. Predefined CV risk factors included current or prior history of smoking, diabetes, hypertension, dyslipidemia, and obesity (BMI > 30). Health behaviors included use of alcohol and marijuana. **Results:** Of the 868 registered runners, 292 (34%) completed the survey. 106 (36.3%) runners had at least one CV risk factor and 15 (5.2%) had known CV disease. Overall, 1.4% of runners reported being a current smoker, 25.3% were prior smokers, 31.3% lived with a smoker, 2.8% consumed alcohol during ultra events, 45.7% consumed alcohol after ultra events, 13.8% were told they drink too much, and 12.4% regularly used marijuana. Runners with at least one CV risk factor were more likely to have consumed alcohol during ultra events ($p = 0.025$) and were told they drink too much ($p < 0.001$). Using marijuana was marginally associated ($p = 0.082$) with having at least one CV risk factor.

Conclusions: These findings suggest that use of alcohol may be associated with increased CV risk in this unique population. Further study is required to explore whether elevated CV risk is the result of extreme doses of exercise, lifestyle habits (alcohol and marijuana use), or a combination of both factors that have not been accounted for in large observational studies.

444 Board #260 May 27 10:30 AM - 12:00 PM
Perceived Barriers And Motivators For Physical Activity In Women With Perinatal Depression

Sylvia E. Badon, Esti Iturralde, Nerissa Nance, Lyndsay A. Avalos. Kaiser Permanente Northern California, Oakland, CA.
 Email: sylvia.e.badon@kp.org
 (No relevant relationships reported)

Physical activity (PA) may help reduce severity of depressive symptoms in women with perinatal depression (depression during pregnancy or postpartum). However, less than one third of pregnant and postpartum women meet national PA recommendations, and PA is likely even lower in women with perinatal depression. Barriers and motivators for PA among women with perinatal depression are not well understood. **PURPOSE:** The aim of this study was to identify barriers and motivators for PA among women with perinatal depression. **METHODS:** Pregnant and postpartum women with perinatal depression were identified using Kaiser Permanente Northern California's universal perinatal depression screening program. We conducted 8 focus groups totaling 35 women with prenatal ($n = 15$) and postpartum depression ($n = 20$). Focus groups were analyzed using an inductive approach. **RESULTS:** Pregnant women were, on average, 27 weeks gestation (range: 11-37) with mild to moderately severe depressive symptoms (Patient Health Questionnaire (PHQ)-8 mean: 10; range:

4-19). Postpartum women were, on average, 12.5 months postpartum (range: 8.5-16.5) with no to moderately severe depressive symptoms (PHQ-8 mean: 7; range: 0-16). Perceived barriers to PA identified by pregnant and postpartum women included low energy and mood, limited time due to other priorities, feeling discouraged when comparing to pre-pregnancy self, and limited geographic accessibility and high cost of group exercise classes. Unique barriers identified by pregnant women were physical discomfort and fear of judgement from others. Postpartum women identified lack of childcare as an additional barrier. Motivators for PA identified by pregnant and postpartum women included self-care ("me time"), improved mood after PA, making progress toward goals, being strong and fit to keep up with their children, and having a social support system. **CONCLUSIONS:** Interventions to increase PA in pregnant and postpartum women with perinatal depression should include components addressing motivation, time, geographic accessibility, and cost barriers. Interventions can also increase PA by promoting potential mood benefits, fostering a sense of accomplishment, and leveraging social support as motivators in pregnant and postpartum women with perinatal depression.

445 Board #261 May 27 10:30 AM - 12:00 PM
Exercise Interests, Identity, And Motivations Across Levels Of Activity And Exercise Preferences: What Moves You?

Katrina Taylor, Emily R. Dunston. Eastern Washington University, Cheney, WA.
 Email: ktaylor31@ewu.edu
 (No relevant relationships reported)

Despite numerous benefits of engaging in adequate moderate-to-vigorous physical activity (MVPA), nearly half of US adults do not meet activity guidelines. Exercise motivations have been positively associated with MVPA; however, little research has investigated exercise interests and identity across levels of MVPA and exercise mode preferences. **PURPOSE:** To determine differences in exercise identity, interests, and motivations across levels of MVPA and exercise mode preferences. **METHODS:** US adults ($n = 170$; age 34.1 ± 13.9 y) completed a survey consisting of the Exercise Identity Scale, Behavioral Regulation in Exercise Questionnaire, and Exercise Interest Scale. Demographic information, MVPA and exercise preferences were also reported. Data were analyzed using one-way ANOVA to determine differences across quartiles of MVPA and exercise mode preferences. **RESULTS:** Exercise identity was significantly lower in Q1 (35.3 ± 12.6) than Q3 (48.8 ± 10.5 , $p < 0.001$) and Q4 (53.2 ± 10.7 , $p < 0.001$). Exercise interests were different across quartiles with Q1 reporting lower scores in the challenge ($p < 0.01$) and creativity ($p < 0.05$) subscales. Intrinsic motivations ($p \leq 0.001$) were different across quartiles of MVPA with higher motivations with increased MVPA. Exercise interests differed across exercise preference, specifically in the outdoor ($p < 0.001$), competition ($p = 0.001$), social ($p = 0.04$), and challenge ($p = 0.02$) subscales. People who prefer outdoor exercise had significantly higher outdoor interest scores (14.1 ± 1.9) compared to those who prefer group (11.3 ± 3.0), individual (11.4 ± 2.9), or sport activities (11.8 ± 2.7 ; $p \leq 0.005$ for all). Further, people who prefer sports had higher competition interest (11.1 ± 2.9) than group (8.1 ± 3.0), individual (8.6 ± 2.9), or outdoor activities (8.4 ± 3.4 ; $p \leq 0.006$ for all). There were no differences in exercise motivation or identity across exercise mode preferences ($p > 0.05$). **CONCLUSIONS:** Our findings suggest exercise identity, interests, and intrinsic motivations may play an important role in MVPA engagement. Further, exercise preference could be determined using the Exercise Interest Scale. Future research should investigate the association between exercise interests, identity and motivations and long-term adherence to MVPA in previously inactive individuals.

446 Board #262 May 27 10:30 AM - 12:00 PM
The Effects Of Frequency Framing On Fitness Center Commitment Contracts

Jessica Ramirez-Magana, Zachary Zenko. California State University Bakersfield, Bakersfield, CA.
 (No relevant relationships reported)

Research from the field of behavioral economics indicates that different frames of similar or equal situations can impact decision making. Rather than only focusing on maximizing utility, decision-makers are influenced by other, nonrational factors, such as the way choices are presented. **PURPOSE:** The purpose of this study was to analyze if the framing effect applied to the context of fitness center commitment contracts. **METHODS:** 145 adults (mean age [SD]: 36 [11] years; 88 men, 56 women) in the United States completed an online survey in which they were randomized to one of two frames. In the Twice/Week group, participants were asked to consider a commitment contract in which attending a fitness center twice per week for one year would result in a 50% membership reimbursement. Participants in the 104/Year group were asked to consider a commitment contract in which attending the fitness center 104 times in one year would result in a 50% membership reimbursement. Both commitment contracts were identical in terms of total commitment and total number of required fitness center visits (i.e., 104 times per year, or twice per week for 52 weeks [$2 * 52 = 104$]) but framed to emphasize either short-term intervals (weekly) or long-

term (yearly). Participants responded to questions about the likelihood of signing up for the promotion, the perceived effectiveness of the promotion for changing exercise behavior, and the perceived effectiveness of the promotion for getting new members to join the fitness center. **RESULTS:** Independent t-tests indicated no difference in reported likelihood of signing up for the promotion ($p = .434$), no difference in the perceived effectiveness for changing exercise behavior ($p = .144$), and no difference in the perceived effectiveness for getting new members to join the fitness center ($p = .324$). **CONCLUSIONS:** In the context of hypothetical fitness center memberships and commitment contracts, different frames of visit frequency did not impact the likelihood of signing up for the promotion, perceived effectiveness for changing exercise behavior, or perceived effectiveness for recruiting new members. The usually robust framing effect may not translate to this situation. These data were about hypothetical commitment contracts; therefore, real-world data are needed to replicate these findings.

An Examination Of Mental Toughness And Physical Activity Among College Students

Daniel James Lange, Benjamin L. Webb. *Southern Illinois University Edwardsville, Edwardsville, IL.*

(No relevant relationships reported)

Despite the abundance of literature examining the effects of mental toughness (MT) on increased athletic performance, challenge appraisal, and motivation within the context of sport, there is a paucity of literature examining mental toughness within the context of physical activity (PA). Furthermore, studies that have examined mental toughness within the context of PA only included athletes in their samples.

Purpose: To examine MT and PA among college students enrolled in a mid-Western university. **Methods:** Participants ($N = 273$) completed online questionnaires regarding age, sex, race, athlete status, MT, and PA. The Mental Toughness Questionnaire-48 (MTQ48) was used to measure MT while the International Physical Activity Questionnaire – Short Form (IPAQ-SF) was used to measure PA. Pearson's Product-Moment Correlations were used to assess correlations between MT and PA. Independent samples *t*-tests were used to determine whether MT and PA varied according to sex (male vs female), race (White vs non-White), or athlete status (athlete vs non-athlete). **Results:** There were no significant correlations between overall MT, total PA, VPA, MPA, and meeting PA guidelines. Of the six subscales of MT, only challenge showed significant correlations with overall PA, $r(273) = .133, p < .05$; VPA, $r(273) = .199, p < .05$; and meeting PA guidelines, $r(273) = .119, p < .05$. Scores on the challenge subscale of MT were higher for athletes compared to non-athletes (3.68 ± 0.37 vs $3.55 \pm 0.43, p < .05$). Furthermore, overall PA was higher for athletes compared to non-athletes (688.65 ± 734.82 vs $324.80 \pm 511.70, p < .05$), as was VPA (444.15 ± 389.63 vs $191.73 \pm 269.78, p < .05$). Additionally, PA was higher for males compared to females (329.57 ± 16.44 vs $220.31 \pm 323.72, p < .05$). No significant differences were found between any form of MT and PA behaviors when regarding age and race. **Conclusion:** Mental toughness was not correlated with PA among college students. However, differences in MT and PA according to sex, race, and athletic status should be examined further.

Do Race, Physical Activity, Body Mass Index, And Sleep Quality Affect Mental Toughness?

Krystal Grant¹, Quinn Astrachan¹, Alexander Anderson¹, Courtnie Moodie¹, Andreas Stamatis², Zacharias Papadakis¹.
¹Barry University, Miami, FL. ²SUNY Plattsburgh, Plattsburgh, NY.

Email: Krystal.grant@mymail.barry.edu

(No relevant relationships reported)

Physical activity (PA) has been linked to health and quality of life benefits. Differences in race and body mass index (BMI) may contribute to health-related disparities. Sleep quality (SQ) has been associated with both PA and health, influencing each other in a two-way interaction. Variations in PA are linked to differences in mental toughness (MT). MT is linked to lower SQ and increased PA, but the influence of race and BMI on MT is still under investigation. **PURPOSE:** To characterize the association and the effects of PA, race, BMI, and SQ on MT. **METHODS:** Sixty-two participants (age 25.4 ± 6.0 SD) completed surveys related to PA, race, BMI, SQ, and MT. Main and interaction effects of the responses analyzed using factorial ANOVA. Significance was set at $p < 0.05$. All analyses were performed using SPSS[®]. **RESULTS:** PA was positive correlated ($r = .246, p = .027$) and SQ was negatively associated with MT ($r = -.470, p = .000$). Race was negatively associated with MT ($r = -.234, p = .033$). SQ had a main effect on MT ($F_{31,1} = 18.568, p = .000, \eta^2 = .382$). PA and BMI interaction had an effect on MT ($F_{31,2} = 5.572, p = .009, \eta^2 = .271$). The interaction of race and BMI had an effect on MT ($F_{31,1} = 2.805, p = .043, \eta^2 = .272$). **CONCLUSION:** As previously reported, poor quality sleepers are mentally tougher compared to good quality sleepers. When PA and BMI are combined, PA and overweight individuals are mentally tougher, followed by the non-PA and underweight ones. When race and BMI are combined, White-overweight and other-normal BMI individuals are the mentally

toughest. Followed by Hispanic-overweight, and Asian underweight and obese I, II, III, with African Americans underweight and overweight having similar values. Health care professionals may find this information valuable when they are trying to address health-related issues that pertain to race, PA, BMI, SQ, and MT.

FUNCTIONAL FITNESS LEVELS REFLECT COGNITIVE HEALTH STATUS

Joshua L. Gills¹, Spencer Smith¹, Jordan M. Glenn², Erica N. Madero², Nick T. Bott², Jennifer Vincenzo², Michelle Gray¹.

¹University of Arkansas, Fayetteville, AR. ²Neurotrack, Redwood City, CA.

Email: jgills@uark.edu

(No relevant relationships reported)

Alzheimer's disease currently affects 5.8 million people in the US and the number is projected to triple by 2050. As the baby boomer population ages, it is important to identify measures that correlate with cognitive decline. Measures that show a relationship with cognitive decline can serve as early indicators that a person is in need of a cognitive evaluation. **PURPOSE:** The purpose of this evaluation was to determine if functional fitness tasks could accurately discriminate between older adults with and without mild cognitive impairment. **METHODS:** Adults 60+ years participated in the present investigation ($n = 107$). Each participant completed demographic questionnaires; completed two stationary cognitive tasks: Montreal Cognitive Assessment (MoCA) and visual paired comparison (VPC); and completed four functional cognitive assessments: dual-task maximal speed (DTMS), dual-task habitual speed (DTHS), sit-to-stand power, timed up and go test (TUG). Participants with MoCA scores ≥ 23 were classified as cognitively intact (CIN), whereas participants with MoCA scores < 23 were classified as cognitively impaired (CIM). A one-way ANOVA determined if there were significant differences between groups for each cognitive task. **RESULTS:** Eighty CIN and twenty-three CIM subjects completed all assessments. The CIN group had higher scores on the VPC task ($p = .02$), while exhibiting faster times to complete DTMS ($p < .001$), DTHS ($p = .002$), and TUG ($p = .02$) compared to the CIM group. No significant differences were found between the cognitive groups in sit-to-stand power variables: peak power ($p = .08$), average power ($p = .07$), and average velocity ($p = .08$). **CONCLUSIONS:** Functional fitness assessments distinguished between CIN and CIM groups. As these results indicate, functional fitness may be an indicator of cognitive status. Future investigations should longitudinally track both functional fitness and cognitive function to further elucidate this relationship.

Do Perceptions Of Physical Environment Predict Physical Activity Intention Among International College Students?

Zi Yan¹, Tao Zhang². ¹Merrimack College, North Andover, MA. ²University of North Texas, Denton, TX. (Sponsor: Kevin Finn, FACSM)

Email: yanz@merrimack.edu

(No relevant relationships reported)

Purposes: International college students were at higher risk of being sedentary compared to domestic students (Yan et al., 2015). Physical environmental factors, such as accessibility and environmental safety, were previously found to predict physical activity (Strand et al., 2010). However, it is not clear whether environmental factors would have an impact on international college students given the fact that most universities have accessible recreation centers and other facilities. This study aimed to examine whether the perceptions of environmental safety and accessibility to physical activity are associated with the physical activity intention among international college students.

Methods: Participants were 249 international college students from a public university in Southern US (48.2% female; $M_{age} = 27.48, SD = 6.12$). The perception of the environmental safety and accessibility to physical activity were measured by a validated scale adapted from Yan (2012). Exemplar question was "It is safe to walk or jog alone where I live during the day". Physical activity intention was measured by three questions on a 7-point Likert scale (Blanchard et al., 2003; Trost et al., 2002). Gender and age were also measured.

Results: The independent T-test showed that males perceived the environment safer than females to do physical activity, $t(245) = 1.94, p = .05$. No gender difference in the perception of physical activity accessibility, $t(245) = .64, p > .05$. The multiple regression model on intention, controlling gender and age, was significant. Perception of environmental safety significantly predicted the physical activity intention ($\beta = .48, P < .001$), but not the environmental accessibility ($\beta = .13, P > .05$).

Conclusion: Compared to accessibility to physical activity, perception of environmental safety is more important for international college students to participate in physical activity. Colleges and universities should make sure the campus and community are safe for international college students to engage in physical activity.

The Desire To Move And Rest: Trait Or State? Crave Scale Validation Across 2 Years

Miguel Blacut¹, Matthew Stults-Kolehmainen², Nia Fogelman³, Carol E. Garber, FACSM¹, John B. Bartholomew, FACSM⁴, Rajita Sinha³. ¹Teachers College, Columbia University, New York, NY. ²Yale New Haven Hospital, New Haven, CT. ³Yale University, New Haven, CT. ⁴University of Texas at Austin, Austin, TX. (Sponsor: Carol Ewing Garber, FACSM)
Email: meb2305@tc.columbia.edu

(No relevant relationships reported)

Purpose

The CRAVE (Cravings for Rest and Volitional Energy Expenditure) Scale measures the intrinsic desire or want for movement and sedentary behaviors, as assessed "right now". The purpose of the current study was to test the reliability of the CRAVE Scale: a) at 6-month intervals over 24-months and b) over 2 time points within the same test day.

Methods

The CRAVE Scale was administered to 127 subjects (57% non-Caucasian, 47% female) at 0, 6, 12, 18 and 24-months and at two time points (Point 1; Point 2) within the same lab session. CRAVE description: 13-items (7-Rest & 6-Move), 1-10 Likert scale. A Linear Mixed Effects (LME) Model was used for the analyses of test-retest reliability of the CRAVE across months and within each day. In addition, an LME was used to test gender and race/ethnic interactions with CRAVE.

Results

The CRAVE Scale showed greater reliability within each day (Table 1) than across months.

Within-day Move scores correlation: $r's = .74-.95$. Within-day Rest scores correlation: $r's = 0.73-0.89$. Move Score correlations across 0-24 months: $r = .49$ for point 1 and $r = .40$ for point 2 (p -values $< .05$). Rest Score correlations across 0-24 months: $r's = 0.37$ for measurements at both points (p -values $< .05$). Therefore, CRAVE scores taken within the same day were more closely associated than scores across 0-24 months. Race/ethnicity, but not gender, had a significant interaction with the CRAVE. Specifically, Asian individuals wanted to move more than Caucasians and African-Americans at 0-months, 6-months and 18-months and Hispanic individuals at 0 months only (p -values $< .05$).

Table 1. Means, standard deviations and correlations for Move and Rest Scores within the same test day (session points 1 and 2)

Time (months)	Move (Point 1)	Move (Point 2)	Move Scores (r)	Rest (Point 1)	Rest (Point 2)	Rest Scores (r)
0	32.7 ± 15.2	35.9 ± 12.8	0.95	25.1 ± 13.9	20.9 ± 11.9	0.89
6	28.4 ± 12.9	26.7 ± 14.5	0.74	24.3 ± 14.2	24.3 ± 16.7	0.73
12	30.6 ± 13.7	28.8 ± 13.6	0.79	24.4 ± 14.6	23.9 ± 15.8	0.82
18	29.0 ± 13.0	29.4 ± 13.1	0.86	28.0 ± 15.9	24.5 ± 15.2	0.76
24	29.9 ± 11.6	28.0 ± 11.7	0.82	26.4 ± 16.0	25.4 ± 16.3	0.84

Conclusion

These findings suggest that the desire (or want) to either move or rest has state-like properties. Individuals' desire to move/rest is does not vary by gender but may by race/ethnicity.

Research support: NIH/NIDDK Grant number: R01-DK099039

Understanding College Students' Motivation In Virtual Reality-Based Exercise: An Expectancy-Value Approach

Joonyoung Lee, Tao Zhang, Ana West, Leigh A. Karch, Jordan Reys. University of North Texas, Denton, TX.
Email: Joonyoung.Lee@unt.edu

(No relevant relationships reported)

With technology advances, virtual reality (VR)-based exercise has been widely used in clinical and rehabilitation training applications. Given the fact that numerous Kinesiologists have investigated the potential benefits of VR-based exercise among college students, it is needed to understand college students' motivation in VR-based exercise in order to promote their health and well-being.

PURPOSE: To investigate college students' motivation in VR-based exercise and exercise intention from the expectancy-value model perspective (Eccles et al., 1983), which includes expectancy-related beliefs and three task-values (i.e., attainment value, intrinsic value, and utility value).

METHODS: Participants were 72 college students ($Mage = 20.72$, $SD = 1.66$; Male = 54.2%) from a public university in the U.S. Among them, 94.4% of the participants reported "never" or "rarely" played VR-based exercise before. They played the VirZoom Arcade (stationary bike game) requiring moderate-to-vigorous pedaling and leaning their body to the left and right for at least 5 minutes. After attending the VR-based exercise session, participants completed VR-based expectancy-value questionnaires adopted from previous studies, which was developed for measuring students' motivation and intention for future participation in VR-based exercise.

RESULTS: The correlation analysis indicated the positive associations among the study variables. A multiple regression analysis revealed a statistically significant effect, $F(3,68) = 30.162$, $p < .001$, $R^2 = 57.1\%$. The utility value ($\beta = .409$), attainment value ($\beta = .296$), and intrinsic value ($\beta = .269$) were three significant predictors of students' intention for future participation in VR-based exercise, but the expectancy-related belief was not a significant predictor of students' intention for future participation in VR-based exercise.

CONCLUSIONS: The findings indicated that VR-based exercise is useful, important, and interesting that can enhance college students' intention to participate in VR-based exercise in the future. VR technology could be considered as an efficient motivational tool to promote exercise, but further research is needed to examine the effects of VR-based exercise on college students' health outcomes using an experimental research design.

Determining The Influence Of The Conative Modus Operandi On Physical Fitness

Keelyn Marin Langston, Camille Thomas. Southern Utah University, Cedar City, UT.

Email: jklangston2213@gmail.com

(No relevant relationships reported)

PURPOSE: Using the Kolbe ATM Index, this study measured observable behaviors produced from striving instincts to determine the influence of the conative modus operandi on physical fitness changes during a 15-week wellness course. **METHODS:** Thirty-four volunteers participated in this study. Participants' height, body weight, percent body fat, aerobic capacity, muscular endurance, muscular strength, and flexibility were measured during week one and week 15. After pre-assessments, the Kolbe A Index was administered. A one-way ANOVA was used to compare the mean gain scores between conative modus operandi groups, and to compare the mean gain scores between the Zones of Operation of Initiating Action, ReActing, and CounterActing for each Kolbe Action ModeTM. Cohen's d effect sizes were calculated to quantify the effect the conative modus operandi group or Zone of Operation had on changes in physical fitness measures. A Pearson product-moment correlation was used to examine the relationship between the conative modus operandi numbers ranging from 1-10 for each Kolbe Action Mode and gain scores. **RESULTS:** Physical fitness gain scores did not differ between conative modus operandi groups. When comparing Zones of Operation, the ReActing Quick Start zone gained a greater amount of weight than the CounterActing (1.59, 95% CI [-0.01, 3.19], $p = .052$, Cohen's $d = 0.90$) and Initiating Action zones (1.99, 95% CI [-0.20, 4.18], $p = .081$, Cohen's $d = 1.34$). The Initiating Action Follow Thru zone reported greater improvements in aerobic capacity than the ReActing zone ($F(1, 29) = 4.593$, $p = .041$, Cohen's $d = 0.87$). The Initiating Action Fact Finder zone improved in number of sit-ups, and the ReActing zone completed fewer sit-ups (12.70, 95% CI [0.285, 25.12], $p = .044$, Cohen's $d = 1.04$). The values of correlation between the conative modus operandi numbers for Quick Start and gain scores in body fat were significant at the 0.05 level (2-tailed). **CONCLUSION:** No statistically significant differences between conative modus operandi groups and physical fitness changes were found; Zones of Operation influenced physical fitness changes to some degree. Therefore, measuring and understanding Zones of Operation may help practitioners promote and encourage changes in physical fitness.

The Role Of Motivation On Physical Activity And Screen Time Among Parent-adolescent Dyads: The Flashe Study

Alexander R. Lucas¹, Joseph Skelton², John M. Salsman², Beverley Levine³, Lee Stoner, FACSM³, Justin B. Moore, FACSM². ¹Virginia Commonwealth University, Richmond, VA. ²Wake Forest School of Medicine, Winston Salem, NC. ³University of North Carolina at Chapel Hill, Chapel Hill, NC. (Sponsor: Justin B. Moore, FACSM)
 Email: Alexander.lucas@vcuhealth.org
 (No relevant relationships reported)

Behavioral theories may inform the development of lifestyle interventions to address low participation in physical activity (PA) and high volumes of screen time (ST). Self-determination theory (SDT) has been shown to explain intrapersonal factors influencing behavior such as self-efficacy for PA or ST and self-regulation of motivation (e.g. intrinsic vs extrinsic). However, less is known about the value of extending SDT into a dyadic context. Actor-partner (i.e. parent-adolescent) interdependence models (APIMs) allow for testing of these dyadic relationships. **PURPOSE:** The purpose of the cross-sectional Family Life, Activity, Sun, Health, and Eating (FLASHE) Study was to evaluate health risk behaviors (including PA and ST) in parent-adolescent dyads. **METHODS:** Parent-adolescent dyads provided responses to online surveys addressing PA and ST behaviors in the context of environmental and family interactions. We examined the influence of SDT-based constructs (observed variables for self-efficacy and a latent construct for motivation) on PA and ST in 1,228 dyads who provided complete data. Structural equations were used to estimate APIMs in STATA 15.1. **RESULTS:** Models specified a priori provided a reasonable fit to the data; however, fit statistics (CFI:0.90, RMSEA:0.09; SRMR: 0.06) suggested that estimates from parent-adolescent models were less robust than those from parent- or adolescent- only models (PA & ST). For both PA and ST, adolescent self-efficacy was a stronger predictor of adolescent motivation than parent self-efficacy for parent motivation ($\beta = 0.40$ vs. 0.25 , $p < .001$). Parent's and adolescent's motivation did predict each other's motivation ($p < .001$) and their own behaviors but not the PA and ST of their dyad partners. **CONCLUSIONS:** Although SDT explains intrapersonal effects, it may not extend adequately to a dyadic setting. Motivational self-regulation of parents and adolescents are related; however, longitudinal studies conducted to evaluate whether changes in SDT variables are associated with change in parent-adolescent PA and ST patterns over time are needed.

455 Board #271 May 27 10:30 AM - 12:00 PM
Self-perception Differences Between Crossfitters And Other Recreational Exercise Participants

Lauren E. Mihalek, Eric E. Hall, FACSM. *Elon University, Elon, NC.*
 Email: lmihalek@elon.edu
 (No relevant relationships reported)

Improved mental health is an important benefit of physical activity participation. However, understanding the benefits that might occur based on different modes of recreational exercise is not often examined. **PURPOSE:** To compare physical activity levels and self-perceptions of CrossFit participants and participants of other exercise modes. **METHODS:** 103 female participants with various exercise habits took an online survey that consisted of questions about subject demographics and the following scales of physical activity, personality and mental health: The Preference for and Tolerance of the Intensity of Exercise Questionnaire, Aerobics Center Longitudinal Study Physical Activity Questionnaire, Multidimensional Body-Self Relations Questionnaire (MBSRQ), Satisfaction with Life Scale (SWLS), Rosenberg Self-Esteem, and the Physical Self-Efficacy Scale. **RESULTS:** Correlation analyses revealed that total mets performed was significantly correlated with tolerance, perceived physical ability, appearance evaluation, fitness evaluation and orientation, health evaluation and orientation, and body area satisfaction ($p < 0.05$). CrossFitters ($n=11$) scored significantly higher than those who participate in other modes of exercise ($n=102$) in total METs of physical activity, preference, tolerance, fitness orientation, health orientation, body area satisfaction, and self-esteem ($p < 0.05$). **CONCLUSIONS:** Participants of all modes of exercise who performed more physical activity exhibited more positive self-perceptions and approach to exercise. Those who participate in CrossFit are more likely to perform more exercise overall, be more satisfied with the size and appearance of their bodies, and have greater self-esteem. They also demonstrate greater preference and tolerance of higher intensity exercise and are more oriented toward living a healthy and fit lifestyle than their alternate exercise counterparts.

The Desire To Move And Rest: Validation Of The Crave Scale Using A Treadmill Test

Philip R. Stanforth, FACSM¹, Miguel Blacutt², Matthew Stults-Kolehmainen³, Susannah Williamson⁴, John B. Bartholomew, FACSM¹, Todd A. Gilson⁵, Rajita Sinha⁶. ¹The University of Texas at Austin, Austin, TX. ²Teachers College, Columbia University, New York, NY. ³Yale-New Haven Hospital, New Haven, CT. ⁴Texas A&M University, College Station, TX. ⁵Northern Illinois University, De Kalb, IL. ⁶Yale University Medical School, New Haven, CT.
 Email: p.stanforth@austin.utexas.edu
 (No relevant relationships reported)

Purpose
 The CRAVE (Cravings for Rest and Volitional Energy Expenditure) Scale measures the intrinsic desire (or want) for movement and sedentary behaviors, as measured "right now". The purpose of this study was a) to evaluate changes in and the construct validity of the CRAVE Scale before and after maximal exercise and b) assess relationships between these desires and with perceptions of energy and fatigue.

Methods
 The CRAVE Scale is made up of 7-Rest & 6-Move questions (1-10 Likert scale). Fatigue and energy were measured with visual analogue scales. The CRAVE was administered to 21 undergraduate students in physical activity classes (ages 19-24 years; 57% non-Caucasian; 58% female). Participants were given the CRAVE within a minute of starting and again within two-minutes of finishing a maximal treadmill test. Changes were assessed with paired t-tests. Correlations were calculated to assess relationships between the CRAVE and mental energy (ME), mental fatigue (MF), physical energy (PE), and physical fatigue (PF).

Results
 Desire to move significantly decreased (39.9 ± 9.6 vs. 29.5 ± 10.7 , $p < 0.01$) while desire to rest significantly increased (17.8 ± 12.3 vs. 29.1 ± 18.1 , $p < 0.01$) from pre- to post-treadmill test. Desire to move pre- was significantly associated with desire to move post- ($r = 0.63$, $p = 0.002$). Baseline desire to rest was significantly associated with desire to rest post- ($r = -0.48$, $p = 0.027$) and with the post-test change in desire to move ($r = 0.53$, $p = 0.014$). Change in desire to move was inversely associated with change in desire to rest ($r = -0.73$, $p = 0.002$).

Baseline desire to move was significantly associated with the post PE ($r = 0.45$, $p = 0.041$). Change in desire to move had a negative association with change in PF ($r = -0.52$, $p = 0.019$), but not with change in PE ($r = 0.31$), ME ($r = -0.10$) or MF ($r = -0.17$). Change in desire to rest had an inverse correlation with change in PE ($r = -0.64$, $p = 0.003$) and a positive correlation with change in PF ($r = 0.53$, $p = 0.016$). It was not correlated with change in either ME ($r = 0.06$) or MF ($r = 0.20$).

Conclusion
 Desires to move and rest change with an exercise stimulus, with desire to move decreasing and rest increasing. Furthermore, these findings suggest that the desire to move and rest are moderately associated with feelings of physical energy/fatigue but not mental energy/fatigue.

457 Board #273 May 27 10:30 AM - 12:00 PM
Relationships Between Confidence To Adhere To Crossfit, Enjoyment, Motivation, And Ability To Do Various Exercise- And Sport- Related Tasks

Blake Goodman. *Kansas State University, Manhattan, KS.*
 Email: blakedgoodman@gmail.com
 (No relevant relationships reported)

High intensity functional training (HIFT) is a mode of exercise where participants exercise at their perceived high-intensity and perform both aerobic and resistance exercises with emphasis on multi-joint movements modifiable and scalable to all ability levels. This may benefit older adults who are recommended to participate in concurrent exercise training to improve functional capacity. Low-self efficacy (SE) (i.e., belief in ability to accomplish a task) is a barrier to exercise for many older adults. **Purpose:** To investigate how one's SE for participation in HIFT is related to enjoyment, motivation, and SE for performing various exercise tasks in older adults. High values in self-efficacy for participation in HIFT was expected to positively correlate with self-efficacy values for performing various exercise tasks. **Methods:** Data were from an ongoing program evaluation study including a cohort of 13 older adults (age $M = 69.1 \pm 7.1$ years, 62% female) participating in a functional fitness and mobility class with workouts modified to fit their needs and abilities. Participants completed an online questionnaire that included demographics, social, and mental measures. Participants assessed their ability to continue HIFT exercise, rated enjoyment and motivation, and assessed their confidence level on a scale of 1 "I cannot do this activity at all" to 10 "I am certain that I can do this activity successfully" for 11 sport and exercise-related tasks. **Results:** SE to continue HIFT was significantly correlated to general exercise motivation ($r = .85$, $p = .000$), 'I can recognize my strengths and weaknesses in different situations' ($r = .80$, $p = .002$), 'I enjoy doing

exercise' ($r = 0.65, p = .017$), and 'I can do physical exercises that require resistance' ($r = 0.59, p = .036$). **Discussion:** SE for continued HIFT participation was positively related to exercise enjoyment and motivation as well as SE for self-awareness and resistance exercises, which can influence group class design. Older adults who have these attributes will have the confidence and knowledge to gauge their intensity appropriately and participate in exercises that may push their functional limits. Future research should analyze if continued HIFT adherence positively influences SE and functional capacity.

458 Board #274 May 27 10:30 AM - 12:00 PM
The Role Of Academic, Cultural, And Language Stresses On Physical Activity Among International College Students
 Tao Zhang¹, Zi Yan². ¹University of North Texas, Denton, TX. ²Merrimack College, N. Andover, MA.
 Email: TAO.ZHANG@UNT.EDU
 (No relevant relationships reported)

There were 1.09 million international college students in the U.S. as of 2018 (Institute of International Education). Previous studies showed that many international students experienced academic stress, as well as language and cultural stresses (Yan & FitzPatrick, 2015). Further, previous studies also indicated that the U.S. cultural may facilitate participation in physical activity for international students (Yan & Cardinal, 2013). It is unclear whether those different types of stresses and time in the U.S. would be associated with their participation in moderate-to-vigorous physical activity (MVPA). **PURPOSE:** The present study aimed to examine whether academic, cultural, and language stresses, as well as time in the U.S. would predict MVPA among international college students. **METHODS:** Participants were 249 international college students (48.2% female; $M_{age} = 27.48, SD = 6.12$) enrolled in a public research university in Southern U.S.. MVPA was measured by the International Physical Activity Questionnaire (Craig et al., 2003). Previously validated scales were used to measure students' perceived academic stress (e.g., "I worry about my academic performance"); cultural stress (e.g., "It's hard for me to develop opposite-sex relationships here"); and language stress (e.g., "My English embarrasses me when I talk to people"). Time in the U.S. was measured by asking how many months they had been in the U.S.. Finally, gender and BMI were also measured. **RESULTS:** The independent T test showed that males participated significantly more MVPA than females (Male: $M = 293.71$ METs; Female: $M = 241.79$ METs); $t(245) = 3.09, p < .01$. The multiple regression model with gender and BMI controlled was statistically significant, $F(6,242) = 3.37, p < .01, R^2 = 7.7\%$. Cultural stress significantly predicted MVPA ($\beta = -.21, p < .01$), with higher cultural stress was associated with lower MVPA. Language stress, academic stress, and time in the U.S. did not predict MVPA. **CONCLUSION:** The results indicated that cultural stress was related to MVPA among international college students. However, it is unclear whether experiencing more cultural stress discourage MVPA or participating MVPA helps international students manage their cultural stress. To answer this question, qualitative studies and interventional studies are needed in the future.

An Executive Function Benefit Persists For Between 30- And 60-min Post-exercise: Evidence From Task-switching
 Diksha Shukla, Matthew Heath. University of Western Ontario, London, ON, Canada.
 Email: dshukla2@uwo.ca
 (No relevant relationships reported)

A single-bout of aerobic exercise produces a short-term 'boost' to executive function. For example, recent work by our group has shown that the high-level executive function of 'switching' between different tasks is improved following a 20-min single-bout of moderate-intensity aerobic exercise. Notably, previous work examined immediate exercise-related task-switching benefits and it is therefore unknown how long the benefit to executive function persists. **PURPOSE:** Here, we employed an AABB task-switching paradigm involving stimulus-driven (SD) saccades (i.e., saccade at target onset) and their executive mediated minimally delayed (MD) counterparts (i.e., saccade at target offset). MD saccades require active response suppression of a SD saccade and are mediated via an extensive frontoparietal network. Further, a SD saccade completed following a MD saccade results in an increase in reaction time (RT), whereas the converse switch does not (i.e., the unidirectional switch-cost) - a result attributed to a task-set inertia within executive networks. **METHODS:** SD and MD saccades were completed prior to and immediately, 30-min and 60-min after a 20-min single-bout of aerobic exercise (via cycle ergometer) at a moderate intensity (80% of HR_{max}). **RESULTS:** The pre-exercise oculomotor assessment revealed a reliable unidirectional switch-cost (22 ms, $SD=18$) ($p < .001$) and the magnitude of this cost decreased at the immediate (9 ms, $SD=12$) and 30-min (11 ms, $SD=15$) post-exercise assessments ($ps < .01$). At the 60-min assessment, a switch-cost (20 ms, $SD=22$) on par

to the pre-exercise assessment was observed. **CONCLUSION:** Accordingly, a single-bout of aerobic exercise provides a boost to the executive function of task-switching that persists between 30- and 60-min post-exercise.

Physical activity (PA) is the well-known lifestyle behavior determining individual health. However, public health concerns exist regarding the low level of PA, particularly among middle-aged and older women, with limited understanding of its modifiable determinants at individual and environmental levels. **PURPOSE:** The purpose of this study was to examine the socioecological factors explaining PA among middle-aged and older women, with specific focuses on subjective social status (SSS) and perceived neighborhood characteristics. **METHODS:** The survey data were collected from a total of 588 women (mean ages: 56.79). The International Physical Activity Questionnaire was used to assess PA levels in leisure-time (LTPA). Individuals were categorized into the three PA groups (i.e., no-LTPA and low-/upper-LTPA groups based on 50th percentile of LTPA levels). Perceived neighborhood characteristics were measured using the Neighborhood scale consisting of 31 items with the Likert scale across seven environmental dimensions (e.g., walkability, safety, social cohesion). SSS was assessed using a 10-rung ladder ranking with higher rungs indicating higher SSS in their neighborhood. A multinomial logistic regression model was established to examine the associations of perceived neighborhood characteristics and SSS with LTPA, after controlling for study covariates including demographic characteristics (i.e., age, race, marital status), objective social status (i.e., education, household income), and health conditions (i.e., body mass index, number of chronic diseases). **RESULTS:** Overall, neighborhood walkability was the environmental characteristic significantly associated with greater odds of being low- (OR = 1.43; 95% CI = 1.10, 1.86) and upper-LTPA (OR = 1.76; 95% CI = 1.34, 2.31), when compared to no-LTPA. Additionally, women with higher SSS demonstrated greater odds of being low- (OR = 1.72; 95% CI = 1.09, 2.71) and upper-LTPA (OR = 1.88; 95% CI = 1.18, 2.99). **CONCLUSIONS:** The present study identified perceived walking environment within a neighborhood as a potential ecological factor determining PA levels in middle-aged and older women. Further, it is suggested that SSS has a unique impact on PA levels, independent of objective social status indicators.

461 Board #277 May 27 10:30 AM - 12:00 PM
The Effects Of Acute Mental Imagery Training On Force Output In College-age Students
 John C. Collieran, Matthew R. Stenson, Mary C. Stenson. The College of Saint Benedict and Saint John's University, St. Joseph, MN.
 (No relevant relationships reported)

Mental imagery training can be an effective tool to enhance endurance and skill-based sport performance, especially long-term mental imagery training. The effects of mental imagery on muscular force production, especially in the field of resistance training, are not as well researched. The effects of acute mental imagery training are also not well studied. **PURPOSE:** To determine the effects of acute mental imagery training on handgrip strength in college-age participants. **METHODS:** A repeated measures design was utilized. 34 participants (17 men, 17 women, 173.3 cm \pm 8.9 cm, 77.0 kg \pm 16.2 kg, 20.2 yrs \pm 1.3 yrs) over two sessions, separated by 48 hours. Handgrip dynamometry was used to assess maximal and average force production over three consecutive trials following a control treatment (passive sitting) or a 10-minute mental imagery treatment. Mental imagery consisted of learning about imagery and practicing with a premade imagery script. **RESULTS:** Average force production was higher overall (38.17 kg \pm 13.03 kg vs. 35.65 kg \pm 13.52 kg; $t(33) = 4.158; p = 0.000; d = 0.190$), for men (48.80 kg \pm 8.55 kg vs. 46.01 kg \pm 10.00 kg; $t(16) = 3.549; p = 0.003; d = 0.3004$), and for women (27.54 kg \pm 6.08 kg vs. 25.28 kg \pm 7.00 kg; $t(16) = 2.388; p = 0.030; d = 0.3445$) after acute mental imagery training. Maximal force production was higher overall (40.08 kg \pm 13.10 kg vs. 38.14 kg \pm 13.85 kg; $t(33) = 3.007; p = 0.005; d = 0.140$) and for men (50.98 kg \pm 8.35 kg vs. 49.02 kg \pm 9.98 kg; $t(16) = 2.352; p = 0.032; d = 0.2135$) following mental imagery training. Women experienced greater maximal force production after mental imagery training, but not significantly greater than the control treatment (29.18 kg \pm 5.65 kg vs. 27.25 kg \pm 6.65 kg; $t(16) = 1.898; p = 0.076; d = 0.3118$). **CONCLUSION:** Acute mental imagery training improves handgrip force production. Mental imagery training may be effective in short term settings and for resistance training and strength and power athletes.

462 Board #278 May 27 10:30 AM - 12:00 PM
Relating Lifestyle Factors To Adolescent Non-Prescription Steroid Use
 Timothy A. Brusseau¹, Ryan D. Burns¹, You Fu². ¹University of Utah, Salt Lake City, UT. ²University of Nevada, Reno, NV.
 Email: Tim.brusseau@utah.edu
 (No relevant relationships reported)

No study has examined multidimensional factors associating with non-prescription anabolic steroid use within a large representative sample of US adolescents.

PURPOSE: The purpose of this study was to examine the cognitive, psychosocial, lifestyle, and activity-related correlates of non-prescription steroid use among US adolescents from data collected using the 2017 National Youth Risk Behavior Survey. **METHODS:** A multi-stage cluster sampling procedure yielded a representative sample of US adolescents in 2017. The number of sampled adolescents with usable data was 14,765. Weighted logistic regression was used to examine the associations between cognitive, psychosocial, lifestyle, and activity-related variables and non-prescription steroid use among US adolescents adjusting for age, sex, BMI percentile, and race/ethnicity. **RESULTS:** The lone cognitive factor relating with non-prescription steroid use was a history of concussion (OR=2.06, 95%CI:1.37-3.13, $p = 0.001$). The psychosocial variable relating with non-prescription steroid use was feelings of sadness and/or hopelessness (OR=2.47, 95%CI:1.72-3.56, $p < 0.001$). Lifestyle factors relating with non-prescription steroid use included cigarette smoking (OR=2.06, 95%CI:1.10-3.84, $p = 0.023$), smokeless tobacco use (OR=2.33, 95%CI:1.19-4.56, $p = 0.015$), and alcohol consumption (OR=4.54, 95%CI:2.69-7.68, $p < 0.001$). No activity-related variables (daily physical activity, sports participation, muscular strength exercising) associated with anabolic steroid use. **CONCLUSIONS:** Salient cognitive, psychosocial, and lifestyle factors relate with non-prescription steroid use among a representative sample of US adolescents. Multidimensional health educational and health behavioral approaches may be needed to properly inform and prevent adolescents from non-prescription steroid use.

463 Board #279 May 27 10:30 AM - 12:00 PM
The Relationship Between Mental Toughness And The Ergogenic Effects Of Music During Exercise
 Kayla Baker¹, Dano Toluoso¹, Jeanette Garcia². ¹Western Kentucky University, Bowling Green, KY. ²University of Central Florida, Orlando, FL.
 Email: kayla.baker@wku.edu
 (No relevant relationships reported)

PURPOSE: Previous research has found that both music and mental toughness (MT) may affect exercise performance; however, no study has examined the relationship between MT and music on exercise performance. Therefore, the purpose of this study was to examine the associations among MT, aerobic fitness, and music during exercise. **METHODS:** Thirty-one recreationally-active individuals (22.13±2.11 yrs, 25.15±2.94 BMI, 42.89±5.31 mL·kg⁻¹·min⁻¹; 65.5% male) were recruited for this study. Participants completed a MT questionnaire and performed a VO_{2max} test on the treadmill. Participants then completed two counterbalanced, experimental trials consisting of exercise with: 1) no music; and 2) self-selected music from a personalized playlist. For each experimental trial, participants performed a time-to-exhaustion (TTE) run at 80% VO_{2max}, separated by at least 48 hours. Independent sample t-tests were used to examine differences between the two trials, while Pearson correlations were conducted to examine the associations among aerobic fitness, MT, and TTE for both music (TTE_M) and non-music (TTE_{NM}) conditions. Linear regression was used to investigate relationships between MT and change in exercise performance (ΔTTE) between music conditions. **RESULTS:** There were no significant differences between minutes for TTE_{NM} (12.23±5.24) and TTE_M (14.18±4.79). Moderate to strong correlations with VO_{2max} were observed for TTE_M ($r=.39$, $p=0.030$), TTE_{NM} ($r=.52$, $p=0.003$), and MT ($r=.40$, $p=0.024$). Linear regression revealed that a higher MT score was associated with a smaller change between the two performance trials ($F_{1,29}=4.42$, $r=-.63$, $p=0.040$), irrespective of order effect or aerobic fitness. **CONCLUSIONS:** Associations existed between aerobic fitness, MT, and exercise performance for both music and non-music trials. Participants with greater MT experienced less of a change between performance trials, suggesting that individuals with greater MT may demonstrate consistent patterns of performance, irrespective of aerobic fitness or the presence of external factors. Understanding the relationship between MT and music during exercise may allow exercise professionals to better tailor their training programs to each individual, increasing exercise performance and adherence.

464 Board #280 May 27 10:30 AM - 12:00 PM
Effects Of Exercise Desks On Activity And Reading Skills In Youth With Neurodevelopmental Disorders
 Sara F. Michaliszyn¹, Kathleen Aspiranti², Meghan Kulisek¹, Hannah Crites¹. ¹Youngstown State University, Youngstown, OH. ²University of Kentucky, Lexington, KY.
 Email: sbmichaliszyn@ysu.edu
 (No relevant relationships reported)

Physical activity improves cognitive function and academic achievement, although many youth remain sedentary during school. Exercise desks may be advantageous to improving physical activity as it does not require any teacher education and does not jeopardize time spent on academic instruction. **PURPOSE:** The purpose of this study was to determine the effect of exercise desks on levels of physical activity and classroom performance in 4th and 7th grade students with neurodevelopmental disorders. **METHODS:** Thirty-five children (N=13 4th grade; N= 21 7th grade) were monitored with an Actigraph accelerometer (wGT3X-BT) worn on the non-dominant wrist during school hours. Derived variables were time (minutes) in sedentary, light, and moderate intensity using published cut points. Using a repeated measures cross over design, students attended school in two different environments for 8 weeks each: traditional school with chairs and desks and a classroom designed with exercise desks composed of pedaling, a stand and spin, and accordion chairs. Students reading skills were assessed using two curriculum-based measurements: Maze Reading Comprehension and Oral Reading Fluency. **RESULTS:** Weight significantly correlated with time spent in sedentary ($r = .43$; $p<0.001$), light ($r = .37$; $p<0.001$) and moderate ($r = -.46$; $p<0.001$) activity. There was a significant main effect of the activity desks on decreasing sedentary activities with a proportional increase in moderate activity once controlling for weight. A main effect for grade showed that 4th graders participated in significantly less sedentary activity and greater moderate activity compared with 7th graders. Compared to the traditional classroom, the kinesthetic classroom significantly increased reading skills in both grades although there was a trend for a slightly greater increase in 7th graders. **CONCLUSIONS:** Exercise desks improved reading skills and decreased time spent in sedentary activities in youth with neurodevelopmental disorders. The greater decline in sedentary activity and concomitant increase in physical activity among fourth graders may suggest that older youth are less inclined to use the exercise desks.

465 Board #281 May 27 10:30 AM - 12:00 PM
Compulsive Exercise And Physical Activity Among Early Adolescents.
 Bratland-Sanda Solfrid, Sabrina K. Schmidt, Michael M. Reinboth. University of South-Eastern Norway, BØ I TELEMARK, Norway. (Sponsor: Jorunn Sundgot-Borgen, FACSM)
 Email: solfrid.bratland-sanda@usn.no
 (No relevant relationships reported)

PURPOSE: The aim of this study was to examine compulsive exercise and associations with physical activity and psychosocial health among early adolescents. **METHODS:** Four municipalities with 15 secondary schools in Telemark County, Norway, were recruited into participate in this cross-sectional study. A total of 644 pupils (age 13.9±0.3 yrs) participated in the study (response rate: 79%). Information about weight regulation and body dissatisfaction was obtained. Instruments included Actigraph GT3x, Behavioural Regulation of Exercise - Questionnaire (BREQ), KIDSCREEN-27, Subjective Vitality Scale (SVS), and Compulsive Exercise Test (CET). High CET score was identified as total CET score ≥ 15 . **RESULTS:** Only 36.5% of the adolescents were sufficiently physically active. Boys had higher total CET score compared to girls (9.97 vs. 9.35, $p=0.046$), and 7% of the respondents had high CET score. A total of 3.5% showed both high CET score and low levels of physical activity, indicating exercise obsessions without compulsions. There was a positive correlation between total CET score and use of exercise mobile apps ($r=.12$, $p=0.003$), and between total CET score and number of weight reduction attempts the past year ($r=.22$, $p=0.02$). No correlation was found between total CET score and physical activity, or between total CET score and sedentary time. A regression analysis showed introjected regulation ($p<0.001$), identified regulation ($p=0.03$) and extrinsic motivation ($p=0.04$), but not intrinsic motivation, amotivation, SVS, KIDSCREEN-27 domains, gender or physical activity level, as significant predictors of total CET score. **CONCLUSIONS:** Total CET score is associated with weight regulation behavior, and predicted by introjected, identified and extrinsic regulation of physical activity. These findings indicate needs for increased understanding about the complexity of cognitions concerning exercise, and not only exercise behaviour per se.

466 Board #282 May 27 10:30 AM - 12:00 PM

The Desire To Move And Rest: Assessing Reliability And Validity Of The CRAVE Scale

Matthew Stults-Kolehmainen¹, Miguel Blacutt², Amanda Divin³, Susannah Williamson⁴, Todd A. Gilson⁵, John B. Bartholomew, FACSM⁶, Rajita Sinha⁷. ¹Yale - New Haven Hospital, New Haven, CT. ²Teachers College, Columbia University, New York, NY. ³Northwestern State University, Natchitoches, LA. ⁴Texas A & M University, College Station, TX. ⁵Northern Illinois University, DeKalb, IL. ⁶The University of Texas at Austin, Austin, TX. ⁷Yale University Medical School, New Haven, CT. (Sponsor: John B. Bartholomew, FACSM)
Email: Matthew.Stults-kolehmainen@YNHH.ORG
(No relevant relationships reported)

Purpose

The CRAVE (Cravings for Rest and Volitional Energy Expenditure) Scale measures the intrinsic desire for movement and sedentary behaviors as assessed "right now". The purpose of this investigation was to evaluate reliability and construct validity of the CRAVE scale before, during and after a university lecture.

Methods

The CRAVE Scale and Thayer Activation-Deactivation (AD) Checklist were administered to 41 students (mean age 22.5±5.1 years; 26.8% non-Caucasian; 24.4% female) around a 50-minute lecture. CRAVE: 13 items (7-Rest & 6-Move), 1-10 Likert scale, given pre-, mid- and post-lecture. AD Checklist: 20 items, 1-10 Likert Scale, measures perceived energy, tiredness, tension and calmness, only assessed pre-lecture. Lectures were at either 9AM, 12PM or 3PM. A linear mixed effects model was used to compare pre-, mid- and post-lecture CRAVE Scores across the day. Correlations were calculated to evaluate CRAVE and AD Checklist relationships.

Results

Desire to Move: significantly higher post-lecture compared to pre (32.2±2.0 vs. 27.5±2.0, $p=0.007$) and higher than mid (28.5±2.0, $p=0.034$). Desire to Rest: lower post-lecture compared to pre (28.3±2.8 vs. 33.4±2.8, $p=0.016$) and lower than mid (33.1±2.8, $p=0.019$). Cronbach alpha coefficients for pre-, mid- and post-lecture (desire to Move: 0.90, 0.94, 0.93, respectively; Rest: 0.89, 0.94, 0.93). Inter-class correlations: Move=.85; Rest=.90.

The desire to move pre- and mid-lecture were similar at different times of the day. The post-class desire to move was significantly higher at 3PM compared to 9AM (44.0±16.6 vs. 28.11±12.2, $p=0.019$). There were no differences in desire to rest based on time of day. Desire to move at baseline was significantly associated with energy ($r=0.38$, $p=0.018$) and calmness ($r=-0.47$, $p=0.003$). Desire to rest at baseline was significantly associated with energy ($r=-0.38$, $p=0.026$), tiredness ($r=0.48$, $p=0.003$). Tension was unrelated to either move or rest.

Conclusion

The desire to move significantly increased while the desire to rest significantly decreased across a lecture period. Desires to move/rest were correlated with energy (positively and negatively), but move was most strongly associated with calmness and rest with tiredness. Finally, the CRAVE Scale showed high internal consistency.

Children's Motivation For Physical Activity

Tyler J. Kybartas¹, Aaron P. Wood², Kelley Strohacker, FACSM², Rebecca A. Zakrajsek², Jedediah E. Blanton², Samantha F. Ehrlich², Dawn P. Coe, FACSM². ¹Illinois State University, Normal, IL. ²University of Tennessee, Knoxville, TN.
Email: tjkybar@ilstu.edu
(No relevant relationships reported)

The establishment of physical activity (PA) routines in childhood is critical to form life-long PA habits. Children are motivated for activities that they enjoy but research is scarce on motivational factors for PA in children younger than eight years old. **PURPOSE:** To explore why children enjoy or do not enjoy physical activities to gather their underlying motivation. Additionally, physical activity and perceived motor competency data were collected to describe the participants. **METHODS:** A mixed-methods study design was employed. Participants ($n=16$) were 2nd and 3rd grade students at two YMCA afterschool programs. Each child wore an accelerometer on the right hip for seven consecutive days and data were converted to min in PA intensities. They also completed Harter's perceived motor competency survey and took part in focus groups. There were two 2nd grade and two 3rd grade focus groups, which consisted of 3-5 participants each. Descriptive analyses were performed on PA and perceived motor competency data. Focus group data underwent thematic analysis using an inductive approach. **RESULTS:** PA data revealed that the majority of participants (57%) met PA recommendation with an average of 63.8±25.4 minutes of moderate to vigorous PA per day. Additionally, the average perceived motor competency score was 3.0±0.6 (out of 4). Information from the focus groups was used to create four over-arching themes which included 1) PA is sport, 2) social influence, 3) perceived competence, and 4) PA characteristics. Within the social influence theme, peers,

parents, siblings, and gender norms appear to make important contributions to this theme. The PA characteristics theme included roughness and danger, movement and action, teammates and competition (enjoyment only), and rules (unenjoyment only). It appears that the social influence, perceived competence, and PA characteristics had overlap on one another, suggesting perhaps all three have a reciprocal interaction that may relate to the enjoyment or unenjoyment of physical activities. **CONCLUSIONS:** Results suggest exposing children early to wide varieties of physical activities may help minimize activities they dislike and build their perceived competence and social bonds, which may be crucial to establishing and continuing PA behaviors.

468 Board #284 May 27 10:30 AM - 12:00 PM
Exploring The Influence Of Pregnancy And Physical Activity Involvement On Physical Activity Levels And Knowledge Exploring The Influence Of Pregnancy And Physical Activity Involvement On Physical Activity Levels And Knowledge

Kellie A. Walters¹, Cindy L. Hartman², Kate Evans³. ¹California State University, Long Beach, Long Beach, CA. ²University of New Hampshire, Durham, NH. ³University of Wisconsin-La Crosse, La Crosse, WI.
Email: kellie.walters@csulb.edu
(No relevant relationships reported)

Little is known about how women's physical activity (PA) involvement and pregnancy status influence their PA levels and knowledge of PA guidelines specific to pregnancy. **PURPOSE:** The purpose of this study was to explore the relationship between pregnancy status, PA involvement, knowledge of appropriate PA behaviors during pregnancy, and PA levels. **METHODS:** Women who were currently pregnant ($N=72$, Mean Age = 31.89 +/- 4.23 years) and not pregnant ($N=196$ and 36.90 +/- 9.22 years) completed a questionnaire which included the physical activity (PA) Involvement Scale (Modified Involvement Scale), and questions pertaining to the appropriateness of PA during pregnancy (ACOG agreement) and their current PA levels (International PA Questionnaire). **RESULTS:** Pregnant women reported significantly higher levels of ACOG agreement ($Z=-2.095$, $U=5909.00$, $P<.005$, $r=.13$) and significantly lower levels of PA ($Z=-2.418$, $U=4459.50$, $P<.005$, $r=-.16$) compared to non-pregnant women. There were no significant differences in ACOG agreement scores between high PA involvement, moderate PA involvement, and low PA involvement ($P>.05$). Women with high PA involvement report significantly more PA participation compared to women with both moderate and low PA involvement ($P<.005$). **CONCLUSION:** Educating mothers and their social network on appropriate PA during pregnancy might be helpful in limiting the amount of misguided information a pregnant woman receives throughout her pregnancy. Public health interventions might improve PA levels by focusing on enhancing a woman's feeling of self via PA (identity affirmation) and desire to engage in PA (attraction). For example, to improve a woman's identity affirmation, health providers should focus on helping women create attitudes and self-perceptions of being a physically active person (i.e., increasing the saliency of this identity). To increase attraction to PA, public health providers can help women identify PA modalities they enjoy and emphasize the importance of PA for the health of themselves, their baby, and their families. Public health interventions that focus on how psychosocial health (e.g., improving PA identity affirmation and attraction) can increase PA during pregnancy are necessary for improved health of pregnant women and their babies.

Sisson, FACSM¹. ¹University of Oklahoma Health Sciences Center, Oklahoma City, OK. ²Pennington Biomedical Research Center, Baton Rouge, LA. ³Oklahoma State University, Stillwater, OK. ⁴Ohio University, Athens, OH. (Sponsor: Susan B. Sisson, FACSM)
Email: Bethany-Williams@ouhsc.edu
(No relevant relationships reported)

Childhood physical activity (PA) is important for adequate growth and development. Child PA is influenced by family health habits, such as encouragement and active involvement. Mothers are of central importance within the family unit, as their personal and supportive behaviors can alter the health-promoting home environment. To better understand the dynamics of family health behavior, maternal characteristics associated with child and family PA must be explored. **PURPOSE:** Determine associations between maternal health characteristics (anthropometrics and PA) with child and family health habits. **METHODS:** Mother-child dyads (children aged 5.0-7.9 years) were recruited. Mother and child height and weight were measured

objectively and body mass index (BMI) was calculated (age- and sex-specific percentiles for children). Mothers completed the International Physical Activity Questionnaire - Short Form to evaluate maternal PA; MET hours PA/week were calculated. Child PA was measured using accelerometry-determined counts per minute. Mothers completed the Family Nutrition and Physical Activity Questionnaire to evaluate family PA participation score, which was the sum of two survey items; higher scores indicate higher frequency of PA practices including family encouragement and involvement. The association between maternal PA and BMI with child PA and family PA participation was assessed using linear regression, and adjusted for maternal age, child hours away from home, household income, and child BMI percentile. **RESULTS:** Fifty-two mother-child dyads participated. On average, mothers were 82.7% Caucasian, 67.3% employed full-time, 46.2% normal weight, and obtained 44.8±48.4 MET hours PA/week. Children averaged 1159.8±262.8 CPM and mothers reported average family PA participation score of 6.2±7.4 (max. score 8). Maternal BMI was not related to child or family outcomes ($p>0.05$). Maternal PA was associated with more frequent family PA participation score ($p=0.028$). **CONCLUSIONS:** In this sample, maternal characteristics were related to beneficial family health habits, rather than individual child PA. Mothers may influence the collective behavior more so than individual behavior. Future research should seek to study the mechanisms driving association between maternal and family PA.

A-52 Free Communication/Poster - Behavioral Aspects of Sport

Wednesday, May 27, 2020, 9:30 AM - 12:00 PM
Room: CC-Exhibit Hall

470 Board #286 May 27 10:30 AM - 12:00 PM Motivational Language Used By Strength And Conditioning Coaches: Are They Developing Their Athletes' Psychological Capital?

Bradley J. Cardinal, FACSM, Dakota B. Dailey, Alexandra Szarabajko, N. Emmanuel Ughelu, Jake D. Wambaugh. *Oregon State University, Corvallis, OR.*
(No relevant relationships reported)

PURPOSE: On the basis of critical discourse analysis, we sought to understand the verbal language of strength and conditioning coaches. Their language was deconstructed and interpreted using the eight developmental dimensions (i.e., goals and pathways design, implementing obstacle planning, experiencing success or modeling others, persuasion and arousal, building assets or avoiding risks, affecting the influence process, building efficacy or confidence, and developing positive expectancy) of the Psychological Capital Model (PCM). These are the conduits through which hope, efficacy, resiliency, and optimism are developed. **METHODS:** Ten "Mic'd up" videos were acquired vis-à-vis YouTube. The videos purposively included both men's and women's sports (i.e., basketball, football, hockey, softball, and volleyball), with half featuring men coaching men and half featuring men coaching women. Every coaches' statement was transcribed verbatim by two coders. Statements were then reviewed by the five-person research team and classified into one of the developmental dimensions. **RESULTS:** The videos were published between 2012 and 2018 ($M = 2015.70$, $SD = 1.94$) and ranged in length from 1:00 min. to 6:20 min. ($M = 2:04$, $SD = 1:35$). A total of 178 statements were recorded. No differences were observed in the use of the developmental dimensions between sports or context (i.e., all $p>0.05$). Three of the PCM developmental dimensions accounted for 136 (76.4%) of the total observations (i.e., experiencing success/modeling others [$n = 54$, 31.2%], building efficacy/confidence [$n = 48$, 27.8%], and implementing obstacle planning [$n = 34$, 19.7%]). Relative to the theoretical model, these were overrepresented (i.e., standard residuals ranging from +2.76 to +7.10). The other five dimensions were underrepresented (standard residuals ranging from -2.23 to -4.18). **CONCLUSIONS:** On the basis of this set of observations, strength and conditioning coaches appear to be employing a limited range of psychological strategies with their athletes. Efforts to develop resiliency among athletes were notably underused. Resiliency relates to the ability to cope with hardship, setbacks, and stress. An outcome of this study has been the development of a catalog of appropriate statements across the eight developmental dimensions of the PCM.

471 Board #287 May 27 10:30 AM - 12:00 PM Acute Effects Of Dumbbell Exercise On Oxygenated Hemodynamic Concentration Of Cerebral Activation: A Fnrirs Study

Yu Liu, Yana Wang, Jiaojiao Lü, Lingyan Huang. *Shanghai University of Sport, Shanghai, China.*
Email: yuliu@sus.edu.cn
(No relevant relationships reported)

Purpose. To examine cerebral cortical activation in the reigns of the prefrontal cortex and parietal lobe during the performance of two types of dumbbell exercise.

Methods. A total of 22 young healthy male adults (mean age = 23.8 ± 2.05 years, height = 1.75 ± 0.06m, weight = 71.4 ± 8.80kg) participated in a crossover design study that involved two experimental exercise conditions: momentum dumbbell and conventional dumbbell. Participants' task performance included 10 10-second sets of single-arm dumbbell exercise, with a rest interval of 60 seconds between sets and a 5-minute washout period between conditions. Primary outcome was oxygenated hemoglobin (HbO₂) concentration in the prefrontal cortex and parietal lobe assessed with functional near-infrared spectroscopy. Secondary outcome measures were upper-limb muscle activation measured by surface electromyography. Outcome data were ascertained during exercise.

Results. A significant difference in HbO₂ was observed in the prefrontal - parietal regions with a high level of brain activation observed during the momentum dumbbell exercise relative to the conventional dumbbell exercise ($p<0.05$). Compared to conventional dumbbell exercise, momentum dumbbell exercise also showed a higher level of muscle activation in the anterior deltoid and posterior deltoid of the upper arm and in the flexor carpi radialis and extensor carpi radialis longus of the forearm ($p<0.05$). No between-condition differences were found, however, in biceps brachii and triceps brachii ($p>0.05$).

Conclusion: A dynamic dumbbell exercise, compared with a conventional dumbbell exercise, resulted in higher hemodynamic responses and greater upper-limb muscle activation in young healthy adults. The new resistance-based training exercise may be suited as a stand-alone exercise modality aimed at promoting brain health. Supported by the Shanghai City Committee of Science and Technology Key Project (17080503200) and National Natural Science Foundation of China (31701041).

472 Board #288 May 27 10:30 AM - 12:00 PM Can You Dig It: The Acute Psychological Responses To Volleyball Participation

Daniel R. Greene. *Augusta University, Augusta, GA.*
(No relevant relationships reported)

Exercise is one of the most beneficial daily habits to increase overall health and wellness. However, failure to enjoy exercise programs has often been cited as a primary reason to cease/not engage in said programs. Among adults, participation in recreational sporting activities is often overlooked as a potentially more enjoyable mode of exercise. **PURPOSE:** Explore the acute effects of recreational sports on affective states. **METHODS:** Participants [$N = 24$, 18 males; age ($M \pm SD$); 29.0 ± 6.8 yrs; BMI ($M \pm SD$); 24.0 ± 4.1] completed three games of recreational volleyball over a one hour duration. Affective states (Activation-Deactivation Checklist: AD ACL) and state anxiety (SAI) were assessed before (pre), immediately (post0) and ten minutes (post10) after activity. Data was analyzed using SPSS 24.0.0, utilizing repeated measures analysis of differences for main outcome measures. **RESULTS:** Participants reported a significant increase in Energy ($M_{diff} \pm SE$); 4.4 ± 0.75 [Cohen's $d = 1.34$] and Tension ($M_{diff} \pm SE$); 2.3 ± 0.57 [Cohen's $d = 1.06$], while reporting a significant decrease in Tiredness ($M_{diff} \pm SE$); 3.0 ± 0.83 [Cohen's $d = 0.88$] and Calmness ($M_{diff} \pm SE$); 4.0 ± 0.62 [Cohen's $d = 1.49$] from pre to post0. However, affective states were not different at post10 relative to pre (all $p's \geq 0.5$). While SAI significantly decreased from post0 to post10 ($M_{diff} \pm SE$); 3.2 ± 0.74 [Cohen's $d = 0.90$], it was not different at post10 relative to pre ($p=0.52$). **CONCLUSION:** While participants experienced significant increases in Energy and Tension, while showing decreases in Tiredness and Calmness consistent to previous literature immediately post exercise, none of these improved affective states were expressed at post10. Additionally, no significant changes in state anxiety were observed 10 minutes post exercise. It is possible that the psychological effects of sport related physical activity differ from more traditional cardiovascular exercise effects. Future work on the psychological responses to recreational activities is needed to further explore these phenomenon.

Relationship Between Sleep Parameters, Perceived Recovery And Aerobic Performance In Runners
 Marco T. de Mello, Aldo Coelho Silva, Luisa F. Nogueira, Andressa Silva. *UFMG - Federal University of Minas Gerais, Belo Horizonte, Brazil.*
 Email: tmello@demello.net.br
 (No relevant relationships reported)

Sleep is considered fundamental for the physical recovery process, being related to the compensation process due to the residual effect of training. In addition, sleep seems to be related to performance in cognitive activities. However, little is known about the relationship of sleep to performance and recovery in long-distance runners. **PURPOSE:** To verify the relationship between sleep parameters, perceived recovery and aerobic performance of runners. **METHODS:** Eight long-distance runners (age, 30.3 ± 5.5 years; maximum oxygen consumption, 59.4 ± 3.4 ml.kg.min⁻¹), classified as good sleepers (Pittsburgh Index Quality <5), had their sleep monitored for six days a priori from a race to exhaustion. Pulse actigraph was used for 15 days to verify sleep parameters (total sleep time, sleep efficiency, number of awakenings and sleep latency). Perceived recovery was assessed by the Total Recovery Quality Scale (TQR) prior to the running session. The run-to-exhaustion session was performed at the anaerobic threshold, determined by the ventilatory equivalent, and presented as the time limit until exhaustion (tLIM). **RESULTS:** Runners had a sleep efficiency of 87.4 ± 9.6%, total sleep time of 350.4 ± 55.9 min (minutes), number of awakenings of 33.8 ± 25.5 min, sleep latency 13.8 ± 18.1 min on the night before the race and on the day of running run, the tLIM was 46 ± 15.3 min. There was a significant association between TQR and number of awakenings ($r = 0.928$; $p = 0.001$) and between TQR and sleep efficiency ($r = -0.844$; $p = 0.008$). In addition, tLIM was associated with sleep efficiency ($r = -0.817$; $p = 0.012$), WASO ($r = 0.773$; $p = 0.021$) and TQR ($r = 0.736$; $p = 0.019$). **CONCLUSION:** These results indicate who running time to anaerobic threshold exhaustion and perceived recovery are associated with sleep parameters of the night before the race.

Is Karate Training Effective in Improving Social Skills and Executive Functions in Children with Autism?

Stefania Cataldi, Gianpiero Greco, Valerio Bonavolontá, Francesco Fischetti *University of Study of Bari "Aldo Moro", Bari, ITALY.*
 Limited research exists exploring recreational activities (e.g. sport) as an integrative approach to therapy to bring benefits in social skills and executive functions. **PURPOSE:** This study examined the effects of 12-week traditional Shotokan Karate training on social-emotional skills and executive functioning of children (8-11 years) with diagnosed autism spectrum disorder. **METHODS:** Twenty-eight children were matched into pairs based on age, gender, and autism severity, and randomly allocated into an intervention ($n = 14$) or waitlist control group ($n = 14$). The intervention group performed Kata techniques training two times per week (45 min). The intervention included typically-developing children that helped facilitate the social skills, and activities targeted to train specific domains of executive functions, namely behavioral inhibition, working memory, and cognitive flexibility. At baseline and after 12 weeks, parents assessed social skills and executive functioning respectively through the Social Skills Improvement System Rating Scale and Behaviour Rating Inventory of Executive Function. **RESULTS:** Findings suggest that intervention group showed significantly greater socio-emotional skills ($\Delta 8.9 \pm 3.1$, $p < 0.001$, $d = 2.85$) and lesser behavioral problems ($\Delta -8.0 \pm 3.1$, $p < 0.001$, $d = 2.64$) than the control group, and decreased the behavioral ($\Delta -3.6 \pm 2.7$, $p < 0.001$, $d = 1.36$), emotion ($\Delta -3.5 \pm 2.1$, $p < 0.001$, $d = 1.63$) and cognitive ($\Delta -2.3 \pm 1.5$, $p < 0.001$, $d = 1.54$) regulation indexes, and the Global Executive Functioning Composite ($\Delta -3.2 \pm 3.3$, $p = 0.003$, $d = 0.97$). **CONCLUSION:** After 12 weeks, children with ASD showed a greater socio-emotional competence such as communication, cooperation and engagement, a better executive functioning ability such as cognitive flexibility, inhibitory control and working memory and a lower aggressiveness, sadness, anxiety and hyperactivity. Since ASD is a broad economic and societal problem that affects individual, family, and community levels.

Goal Orientation And Beliefs About Success In Age Group Swimmers
 Nathan Rhea, Courtney Jensen, J. Mark VanNess. *University of the Pacific, Stockton, CA.*
 (No relevant relationships reported)

Determining a swimmer's goal orientation and what they believe makes them successful can help coaches create better workouts and outcome measures in young athletes. **PURPOSE:** Goal orientation (task vs ego) and success beliefs (effort, deception, ability and external factors) were examined in age group swimmers to determine if achievement theory differed by age. **METHODS:** Eighty ($N=80$), 11-18 year old USA Swimming club members, completed the Task and Ego Orientation in Sport Questionnaire (TEOSQ) and the Beliefs About the Causes of Sport Success Questionnaire (BACSSQ). Parent consent and child assent was obtained. Regression and multivariate analyses were used to examine differences between age groups. **RESULTS:** Athletes with Ego orientation had significant positive relationships with ability and deception as beliefs about the causes of sport success (Wilks' $\Lambda = 0.010$, $F(6, 69) = 1.195$, $p < 0.001$ and $p < 0.05$ for age categories, subsequent post hoc tests reached $p < 0.05$ for significance). Those with Task orientation had a positive relationship with higher effort and negative relationship with deception as a belief about the cause of sport success. Age comparisons showed 13-14 and 15-18 year old age groups had significantly higher ego orientation than the 11-12 age group, the 15-18 age group having a significantly lower task orientation than both the 11-12 and 13-14 age groups. The 13-14 age group attributed deception to success in swimming significantly more than the 11-12 age group. **CONCLUSION:** Older swimmers develop a higher ego orientation and lower task orientation due to more visible differences in ability and an increased focus on performance.

Ironic Process Theory In Softball Pitching: How Knowing Information About An Opponent's Strengths Affects Performance
 Ronald Otterstetter, FACS¹, Mackenzie Conrad¹, Mallory Kobak², Brian Miller¹, Judith Juvancic-Heltzel¹. *¹The University of Akron, Akron, OH. ²Hiram College, Hiram, OH.*
 (No relevant relationships reported)

INTRODUCTION: As athletic competition and college athletics continue to grow and flourish, there is an increased emphasis on game preparation. Collegiate softball pitchers are expected to handle an immense amount of pressure, perform with precision, and incur few errors. **PURPOSE:** Examine the Ironic Process Theory related to fast pitch softball pitching and to determine how knowing information about an opponent's strengths affects experienced pitcher's performance under pressure. **METHODS:** Experienced college softball pitchers ($n = 12$) were recruited as subjects. Each pitcher was randomly instructed through two 30 pitch phases (a high and low pressure phase) with two different conditions: black target only condition (BOTC) or black and red target condition (BRTC). Subjects were asked to aim and hit the black target and avoid the red target. The black target represented the weakness of the opponent and the red target represented the strength of the opponent. Performance pressure was measured before each phase using the Mental Readiness Form (MRF-3) (Krane, 1994). **RESULTS:** Pre-MRF-3 reached statistical significance across the between-subjects factor of pressure, [$t(22) = 3.102$, $p = 0.005$] with a mean difference of 4.75 (95% C.I. 1.57 to 7.92) indicating that the pressure situation induced an increase in perceived anxiety and stress. ANCOVA did not reach statistical significance on the main effects of black targets hit nor the interactions terms for black targets hit by MRF-3 and black targets hit by Pressure. This finding asserts that there was no difference in performance between BRTC and BOTC across pressure after adjusting for perceived anxiety. There was no statistically significant difference of red target hit between the high pressure and low pressure situations, $d = 0.25$ (95% C.I. -0.463 to 0.963), $t(22) = 0.723$, $p = 0.963$. **DISCUSSION:** Practically speaking, the pitchers in this study did perform more effectively in the high pressure situation. Although different from previous Ironic Theory research, it is important to note this increased ability for pitchers to hit a desired target while under pressure. Even if not statistically significant, this can help pitchers and coaches understand the link between pressure and performance more effectively, and add training components to improve in stress situations.

The Effect Of Random And Blocked Practice In Volleyball Attack Learning

Nektarios A.M. Stavrou¹, Natalia Kompodieta², Nikolaos Bergeles². ¹National and Kapodistrian University of Athens, Faculty of Physical Education and Sport Science - Hellenic Sports Research Institute, Olympic Athletic Center of Athens "Spyros Louis", Athens, Greece. ²National and Kapodistrian University of Athens, Athens, Greece.
 Email: nstavrou@phed.uoa.gr
 (No relevant relationships reported)

Several practice methods have been used by coaches in order to improve athletes' performance through the permanent changes in movement performance. Two of the widely used practice tasks are blocked and random schedule. In random schedule, the practice target is unpredictable for the athletes. On the other hand, in blocked practice, the athlete executes the same motor movement repeatedly before moving to the next skill. **PURPOSE:** The purpose of the present study was to examine the effect of contextual interference (random, blocked practice) on improving the volleyball attack (spike). **METHODS:** Thirty six (36) amateur volleyball players ranging in age from 18 to 25 years old volunteered to participate in the study. The participants were randomly assigned into three experimental conditions: (a) random practice, (b) blocked practice, and (c) control group. The intervention program lasted 6 weeks, and each participant underwent two 90 minute training sessions per week. During the training, each participant performed a total of 40 blows per training session. Three measures were applied: The first measure (pre-test) performed just before the commencement of the intervention program, one immediately after its end (post-test), and the third measure a week after the program completion (follow-up). **RESULTS:** The results indicated a significant improvement in the random schedule experimental group in the post-test compared to the pre-test ($p < .001$) as well as in the follow-up measure ($p < .01$). The blocked schedule group showed also an improvement in the post-test and follow-up measure compared to the pre-test ($p < .05$, $p < .05$). Additionally, the random group was significant better than blocked and control group in the post-test ($p < .01$, $p < .05$). **CONCLUSIONS:** Practice schedule differentiates the improvement of skill acquisition, indicating that the random practice participants revealed higher improvement and retention of the performed activity.

Effect Of Bodybuilding Calisthenics Training On Executive Ability In Old Women Adults

Chunmei Cao¹, Hengnan Jiang¹, Keying Zhang¹, Yu Liu².
¹Tsinghua University, Beijing, China. ²Peking University, Beijing, China.
 Email: caocm@tsinghua.edu.cn
 (No relevant relationships reported)

The interest in research on the exercise ways to improve executive ability has grown rapidly in the last decade due to the aging global population. The exercise programs were mainly involved in walking, swimming and Tai Chi. However, there is little report about the bodybuilding calisthenics training efficiency in improving executive ability of old women adults.

PURPOSE: To examine the effect of bodybuilding calisthenics training on executive ability in old women adults.

METHODS: One hundred and twenty-seven old women adults (Age: 70.2 ± 7.6 yr., Height: 158.2 ± 4.9 cm, Mass: 59.4 ± 8.5 kg) were recruited from local newspaper advertisement, whose Mini-Mental Status Examination scores were above 25. All subjects were randomly divided into experimental group (EG, $n = 75$) and control group (CG, $n = 52$). The EG conducted bodybuilding calisthenics training 2 times a week, 45 minutes each, for 25 weeks, and the CG continued to follow normal daily activities. The Trail Making Test A and B (TMT-A, TMT-B) and Tapping Test were used to evaluate the executive ability, which were measured before and after intervention. Two-way (group vs. time) repeated measures ANOVAs were performed for each of the outcome parameters. Tukey's HSD tests were employed for post-hoc comparisons. The alpha level was set at $p < 0.05$.

RESULTS: 1. There were statistically significant group by time interactions for TMT-A ($F_{(1,124)} = 6.90$, $p < .001$), TMT-B ($F_{(1,124)} = 6.64$, $p < .005$) and Tapping Test ($F_{(1,124)} = 3.99$, $p < .05$). 2. The main effect for time was significant for TMT-A ($F_{(1,129)} = 29.48$, $p < .001$), TMT-B ($F_{(1,125)} = 22.09$, $p < .001$) and Tapping Test ($F_{(1,125)} = 9.35$, $p < .005$). The main effect for group was significant for TMT-A ($F_{(1,125)} = 4.77$, $p < .01$), TMT-B ($F_{(1,125)} = 4.74$, $p < .05$) and Tapping Test ($F_{(1,125)} = 3.14$, $p < .05$).

CONCLUSIONS: bodybuilding calisthenics training helped improving executive ability for old women adults.

Grit And Ultramarathon Running

Julie M. Cousins, Madeline J. Peterson, Andrew N. Christopher, Andrea P. Francis, Heather H. Betz, FACSM. Albion College, Albion, MI. (Sponsor: Heather Betz, FACSM)
 Email: jcousins@albion.edu
 (No relevant relationships reported)

Ultramarathons consist of any race that is longer than 26.2 miles (42 km). Grit is the tendency to pursue long-term challenging goals with perseverance and passion. It has been assumed that ultramarathon runners have a high level of grit because of the challenges they must overcome to run such a long distance. **PURPOSE:** The purpose of this study was to investigate the association between ultramarathon running and grit-perseverance and grit-passion. **METHODS:** A total of 153 ultramarathon runners (age = 40.5 (9.0) years) participated in this study. The ultramarathon runners completed a demographic survey and the 12-item grit survey via Google Forms. The grit scale is comprised of two major components (a) consistency of interest (passion), and perseverance of effort. The ultramarathon runners were recruited through emails from race directors, facebook groups, and email invitations from the primary investigator. Statistical analyses were performed using Pearson product-moment correlations and a one-way ANOVA. Significance was set to $p < 0.05$. **RESULTS:** There was a positive correlation between number of years running and grit-passion ($r = 0.167$, $p = 0.039$). On average, participants had spent 14.4 (9.8) years running and had competed in ultramarathons for 4.3 (3.5) years. A positive correlation was found between the number of miles run per week and grit-passion ($r = 0.217$, $p = .007$). Participants, on average, ran 36.0 (13.3) miles per week. There was no significant difference across categories of ultramarathon distances completed and grit-passion or grit-perseverance. Failure to complete their last ultramarathon was not significantly associated with grit-passion or grit-perseverance. **CONCLUSION:** Grit was not found to be associated with ultramarathon distance or successful completion of an ultramarathon. Grit-passion was correlated with number of years running and weekly miles run. One limitation of this study was that 85% of the study participants were female.

The Effect Of Advanced Imagery Training On NCAA Shot Putter Performance

Conrad L. Woolsey¹, Tucker D. Woolsey¹, Scott Strohmeier², Stephen Walker¹, Wendell Otto¹, Brandie C. Cheshier³, Cody Diehl³, Bert H. Jacobson³. ¹University of Western States, Portland, OR. ²University of Central Missouri, Warrensburg, MO. ³Oklahoma State University, Stillwater, OK.
 (No relevant relationships reported)

Imagery training is practiced with the goal of improving consistency of performance under pressure and to maximize skill execution. A recent model for advanced imagery training incorporates seven areas into the protocol to make it more realistic and vivid for athletes. These include Physical, Environment, Task, Timing, Learning, Emotion, and Perspective (PETTLEP). **PURPOSE:** To investigate the effect of a PETTLEP-based imagery script on college shot put performance as measured by peak force (PF), release angle (RA), release height (RH), release velocity (RV), and distance thrown (DT). **METHODS:** Ten NCAA shot putters ($n=5$ females & $n=5$ males) participated in this study. Each participant created a personal imagery script with personal cues. Imagery was conducted five days per week for three weeks. A pre- and posttest design was used to evaluate the efficacy of PETTLEP-based imagery. Data was recorded using advanced force plate technology, biomechanical sensors, and infrared camera equipment and performance variables recorded included peak force, release angle, height of release, and release velocity. **RESULTS:** While all dependent variables increased in value, results yielded no significant difference in pre- to posttest for PF (Pre: 969.50 ± 185.18 N; Post: 1030.16 ± 201.37 N, $p > 0.05$), RA (Pre: $33.42 \pm 4.62^\circ$; Post: $36.95 \pm 8.08^\circ$, $p > 0.05$), RH (Pre: 2.00 ± 0.11 m; Post: 36.95 ± 8.08 m, $p > 0.05$), and RV (Pre: 10.89 ± 0.97 m/s; Post: 11.29 ± 0.79 m/s, $p > 0.05$). However, a significant difference was found for DT (Pre: 12.49 ± 2.14 m; Post: 11.29 ± 1.67 m, $p < 0.05$). Additionally, release velocity significantly correlated with distance thrown in both the pre- and post-tests ($r = .962$ and $r = .834$ respectively). Findings from the pretest linear regression analysis support using the model for release angle, release height, release velocity, and peak force production as a predictor of distance thrown with a level of confidence ($F(4,5) = 26.29$, $p < 0.001$; R^2 of .918). **CONCLUSION:** While these findings are encouraging, the PETTLEP-based imagery training model employed in the present study needs to be evaluated further to determine its effectiveness for consistently enhancing athletic performance.

Motivation, Personality, And Trait Self-handicapping In College Club Athletes
 David A. Tobar, Jordan Allen, Bonnie G. Berger. *Bowling Green State University, Bowling Green, OH.*
 Email: dtobar@bgsu.edu
 (No relevant relationships reported)

According to Self-Determination Theory (Ryan & Deci, 2017), motivation lies on a continuum from least (amotivation) to most self-determined (intrinsic). Personality traits have been shown to be related motivation in sport (e.g., Brinkman et al., 2016). Trait self-handicapping may be related to less self-determined motivation as athletes who use these strategies often fear failure for an upcoming, evaluative event and wish to control how they are perceived by others (Berger & Tobar, 2019). Despite about two million college students participating in club sports, research on these variables in this population is almost non-existent. **PURPOSE:** To examine the relationship between Big Five personality traits, trait self-handicapping, and motivation in college club athletes. **METHODS:** Data were collected from rugby (12 females, 28 males) and volleyball (15 females, 12 males) club athletes at a D-I university in the Midwest. Participants completed the Big Five Inventory, Self-Handicapping Scale, and Sport Motivation Scale - II. Factorial ANOVA and MANOVA were used to examine gender and sport differences for self-handicapping (SH), personality, motivation [intrinsic (INT), integrated (ITG), identified (IDN), introjected (ITJ), external (EXT), and amotivation (AMT)], and relative autonomy index (RAI). Personality traits and SH were included in stepwise multiple regression analyses to predict each type of motivation and RAI. **RESULTS:** Personality, SH, motivation, and RAI did not differ by gender or sport ($p > .05$). Thus, data were collapsed across gender and sport. Regression analyses revealed that Extraversion was the only significant predictor of INT [$R = .32, p < .01$], ITG [$R = .36, p < .005$], and IDN [$R = .40, p < .001$]. Negative Emotionality predicted ITJ [$R = .29, p < .05$] and SH predicted EXT [$R = .26, p < .05$]. No traits significantly predicted AMT ($p > .05$). Extraversion and SH predicted RAI in the final model [$R = .38, p < .01$]. **CONCLUSION:** Extraversion was related to more self-determined motivations in college club athletes. Athletes with more negative emotionality or who tended to use self-handicapping strategies reported less self-determined motivation. For these athletes, interventions that emphasize the intrinsic value of club sport participation may help decrease distress and self-handicapping behavior.

Factors Associated With Perceived Safety Norms Within Children's Sports Environments
 Aliza K. Nedimyer¹, Avinash Chandran¹, Melissa C. Kay², Paula Gildner¹, K. Hunter Byrd¹, Johna K. Register-Mihalik¹, Zachary Y. Kerr¹. ¹University of North Carolina at Chapel Hill, Chapel Hill, NC. ²University of Southern Mississippi, Hattiesburg, MS.
 (No relevant relationships reported)

Purpose: Middle school (MS) aged children participate in sports in multiple settings. Parents' perceptions of safety norms in these settings likely influence their decisions regarding children's sport participation. This study looked at factors associated with parents' perceived safety norms (ie. concussion risk) of their MS children's sport settings.

Methods: Randomly-selected US parents (aged ≥ 18 years) of MS children ($n=772$) completed an online questionnaire capturing parent and child characteristics, and parent knowledge, attitudes, and norms regarding concussion and safety. The main outcome, perceived safety norms related to children's sports settings, originated from a pre-validated measure [11 7-point scale items (range: 11-77; higher scores=better norms regarding safety)]. Parent (age, gender, race/ethnicity, education, concussion history, concussion knowledge, concussion care-seeking attitudes) and child characteristics (concussion history, contact level of sports played) served as explanatory variables. Multivariable logistic regressions modelled odds of better safety norms; norms scores were categorized by the median split of the possible score range (i.e., 11-44, 45-77). Separate analyses assessed norms for parents with children in MS sports ($n=617$) and club/rec league sports ($n=581$).

Results: Most respondents were female (60%), white/non-Hispanic (52%), and had at least a bachelor's degree (50%). Parents' mean age was 58 ± 9 years; 31% had a concussion history and 23% had a MS-aged child with a concussion history. Among parents with children in club/rec league sports, higher odds of better safety norms were associated with older age (5-year increase, OR=1.29; 95%CI=1.06-1.58), and higher concussion care-seeking attitudes (10% scale increase, OR=1.33; 95%CI=1.16-1.52). Among parents with children in MS sports, higher odds of better safety norms were associated with higher concussion-related knowledge (10% scale increase, OR=1.25; 95%CI=1.06-1.48) and higher concussion care-seeking attitudes (10% scale increase, OR=1.34; 95%CI=1.18-1.52).

Conclusions: Parental factors associated with safety norms varied based on child specific sport settings. Parents should taking setting into account when making decisions related to their children's sport participation.

Mental Preparation In High Altitude Mountain Climbers
 Kelly Rae Rice-McNeil. *Eastern Oregon University, La Grande, OR.*
 Email: krice@cou.edu
 (No relevant relationships reported)

Elite athletes use mental strategies to enhance performance. High altitude mountain climbers also require rigorous training to meet physical, and dangerous, demands of climbing. However, little is known about the mental strategies used by this population. **PURPOSE:** The purpose was to pilot test a survey which asked the following: 1) what do mountaineers do to prepare for a climb, 2) what mental strategies are used to overcome obstacles, and 3) do these strategies affect chances of summit success? **METHODS:** Pre-surveys were distributed to clients before mountain climbs on two high altitude peaks in Washington State (Baker and Rainer). Post-surveys were distributed 7 days post-climb via an online form. All clients were on guided trips. **RESULTS:** Males = 39 (78%) and Females = 11 (22%) climbed either Mt Rainer = 33 (66%) or Mt Baker = 17 (34%). 92% of clients had a bachelor's degree or above and 60% identified as White, 24% Asian, 16% other. For 86% of the clients, this was their first attempt on that mountain. All clients (100%) physical trained an average of 4.82 months, 4.16 days/week and 81.8 min/day. 50% mentally trained for 3.26 months, 2.26 days/week and 22.5 min/day. Self-identified mental preparation ranged from researching gear ($n=5$), reading about climbing($n=5$), visualization ($n=3$) and meditation ($n=4$). 23 clients completed post-survey, the summit success rate was 46.2% ($n=12$) reached the summit, 42.3% ($n=11$) did not. **CONCLUSION:** Understanding of mental preparation among mountain climbers appears limited. An intervention that can be delivered to high altitude mountain climbers to implement mental strategies may help increase summit success.

- 484** Board #300 May 27 10:30 AM - 12:00 PM
Examination Of Quality Of Life And Activities Of Daily Living After Sport Participation
 Heather E. Key, Toni Torres-McGehee, Samantha R. Weber, Rachel Sharpe, Eva Monsma, Mike McCall. *University of South Carolina, Columbia, SC.*
 (No relevant relationships reported)

Context: Athletes often develop positive self-esteem during sport participation but may have negative repercussions once an athlete retires. Preparation for retirement of sport is important in order to prevent negative mental health consequences and decreases in quality of life and activities of daily living.

Purpose: To examine quality of life and activities of daily living in retired athletes. The secondary purpose will examine differences between gender, the type of sport played, and length of time in retirement.

Methods: Cross-sectional study examined retired athletes ($n=180$; ages: 28.5 ± 10.4 years; males: $n=72$; females: $n=107$). Each participant completed at minimum of 4 years of high school sports, or 2 years of collegiate athletics, or 2 years of professional sports. The survey included demographic questions related to activities of daily living (e.g., health status, activity level, basic mood levels, and the Quality of Life Index (QLI)). Basic descriptive, independent samples t-tests, and ANOVAs were used.

Results: No significant differences were found between females and males' total score for sport type and QLI. A significant difference was found between Time in Retirement and QLI total scores ($p=.008$). A significant difference ($p \leq 0.01$) was found between gender and Time in Retirement in the amount of vigorous activities (e.g., running, strenuous exercise, etc.) and mood/nervousness ($p=0.006$) with females between 0-5 years of retirement displaying the highest concern. Majority of participants 84.4% ($n=60$) felt they were healthy for their age and 93.9% ($n=69$) felt their health does not prevent them from working and/or decreases their activities of daily living. Only 13.4% ($n=24$) reported feeling bad in the past 30 days.

Conclusion: While it is suggested that retirement from sport may have negative repercussions on health and quality of life, the overall results indicated the opposite. Individuals reported their quality of life and health did not prevent them from completing activities of daily living. It is important to prepare athletes for retirement and encourage continuation of physical activity and maintenance of their health.

Light Physical Activity Is Associated With Reduced Signs Of Immune Aging In Healthy Older Adults**

Eunhan Cho¹, Bailey Theall¹, James Stampely¹, Brett Davis¹, Heather Quiarte¹, Frank Greenway², Neil Johannsen¹, Guillaume Spielmann¹, Brian A. Irving, FACSM¹. ¹Louisiana State University, Baton Rouge, LA. ²Pennington Biomedical Research Center, Baton Rouge, LA. (Sponsor: Brian Irving, FACSM)

(No relevant relationships reported)

Aging is associated with a progressive accumulation of late differentiated T-cells and increased risk of infection and mortality. A higher level of cardiorespiratory fitness (VO₂ peak) in adults over 65 years old are associated with improved T-cell phenotypic characteristics. However, little is known on the impact of light intensity physical activity (LPA) on the proportions of late differentiated T-cells in sedentary elderly. **Purpose:** We aimed to examine the association of LPA and the age-related accumulation of memory T-cells in an elderly sedentary population. **Methods:** We studied 16 physically inactive, community-dwelling, older adults (70 ±4y) from an on-going exercise intervention (REALPA). At baseline participants performed a VO₂ peak exercise test on a treadmill. Participants also wore a physical activity monitor (Actigraph, GT9X) on their thigh 24-h/d for 7-days to quantify total non-bouted physical activity (PA). Fasted blood was drawn and peripheral blood mononuclear cells were isolated and stained with anti-CD3, CD4, CD8, CD57, and killer cell lectin-like receptor G 1 (KLRG1) monoclonal antibodies. T-cell phenotypes were analyzed by four-color flow cytometry (BD Accuri C6). Pearson's correlation coefficients were used to determine linear correlations between T-cell phenotype and PA. **Results:** Participants VO₂ peak ranged from 12.2 to 29.9 mL/kg/min (20.5 ± 5.1 mL/kg/min) and spent 317.4 ± 56.9 minutes of LPA/day, 22.5 ± 14.3 minutes of Moderate-Vigorous intensity PA (MVPA)/day and accumulated 4,595 ± 1,091 steps/day. The number of pan memory T-cells (CD3+/KLRG1+) were inversely correlated with VO₂ peak (r = -0.51, p=0.045), while the percentage of pan memory T-cells were negatively associated with volume of LPA (r = -0.54, p=0.033), but not with MVPA (p>0.05). Additionally, actigraphy analysis showed that a greater number of daily steps were associated with reduced numbers of memory CD4+ T-cells (KLRG1+/CD57-) (r = -0.53, p=0.035). **Conclusions:** Our data support the benefits of high VO₂ peak on immune aging in a cohort of sedentary elderly adults. More importantly, LPA and increased daily steps are associated with reduced markers of immune aging, even in elderly individuals with moderate-low aerobic fitness. This study was supported by the NIA 5R21AG058181-02.

Work-week Sleep Restriction Modifies Physical Activity But Not Glucose Or Insulin Responses In Overweight Adults.**

Jay W. Porter, Ryan Pettit-Mee, Travis Emerson, Jill Barnas, Jill Kanaley, FACSM. University of Missouri, COLUMBIA, MO. (Sponsor: Jill A Kanaley, FACSM)
(No relevant relationships reported)

Insufficient sleep and inadequate amounts of physical activity (PA) are common lifestyle behaviors, but there is a paucity of research examining the interaction between insufficient sleep and PA. **PURPOSE:** To establish how sleep restriction affects PA, and the role this plays in sleep restriction-induced insulin resistance (IR) in overweight adults. **METHODS** Thirteen overweight adults, who regularly sleep 7-9 h/night, underwent two study conditions; 5 days of modest sleep restriction (6-h time-in-bed, SR), and 5 days of SR+exercise (SREX), followed by a weekend recovery period (WR). Sleep (Actigraphy) and PA (Actigraph) were monitored for 7 days prior to each condition, throughout each condition, and during WR. Blood samples were collected during a mixed meal tolerance test (MT) after baseline (B), SR/SREX, and WR. Daily exercise, SREX, was 45 minutes of treadmill walking (65% VO₂ peak). **RESULTS** Subjects slept 8.0±0.2 h during B weekdays compared to SR and SREX (5.9±0.1 h; 5.9±0.0 h, respectively) and 7.4±0.2 hours on weekend (7.4±0.3; 8.2±0.4, respectively). Steps were maintained during SR compared to B (B-SR, 8276±622; SR, 7656±676 steps/day) but were increased during SREX (B-SREX, 8550±776; SREX 13182±789 steps/day, p<0.001). Steps during the B weekend period were reduced compared to B (p<0.001) and during WR following SR±EX (SR, p<0.01; SREX,

p<0.001). Subjects performed less light (LT) PA during SR±EX (p=0.001). Sedentary (SED) PA tended to be higher during SR compared to B (p=0.07) but tended to be reduced during SREX (p=0.09). Moderate-vigorous PA (MVPA) was elevated during SREX (p<0.001) and reduced during SR (p<0.05) compared to B. During MT, glucose and insulin response did not differ by condition or across time. Matsuda calculations tended to also show improvements in IR (time, p=0.06), where WR improved compared to B (p<0.05), no differences between B and SR±EX. **CONCLUSION** Overweight adults maintained steps during SR, but reduced time spent performing MVPA. When subjects performed EX daily (SREX), SED was replaced with MVPA with no changes in LTPA observed. Subjects increased SED and decreased LTPA and MVPA during WR compared to B weekend, likely due to the reduced step counts. Modest SR did not induce IR in overweight adults, but despite reduced PA during WR, IR was improved compared to B.

Acute Resistance Exercise Fails To Improve Influenza Vaccine Response In Older Adults**

Emily C. LaVoy, Mahmoud T. Elzayat, Melissa M. Markofski. University of Houston, Houston, TX.
Email: eclavoy@uh.edu
(No relevant relationships reported)

Older adults are at elevated risk for morbidity and mortality caused by influenza. Vaccination is the primary means of prophylaxis, but the magnitude and duration of the protective response is often compromised in older adults. As acute eccentric resistance exercise can mobilize immune cells into targeted muscle, it may enhance immune responses to vaccination. **PURPOSE:** To compare immune responses to influenza vaccination in older adults who performed eccentric resistance exercise prior to vaccination to those who did not exercise. **METHODS:** 29 resistance training naive older adults (20 women, 73.9 ± 5.6 years) were randomized to 1 of 3 groups: 1) exercise in the vaccinated arm (EX-S), 2) exercise in the opposite arm (EX-OP) and 3) control (NO-EX). Exercise consisted of 10 sets of 5 repetitions at 85% of each subject's pre-determined concentric one repetition maxima. Lateral raises were alternated with bicep curls, with 15 sec rest between exercises and 30 sec rest between sets. Focus was on the eccentric component of the exercise. NO-EX sat quietly for 20 min. Following treatment (EX or NO-EX), all subjects received the 2018 quadrivalent influenza vaccine (Seqirus Afluria) in the deltoid of the non-dominant arm. Antibody titers against the 4 influenza strains in the vaccine were determined by hemagglutinin inhibition assays at 6- and 24-weeks post-vaccination. Group differences in antibody titers by time were assessed by maximum likelihood linear mixed models; sex was included as a covariate. Fold-changes in antibody titers at 6 and 24 weeks from baseline were compared between groups by Kruskal-Wallis H tests. **RESULTS:** Subjective reports of soreness did not differ between groups. One subject (EX-S) reported flu-like symptoms 18 weeks post-vaccination. No significant group x time effects were found for any strain. Women had greater titers to strain A/Singapore compared to men (F (1,28.12) = 5.85, p=0.022). There was a trend for group differences in fold-increase in antibodies against B/Colorado at 6 weeks (H(2)=4.512, p=0.105) with a mean rank antibody titer of 16.88 for EX-S, 12.29 for EX-OP, and 10.40 for NO-EX. **CONCLUSION:** Acute eccentric resistance exercise of the deltoid and bicep brachii did not significantly influence antibody titers to the influenza vaccine delivered post-exercise in older adults.

(No relevant relationships reported)

Reduced physical activity and associated chronic low-grade inflammation have long been recognized as risk factors for the development of type 2 diabetes (T2D). Various types of exercise interventions are designed to improve the management of T2D; however, the impact of different modes of exercise training on immune activation in patients with T2D remains unclear. **Purpose:** This study aimed to determine the impact of 9 months of exercise training on Free Light Chains (FLC), a near real-time blood indicator of B-cell activation, in people with T2D. **Methods:** Retrospective analysis was performed on 258 archived plasma samples collected during the HART-D study (NCT00458133) from sedentary individuals with T2D after nine-months of resistance (RT), aerobic (AT), combined exercise (ATRT), or no-exercise control (CON). Aerobic fitness (VO₂ peak) was measured before and after the intervention using a graded treadmill test, and muscle quality was determined by dividing peak torque during concentric isokinetic knee flexion by lean mass using DXA scanner. Samples were

analyzed for total ($\kappa + \lambda$) FLCs and kidney function was estimated by measuring plasma Cystatin C. Linear mixed models were used to analyze changes in FLC in response to the exercise interventions, after controlling for confounding factors. **Results:** At baseline, VO_{2peak} and muscle quality were both negatively correlated with total FLC ($r^2=0.118$, $\beta=-0.312$; $p<0.001$ and $r^2=0.100$, $\beta=-0.220$; $p=0.004$, resp.), even after adjustment for age, sex, ethnic group and HbA1c level. Following 9 months of exercise, changes in VO_{2peak} in CON, AT, RT and COMB were not associated with changes in total FLC ($p>0.05$). Total FLC levels were significantly reduced in those that exhibited improvements in muscle quality ($r^2=0.058$, $\beta=-0.140$; $p=0.047$) in all exercising groups. No significant difference in total FLC were observed between the exercising groups, nor change in kidney in any of the groups. **Conclusion:** Lower physical fitness and muscle quality in people with T2D is associated with elevated FLCs, indicating a heightened state of B cell activation. Exercise-induced improvements in muscle quality corresponded with reduced circulating FLCs and systemic low-grade inflammation in T2D.

(No relevant relationships reported)

Breast cancer therapy impairs immune function that may be attenuated with exercise, though the specific changes that occur remain unclear. **PURPOSE:** 1) To examine monocyte function in breast cancer survivors (BCS) following acute exercise and 2) to determine if this response changes with exercise training. **METHODS:** 9 BCS [Age: 58±8, BMI: 27.9±6.7] completed a cardiopulmonary exercise test (CPET). In a subsequent trial, 45 min of intermittent cycling at 60% of CPET peak wattage was performed. Blood was taken at rest, immediately (0h) and 1h after exercise. Monocyte phagocytosis and oxidative burst were assessed following *E. coli* exposure. Toll-like receptor 2 (TLR2) and 4 (TLR4) expression was determined on CD14⁺CD16⁺ and CD14⁺CD16⁻ monocytes. All assays were performed before (pre) and after (post) 16 wk of combined aerobic and resistance training. Data are presented as mean fluorescence intensity ± SD. **RESULTS:** Phagocytosis increased 1h after acute exercise before (rest: 3396±941 0h: 3257±772, 1h: 3692±824, $p=0.035$) but not after training. There was a trend for greater phagocytosis with training (pre: 3533±815 post: 5027±2039, $p=0.078$). Oxidative burst was unchanged with acute exercise but improved following training (pre: 4264±1061 post: 5446±1287, $p=0.026$). CD16⁺ TLR2 expression decreased acutely at 1h compared to rest and 0h both before and after training (rest: 350±70, 0h: 328±73, 1h: 287±41, both $p<0.05$) while CD16⁺ decreased acutely before training only (pre rest: 355±115 0h: 339±98 1h: 291±87. CD16⁺ TLR4 expression tended to decrease with acute exercise ($p=0.067$) whereas CD16⁺ TLR4 expression decreased across all time points (rest: 140±15, 0h: 135±15, 1h: 123±18, all $p<0.05$) with neither population affected by training. **CONCLUSIONS:** In BCS, monocyte phagocytic capacity of bacteria increased following acute exercise, while training increased both phagocytosis and oxidative burst. Training appeared to mitigate the acute response, possibly due to higher resting function. Expression of TLR2 and TLR4 were progressively reduced with acute exercise that was mostly independent of training. The reduction of monocyte TLR2 and TLR4 may represent an anti-inflammatory response to acute exercise that promotes enhanced elimination of bacteria. Supported by Breast Cancer Research Foundation (New York, NY).

Association Between Circulating FGF21 Levels And Physical Activity In Abdominal Obese Adults

Masahiro Matsui¹, Keisei Kosaki², Koichiro Tanahashi³, Nobuhiko Akazawa⁴, Yosuke Osuka⁵, Kiyoji Tanaka, FACSM¹, Makoto Kuro-o⁶, Seiji Maeda¹. ¹University of Tsukuba, Ibaraki, Japan. ²Waseda University, Saitama, Japan. ³Kyoto Pharmaceutical University, Kyoto, Japan. ⁴Japan Institute of Sports Sciences, Tokyo, Japan. ⁵Tokyo Metropolitan Institute of Gerontology, Tokyo, Japan. ⁶Jichi Medical University, Tochigi, Japan. (Sponsor: Kiyoji Tanaka, FACSM)
Email: masahiromatsui0708@gmail.com
(No relevant relationships reported)

PURPOSE: Circulating fibroblast growth factor 21 (FGF21) is increased with abdominal obesity and may lead to the development of several chronic diseases such as diabetes and cardiovascular disease. Currently, the effect of daily physical activity on circulating FGF21 levels in abdominal obese adults is unclear. This study aimed to examine the cross-sectional association between circulating FGF21 levels and physical activity in abdominal obese adults.

METHODS: This study recruited 207 middle-aged and older adults and classified them as 160 non-obese and 47 abdominal obese adults according to their abdominal circumference (men: ≥ 85 cm, women: ≥ 90 cm). Circulating serum FGF21 levels were evaluated using the ELIZA methods. Daily physical activity levels were objectively assessed using a uniaxial accelerometer and categorized into light-intensity physical activity (LPA) and moderate- to vigorous-intensity physical activity (MVPA).

RESULTS: Abdominal obese adults had a higher median value of serum FGF21 levels when compared with non-obese adults (102 pg/mL vs. 139 pg/mL, $P = 0.006$). Serum FGF21 levels were correlated negatively with the time spent in LPA ($r_s = -0.326$, $P = 0.025$) and MVPA ($r_s = -0.349$, $P = 0.016$) in abdominal obese adults, but not in non-obese adults. When the participants were divided into four groups according to abdominal obesity and physical activity status, the significant interaction was indicated between abdominal obesity and MVPA ($F = 7.386$, $P = 0.007$), but not LPA. Additionally, abdominal obese adults with higher MVPA levels had lower serum FGF21 levels ($P = 0.004$). Furthermore, the association between abdominal obesity, MVPA status and FGF21 levels remained significant after adjusting for age, sex, peak oxygen consumption, blood lipid and glucose, current smoking status, and using medications ($F = 6.229$, $P = 0.013$).

CONCLUSIONS: Lower serum FGF21 concentration was inversely related to higher physical activity levels, particularly in abdominal obese adults. These findings suggest that daily MVPA is effective for decreasing serum FGF21 levels in middle-aged and older adults with abdominal obesity.

Diabetes Risk Variants Associate With Impaired Insulin Sensitivity In Healthy Adults Following Bed Rest

Jean Lorraine Fry¹, Emily J. Arentson-Lantz², Christopher S. Fry¹, Douglas Paddon-Jones, FACSM². ¹University of Kentucky, Lexington, KY. ²The University of Texas Medical Branch, Galveston, TX. (Sponsor: Douglas Paddon-Jones, FACSM)
Email: jfr282@uky.edu
(No relevant relationships reported)

More than 80 genetic variants increase risk for type 2 diabetes. We hypothesized that increased genetic risk for diabetes may increase susceptibility to impaired insulin sensitivity following bed rest. **PURPOSE:** To determine whether type 2 diabetes genetic risk variants in healthy older adults are associated with impaired insulin sensitivity following bed rest. **METHODS:** 37 nondiabetic adults (65.9 ± 7.9 years, BMI 27.1 ± 3.0, 82.2 ± 6.4 mg/dL fasting blood glucose) completed bed rest studies at the University of Texas Medical Branch. The protocol consisted of a 3 day run-in period, 7 days of bed rest and 7 days of rehabilitation. OGTT (75g) were administered before and after bed rest protocol and following rehabilitation. Venous blood was collected at baseline, 0, 30, 60, 90, and 120 minutes, and the Matsuda Insulin Sensitivity Index (Mat-ISI), HOMA-IR, Insulinogenic Index (II), and the Disposition Index (DI) were calculated. DNA from whole blood was used to genotype for MTNR1B (rs10830963), NOTCH2 (rs10923931), RASGRP1 (rs7403531), PROX1 (rs2075423), HHEX (rs1111875), IGF2BP2 (rs4402960), CDKAL1 (rs7754840), SLC30A8 (rs13266634), ZFAND6 (rs11634397), and TCF7L2 (rs7903146) risk variants using TaqMan Assays. Results were collated into an unweighted risk score based on the total number of risk alleles (possible range from 0-20). SPSS version 26 (IBM, Chicago, IL) was used to build a multivariate model including all outcome indices and risk variants. **RESULTS:** Genetic risk scores ranged from 5 to 11. HOMA-IR and II were not associated with risk scores at any point in the study. Higher overall risk scores were inversely associated with the Mat-ISI and the DI only immediately after the completion of the bed rest period ($p = 0.035$ and $p = 0.017$, respectively), but not at baseline or after rehabilitation. Post-bed rest Mat-ISI ranged from 18.1 ± 11.6 for those in the lowest risk group vs. 6.8 ± 0.26 in the highest risk group. Post-bed rest DI was 16.8 ± 12.9 for

those in the lowest risk group and 5.8 ± 3 in the highest risk group. **CONCLUSION:** These results indicate that people with a higher genetic risk for type 2 diabetes may be at increased risk of disuse-related loss of insulin sensitivity. The work was supported by the Claude D. Pepper Older Americans Independence Center (P30 AG024832).

Metabolic Effects Of High-intensity Interval Training With Probiotics Supplementation In Obese Women

Yi-Chen Chen¹, Ting-Yao Wang², Chien-Wen Hou¹. ¹*Institute of Sports Sciences, Taipei city, Taiwan.* ²*Holistic Education Center, Hualien city, Taiwan.* (Sponsor: Chia-Hua Kuo, FACSM)
Email: qute3332@gmail.com
(No relevant relationships reported)

The rising of cardiovascular disease and obesity is a pandemic issue over the past years. High-intensity interval training (HIIT) has been shown to improve aerobic capacity, increase metabolic rate, and reduce body fat. Lactobacillus plantarum TWK10, a type of probiotics isolated from Taiwan pickled vegetables, was also found to provide similar performance and metabolic outcome. However, the additive effects of probiotics with HIIT is unclear. **PURPOSE:** To investigate the additive effects of probiotics supplementation in combination with HIIT on cardiopulmonary fitness, body composition and metabolic syndrome blood biomarkers. **METHODS:** The placebo-controlled, double blinded study recruited obese women ($n = 23$, age = 45.8 ± 6.4 y, weight = 62.9 ± 9.2 kg, body fat % = 39.3 ± 3.8 %) and assigned into two groups: probiotics group (TWK10) and placebo group (PLA). Participants in both groups consumed supplements daily before breakfast and participated in a self-monitored HIIT training (treadmill running 7 x 2 minutes at 85-90 % $\dot{V}O_{2max}$ with 1-minute resting interval) for 3 sessions per week for 8 weeks. Cardiopulmonary fitness - $\dot{V}O_{2max}$ and time to exhaustion, body composition - body weight and body fat %, waist and hip circumferences, and blood sugar and lipid profile - fasting blood glucose (FBG), triglyceride (TG), and high-density lipoprotein (HDL) were measured at baseline and after the exercise intervention. Data was analyzed using paired t-test and ANCOVA. **RESULTS:** Time to exhaustion significantly increased in TWK10 ($+11.4\%$, $p = .008$) and PLA ($+8.8\%$, $p = .004$). Hip circumference reduced significantly only in TWK10 group (-2.1% , $p = .018$) and waist circumference increased significantly only in PLA group ($+1.7\%$, $p = .008$). No significant group effects were found in waist and hip circumference respectively. FBG increased significantly in PLA group ($+4.5\%$, $p = .027$) but no significance was found in TWK10 group and between both groups. No significant time and group effects were found in $\dot{V}O_{2max}$, body weight, body fat %, TG, and HDL. **CONCLUSION:** Probiotics supplement in combination with HIIT may only control body circumferences and stabilize FBG over time, but does not have additive benefits in overall cardiopulmonary fitness and metabolic biomarkers.

Hemoglobin A1c, Physical Activity, And Sport Participation Among Children With Type 1 Diabetes

Kristi M. King, Jason R. Jagers, FACSM, Timothy McKay, Kupper Wintergerst. *University of Louisville, Louisville, KY.* (Sponsor: Jason Jagers, FACSM)
Email: kristi.king@louisville.edu
(No relevant relationships reported)

Children with type 1 diabetes (T1D) should engage in a minimum of 60 minutes of moderate- to vigorous-intensity physical activity (PA) daily, the same as children without T1D; however, care must be taken to prevent or address hypoglycemia or hyperglycemia during and after PA. **PURPOSE:** The purpose of this study was to determine if PA or sport participation predicted hemoglobin A1c (HbA1c) in children with T1D. **METHODS:** This study was conducted within a nationally certified pediatric diabetes care and academic medical center. Patients 7 to 17 years old with T1D presenting for their regularly scheduled pediatric endocrinology appointment were invited to complete a physical activity and sport participation electronic survey. Data were linked to their medical records for age, T1D diagnosis duration, ethnicity, race, gender, insurance type, body mass index (BMI), continuous glucose monitor (CGM) and insulin pump usage, and the primary outcome variable HbA1c. **RESULTS:** Participants consisted of 73 females (47.7%) and 80 males (52.3%), 12.97 ± 2.82 years old, with an average HbA1c of 8.78 ± 1.87 . They were physically active for 60 minutes or more 3.48 ± 1.95 days per week with only 7.9% ($n = 12$) meeting the recommendation of daily PA, yet almost two-thirds played sports within the past year ($n = 98$, 64.1%). A multiple linear regression model indicated that although HbA1c

decreased by .175 for each day a child engaged in PA and decreased .121 for every sport team a child played only the number of days active per week was a significant predictor of better HbA1c ($p < .05$). **CONCLUSION:** Since the number of days active per week was a significant predictor of better HbA1c, it behooves diabetes care teams to encourage PA in addition to sport participation alone. Further investigation should address socioecological barriers to PA and sport participation. This study was made possible by support from the Christensen Family, Children's Hospital Foundation, and University of Louisville Foundation.

Effects Of Aerobic And Resistance Training On The Lipoprotein Subclass Profile In Type 2 Diabetics

Jacob L. Barber¹, Neil M. Johannsen², William E. Kraus, FACSM³, Timothy S. Church⁴, Mark A. Sarzynski, FACSM¹. ¹*University of South Carolina, Columbia, SC.* ²*Louisiana State University, Baton Rouge, LA.* ³*Duke University School of Medicine, Durham, NC.* ⁴*Pennington Biomedical Research Center, Baton Rouge, LA.* (Sponsor: Mark Sarzynski, FACSM)
(No relevant relationships reported)

Purpose: Type 2 diabetes (T2D) is associated with dysfunctional lipid metabolism in addition to impaired glucose metabolism. Exercise is widely prescribed in the treatment of T2D; however, the effects of exercise on complex lipoprotein traits in T2D are not fully understood. **Methods:** Change in lipoprotein subclass profile was examined in 214 patients with T2D from the HART-D cohort. Patients were randomized to 9 months of either control ($n=33$), aerobic training (AT, $n=62$), resistance training (RT, $n=55$), or combination of aerobic and resistance training (AT/RT, $n=64$). NMR spectroscopy was used to quantify lipoprotein size, total and subclass concentrations of triglyceride rich lipoproteins, low-density lipoproteins, and high-density lipoproteins (TRL-P, LDL-P, and HDL-P respectively). Paired t-tests were used to assess the effects of exercise within each intervention, and general linear models (GLMs) adjusting for group, sex, race, age, baseline BMI, and baseline trait value were used to compare changes in lipoprotein subfractions in exercise groups to changes in control. **Results:** AT resulted in nominal ($p < 0.05$) changes in small HDL-P (H2 (7.8nm): $-0.69 \mu\text{mol/L}$, $p=0.032$, H1 (7.4nm): $0.44 \mu\text{mol/L}$, $p=0.03$), and RT increased medium LDL-P (43.89 nmol/L , $p=0.002$), while AT/RT failed to produce changes in any lipoprotein subclass. Adjusted GLMs revealed the change in H2 HDL-P was less in AT compared control ($p=0.01$). Additionally, despite no training response in large LDL-P subclass concentration following AT, change in large LDL-P was less in the AT group compared to control ($p=0.01$). **Conclusions:** Overall, exercise training resulted in minimal changes in the lipoprotein subclass profile in patients with T2D. Further studies are needed to elucidate the potential effects of exercise dose on lipoprotein subfractions to improve upon the clinical utility of exercise prescription in the treatment of T2D.

PURPOSE: The aim of this study was to compare the Heart Rate Recovery (HRR) kinetics and Heart Rate variability (HRV) in diabetic mellitus type 2 (T2DM) after high-intensity interval training (HIIT) and moderate-intensity continuous training (MICT) protocols. **METHODS:** Forty-four elderly people diagnosed with T2DM for less than 5 years (BMI = $30.57 \pm 2.56 \text{ kg/m}^2$, age = 56.83 ± 5.73 years) participated in the study, this study has the characteristics of a randomized clinical trial. This project was approved by the ethics committee under number 1,643,562. The participants performed cardiopulmonary exercise testing (CPET) to obtain oxygen uptake ($\dot{V}O_{2max}$). Subsequently, they were allocated to three different groups and used for eight weeks of physical exercise, which were: MICT (14' at 70% of $\dot{V}O_{2max}$), G2:2 (5 - 2' at 100% of $\dot{V}O_{2max}$ with 2' of passive rest) and G30:30 (20 - 30' at 100% of $\dot{V}O_{2max}$ and passive rest). To capture HR, a heart rate monitor (Polar, v800, Finland)

was used. HRV data were analyzed using Kubios HRV software, and exponential data were analyzed using CardioKin software. To compare the protocols, the two-way ANOVA test with repeated measures, $p = 5\%$ was used. **RESULTS:** group x time interaction was observed in the SDNN [F (2.82) = 3.462; $p = 0.036$]. After performing multiple comparisons on SDNN variable, as a function of time, only the HIIT-30:30 group showed a significant difference ($p = 0.025$), the rMSSD variable showed no difference in any evaluation. In the off parameters, group effect was found in the TAUoff variables [F (2.82) = 4.710; $p = 0.012$] time effect for AMPoff was found [F (1.82) = 4.881; $p = 0.030$]. It was also observed group x time interaction in TAUoff [F (2.82) = 3.146; $p = 0.048$]. In the variables in which group x time interaction was observed post hoc to obtain multiple comparisons, the MICT group presented higher TAUoff values when compared to the groups HIIT-30:30 and HIIT-2:2 ($p = 0.001$ and 0.013 , respectively) representing a demonstrated post-exercise sympathetic hyperactivity. **CONCLUSION:** Of all evaluated protocols, the 30:30 protocol was the one that presented the best HR response, and thus, the application of this protocol is effective in improving autonomic control, without greater risk for diabetics.

 (No relevant relationships reported)

Diabetes Mellitus (DM) is one of the most common lifestyle-associated diseases worldwide. DM is often correlated to sedentary lifestyle, poor nutritional behaviors and high body fat. Therefore sedentary and overweight people are at high risk of having DM. However, there are also normal weight diabetics in which these factors may be less strongly correlated. **PURPOSE:** To comprehensively describe differences between normal and overweight patients with DM using cardiopulmonary exercise testing. **METHODS:** As part of two separate exercise trials being run on normoweight (STRONG-D) and overweight (IMPACT) diabetics, patients performed individualised ramp CPET. Results of CPET were compared between the groups using statistics for multiple between group comparisons. **RESULTS:** Besides known demographic and anthropometric differences, the normoweight group also reached significantly ($p < 0.01$) higher workload (17%), higher peak ventilation (11%) and oxygen uptake (12%), higher heart rate recovery (6%), and had lower resting heart rate (11%) and ventilatory efficiency (21%). **CONCLUSIONS:** DM is in itself a risk factor for further cardiovascular disease, but the DM risk profile may be more sensitively identified through examination of exercise performance.

498 Board #314 May 27 10:30 AM - 12:00 PM
Influence Of Fasting Blood Glucose On Cardiopulmonary Responses To Maximal Exercise

Danielle R. James, James E. Peterman, Bradley S. Fleenor, Mitchell H. Whaley, FACSM, Leonard A. Kaminsky, FACSM, Matthew P. Harber, FACSM. Ball State University, Muncie, IN. (Sponsor: Matthew P. Harber, FACSM)
 (No relevant relationships reported)

Cardiopulmonary exercise testing (CPET) is used in the diagnosis and prognosis of several chronic diseases. However, the impact of impaired fasting glucose regulation on CPET responses is unknown. **PURPOSE:** To examine the influence of fasting blood glucose status on CPET responses to maximal exercise. **METHODS:** Apparently healthy adults ($n = 3863$) from the Ball State Adult Fitness Longitudinal Lifestyle Study (BALL ST) were examined. Participants were categorized by fasting blood glucose status according to American Diabetes Association guidelines as normal (NORMAL, $n = 2738$, 50% male, plasma glucose 88 ± 9 mg·dl⁻¹), prediabetes (PRE, $n = 938$, 66% male, plasma glucose 107 ± 9 mg·dl⁻¹) or diabetes mellitus (DM, $n = 187$, 60% male, plasma glucose 152 ± 51 mg·dl⁻¹). All participants performed a maximal CPET for the determination of cardiorespiratory fitness (CRF), ventilatory threshold (VT), ventilatory efficiency slope ($V_{E, slope}$), oxygen uptake efficiency slope (OUES), oxygen pulse (O_2 pulse), exercise ventilatory power (EVP), and exercise circulatory power (ECP). Analysis of variance (ANOVA) was used to compare group means. **RESULTS:** Age- and sex-adjusted CRF (expressed as percentiles based on the Fitness Registry and Importance of Exercise National Database (FRIEND)) was inversely related to fasting blood glucose status (NORMAL > PRE > DM; 47 ± 28 , 41 ± 28 , 26 ± 24 percentile, $p < 0.05$ for all) as was VT (NORMAL > PRE > DM; 19.5 ± 8.0 , 17.9 ± 6.8 , 15.1 ± 5.2 ml·kg⁻¹·min⁻¹, $p < 0.05$ for all), EVP was lower ($p < 0.05$) for NORMAL (6.6 ± 1.7 mmHg) compared to PRE (7.1 ± 1.8 mmHg) and DM (7.2 ± 2.8 mmHg). ECP was lower ($p < 0.05$) for DM (4575 ± 1611 mmHg·ml·kg⁻¹·min⁻¹) compared to NORMAL (5498 ± 1986 mmHg·ml·kg⁻¹·min⁻¹) and PRE (5410 ± 1790 mmHg·ml·kg⁻¹·min⁻¹). O_2 pulse was higher ($p < 0.05$) in PRE (15.4 ± 4.5 ml·beat⁻¹) compared to NORMAL

(14.5 ± 5.3 ml·beat⁻¹) and DM (13.9 ± 4.0 ml·beat⁻¹). No differences between groups existed for $V_{E, slope}$ or OUES. **CONCLUSION:** These data demonstrate that impaired fasting glucose regulation is associated with altered CPET responses indicating that CPET may be an additional diagnostic tool in the diagnosis of diabetes.

The Effects Of Resveratrol And Exercise Training On Functional Fitness In Elderly With T2dm

Yae-Young Kim¹, Man-gyoon lee², Won-Sang Jung³, Da-som Heo². ¹Deagu Haany University, Gyeongsan-si, Gyeongsangbuk-do, Korea, Republic of. ²Kyung Hee University, Giheung-gu, Yongin-si, Gyeonggi-do, Korea, Republic of. ³Konkuk University, Gwangjin-gu, Seoul, Korea, Republic of.
 Email: kyy@dhu.ac.kr
 (No relevant relationships reported)

Although resveratrol has potential to be an 'exercise pill', studies that have observed the effects of resveratrol after it was consumed by diabetics, to whom exercise was very important, were limited. In particular, studies that both observed and compared the effects of resveratrol intake and aerobic exercise done at the same time by T2DM elderly women, who tend to lack treatment and care the most, were needed. Thus, in this study, the body composition, aerobic exercise ability and functional fitness effects in T2DM elderly women was observed throughout 8 weeks of treatment. **PURPOSE:** The purpose of this study was to investigate the effects 8 weeks of aerobic training and resveratrol supplementation on body composition, aerobic exercise capacity, and functional fitness in T2DM elderly women. **METHODS:** Fifty T2DM elderly women (70.5 ± 4.4) were randomly assigned to either a combined aerobic training and resveratrol supplementation group (EX+R: $n = 12$), an aerobic training only group (EX: $n = 12$), a resveratrol supplementation only group (R: $n = 13$), or a control group (CON: $n = 13$). The subjects in EX exercised three sessions per week, the subjects in R took in resveratrol for 500 mg·d⁻¹ for 8 weeks, 40 minutes per session for 8 weeks, and the subjects in EX+R participated in both treatment. **RESULTS:** Body composition did not change significantly in all groups. However, aerobic exercise capacity (VO_{2max}) increased significantly in EX+R (38.2 ± 2.9 vs. 42.8 ± 2.5 ml/kg/min, $p < .001$) and R (33.9 ± 7.5 vs. 37.3 ± 7.9 ml/kg/min, $p < .05$). Functional fitness Chair sit-to stand was increased significantly in EX+R (19.1 ± 4.9 vs. 21.4 ± 4.1 reps), EX (19.8 ± 3.3 vs. 22.5 ± 4.3 reps), and R (20.6 ± 4.4 vs. 22.3 ± 3.6 reps). Foot tapping in a sitting down was increased significantly in EX+R (26.6 ± 3.8 vs. 30.3 ± 3.6 reps, $p < .05$) and EX (26.5 ± 5 vs. 31.2 ± 4.2 reps $p < .01$). Also, pegboard increased significantly in EX+R (38.8 ± 4.0 vs. 41.5 ± 3.8 reps, $p < .05$), EX (39 ± 4.5 vs. 41.4 ± 4 reps, $p < .05$) and R (38.3 ± 2.4 vs. 41.2 ± 2.9 reps, $p < .01$), whereas the other functional fitness-related variables showed no significant changes in all groups. **CONCLUSIONS:** It was concluded that the 8 weeks of resveratrol supplementation and aerobic training combined had positive effects on aerobic exercise capacity and functional fitness of T2DM elderly women.

500 Board #316 May 27 10:30 AM - 12:00 PM
No Difference In Heart Rate Recovery During Graded Treadmill Testing In Patients With And Without Nonalcoholic Fatty Liver Disease (NAFLD)

Patrick Austin, Jillian K. Price, Carey Escheik, Lynn Gerber, Zobair M. Younossi. Inova Health Systems, Falls Church, VA. Email: patrick.austin@inova.org
 (No relevant relationships reported)

Cardiac Mortality is the most common cause of death for nonalcoholic fatty liver disease (NAFLD), which is linked to physical inactivity and obesity. **PURPOSE:** To determine whether individuals with NAFLD show heart rate recovery impairment (iHRR is ≤ 12 beats per minute at 1 minute post-exercise, an independent predictor of mortality) compared to non-NAFLD participants following graded treadmill testing (GTT) to volitional exhaustion. **METHODS:** Non-pharmacological clinical research participants with and without NAFLD were included. All performed symptom-limited, Modified Bruce GTT. Gas exchange captured cardiorespiratory variables and impedance cardiometry assessed heart rate, stroke volume, and cardiac output (CO) continuously during rest, testing, and recovery. Participants completed nutrition, activity, and fatigue questionnaires. Linear regression assessed effects of covariates on HRR. **RESULTS:** 86 participants (48.8% Male, 62.8% Caucasian, 65.8% NAFLD/ NASH, Age 48 ± 13.6 years) were included for analysis. T-test comparisons showed individuals with NAFLD to be older (52 vs 41.4 years, $p = .001$), have higher body mass index (31.2 vs 28.4 kg/m², $p = .007$), and increased body fat percentage, (34.1% vs 28.6% , $p = .006$) but showed no differences for resting pulse, blood pressure, gender, or ethnicity. Per GTT, individuals with NAFLD had reduced oxygen consumption at anaerobic threshold (AT) (12.3 vs 15.6 mL/kg/min) and peak exertion (23.1 vs 31.2 mL/kg/min, $p < .001$) compared to non-NAFLD. The NAFLD cohort also reported reduced maximal and average activity scores compared to the non-NAFLD group (MAS 89.8 vs 81.4 , $p = .001$; AAS 88.1 vs 77.6 , $p < .001$). No group differences were

found for iHRR presence or continuous HRR measure. Stepwise linear regression showed peak CO ($B=0.317$, $p=.041$) and MAS ($B=.348$, $p=.025$) to be significant predictors of HRR for all participants ($R^2=.261$).

CONCLUSIONS: No HRR post exercise differences were found between NAFLD and non-NAFLD individuals. Increased CO and self-reported exercise capacity may indicate lower probability of impaired HRR. AAS and MAS were reduced in the NAFLD group, which may reflect reduced aerobic capacity at peak performance and AT. NAFLD individuals may benefit from exercise participation encouragement to improve tolerance of physical activity.

A Simple Smartphone-based Physical Activity Level Did Not Predict Obesity Prevalence In Type 2 Diabetes Patients In Korea

Ah Reum Jung¹, Shinae Kim², Kun Tae Kim², Youn Ju Lee², Dae Taek Lee¹, Kun Ho Yoon³, Yoon Hee Choi³. ¹Kookmin university, Seoul, Korea, Republic of. ²Medical Excellence Inc., Seoul, Korea, Republic of. ³The Catholic University of Korea Seoul ST. Mary's Hospital, Seoul, Korea, Republic of.
 Email: jal003@naver.com
 (No relevant relationships reported)

PURPOSE: Obesity management in patients with type 2 diabetes (T2DM) is very important for improving insulin resistance. One of the factors affecting obesity management is physical activity level (PAL). The purpose of this study was to investigate the relationship between obesity and the daily physical activity level monitored by smart-phones in T2DM patients.

METHODS: A total of 325 patients with T2DM who have enrolled a diabetes self-management App (iCareD, Medical Excellence Inc., Korea) linked to an electronic medical record (EMR) at least for 30 days was enlisted. The daily walking steps were monitored by a 3-axis accelerometer embedded in the smartphone. And 268 patients who walked over an average of 1,000 step/day in 30 days (163 men; 58.1±11.8 yrs, 170.9±5.8 cm, 73.7±11.4 kg, and 25.2±3.5 kg/m², 105 women; 55.3±14.6 yrs, 158.1±5.2 cm, 61.0±11.7 kg, and 24.3±4.0 kg/m²) were selected for the analyses of PAL. The medical record (height, weight, and body mass index: BMI) of those selected subjects were retrieved from the hospital. PAL was divided into quartile, and the obesity prevalence was compared by groups. Statistical software SAS version 9.4 were used and statistical significance was set at $p<0.05$.

RESULTS: The average daily PAL for 30 days was 5,209±3,276 step/day ($n=268$). Those who walked >7,500 step/day were 20.8% ($n=56$). The quartile was divided by 67 patients at ≤2,452, between >2,452 and ≤4,655, between >4,655 and ≤7,009, and >7,009 step/day, for the 1st, 2nd, 3rd, and 4th quartile, respectively. The total obesity prevalence with BMI ≥25 kg/m² was 41.7% ($n=112$). The group obesity prevalence was 47.7% ($n=32$), 44.7% ($n=30$), 40.2% ($n=27$), and 34.3% ($n=23$), in 1st, 2nd, 3rd, and 4th quartile, respectively ($p=0.459$).

CONCLUSIONS: This study revealed a quantification of PAL monitored by smartphones in Korean T2DM patients. The majority of the subjects did not meet the recommended activity level guided by the American Diabetes Association (7,500–9,999 step/day). The low level of PAL may be due by data collection modality such as smartphones. Further studies are required. (study funded by NRF-2014M3A9D7070333).

Acute Vs. Chronic Responses To Exercise Training In Type-2 Vs. Pre-diabetic Adults.

Joshua Muench¹, Rachel N. West¹, Jacklyn P. Hensel¹, Sean T. O'Neil², Noah J. Curtis³, Gabe N. Neil¹, Rachael K. Nelson¹. ¹Central Michigan University, Mt Pleasant, MI. ²St. Judes Childrens Hospital, Memphis, TN. ³Beaumont Health, Southfield, MI.
 (No relevant relationships reported)

Exercise is recommended for improving glycemic control yet it remains unclear whether exercise training produces similar acute and chronic adaptations in T2DM vs. pre-diabetic individuals given their varying states of insulin resistance. **PURPOSE:** To compare acute and chronic exercise training adaptations in response to the same exercise training program in T2DM vs. pre-diabetic individuals. **METHODS** 18 male ($n=8$) and female ($n=10$), previously inactive (no planned physical activity), adults with T2DM ($n=10$) or pre-diabetes ($n=8$) completed the same exercise training program (3 days/wk, 8 wks). Before and exactly 72-hr after participants' last exercise session, chronic adaptations in body fat percentage ([BF%]) assessed via dual x-ray absorptiometry), fitness determined by a 6-minute walk test, resting systolic (SBP) and diastolic (DBP) blood pressure, fasting blood glucose (BG), and self-efficacy using the Self-Efficacy for Exercise Scale (SEE) were measured. Participants' SBP, DBP, and BG were also monitored immediately before and 5-min after each exercise session to determine acute responses to exercise. **RESULTS:** A significant improvement in 6MWT was observed for T2DM (1544 ± 82 vs. 1752 ± 80 ft., $p<0.01$) and pre-diabetic

(1414 ± 97 vs. 1624 ± 115 ft., $p<0.01$) participants. No significant chronic or acute changes were observed in SBP for either group. A significant improvement in resting DBP was observed in T2DM (80 ± 2 vs. 75 ± 3 mmHg, $p=0.03$) but not pre-diabetic (75 ± 2 vs. 79 ± 3 mmHg, $p=0.13$) participants yet no acute changes were observed in DBP for either group. No significant changes were observed in fasting BG in either group. Acutely exercise resulted in significantly lower BG in diabetic (172 ± 12 vs. 145 ± 11 mg/dL, $p<0.01$) and pre-diabetic (104 ± 4 vs. 95 ± 3 mg/dL, $p<0.01$) participants. A significant improvement in SEE was observed in diabetic (34.3 ± 9.0 vs. 65.0 ± 9.0 , $p=0.029$), but not pre-diabetic (38.8 ± 12.8 vs. 60.0 ± 12.8 , $p=0.24$) participants. **CONCLUSION:** Despite varying states of insulin resistance, exercise training resulted in similar improvements in fitness and acute improvements in blood glucose in both diabetic and pre-diabetic adults. However, unlike pre-diabetics, diabetic participants experienced additional benefits in resting diastolic blood pressure and exercise self-efficacy.

503 Board #319 May 27 10:30 AM - 12:00 PM
Accuracy Of Continuous Glucose Monitoring During Exercise In Type I Diabetes Patients

Matteo Vandoni¹, Vittoria Carnevale Pellino¹, Luca Correale¹, Giulia Liberali¹, Valentina Natalucci², Silvia Bonfadini³, Angela Girelli³, Cosme Franklim Buzzachera¹. ¹University of Pavia, Pavia, Italy. ²University of Urbino Carlo Bo, Urbino, Italy. ³ASST Spedali Civili di Brescia, Brescia, Italy.  (No relevant relationships reported)

Subcutaneous continuous glucose monitor devices provide a more detailed description of glycemic control. This may be particularly useful as a tool to detect hypo- or hyperglycemia during exercise. Performance of continuous glucose monitor devices, however, is likely to be lower when glucose levels are changing rapidly, such as occurs during exercise. **PURPOSE:** To determine the accuracy of a subcutaneous continuous glucose monitor during exercise in Type I Diabetes patients. **METHODS:** Paired subcutaneous continuous glucose monitor (Freestyle Libre, Abbott Diabetes Care, Witney, UK) and capillary glucose values were collected, from 38 adults (20 women and 18 men; mean ± SD, 45 ± 14 years) with Type I Diabetes, at rest, low- (40%HRR), moderate- (70%HRR), and high-exercise intensity (>85%HRR). Mean Absolute Relative Differences (MARD) was used to determine accuracy. **RESULTS:** The glucose values (mg/dL) for subcutaneous continuous glucose monitor and capillary glucose monitor did significantly differ at low- (mean ± SD; 164 ± 70 vs 144 ± 54) and moderate-exercise intensity (148 ± 61 vs 131 ± 50) ($P < 0.05$), but not at rest (177 ± 72 vs 170 ± 59) and high-exercise intensity (142 ± 53 vs 144 ± 45) ($P > 0.05$). MARD at rest was 4%, while the individuals MARDs were 14%, 13%, and 2% for low-, moderate-, and high-exercise intensity, respectively. **CONCLUSIONS:** Continuous glucose monitoring was not sufficiently accurate to describe glucose levels at low-to-moderate exercise intensities in Type I Diabetes patients and require confirmatory capillary glucose measurements.

Influence Of Monetary Incentives On Exercise Compliance & Health Among Hyperglycemic Adults: Preliminary Analysis.

Sean O'Neil¹, Noah J. Curtis², Rachel N. West³, Jacklyn P. Hensel³, Gabe N. Neil³, Joshua P. Muench³, Rachael K. Nelson³. ¹St. Judes Children's Hospital, Memphis, TN. ²Beaumont Health, Southfield, MI. ³Central Michigan University, Mt Pleasant, MI.
 (No relevant relationships reported)

A major obstacle in exercise-based rehabilitation is exercise compliance. Monetary incentives are associated with greater exercise compliance and improvements in health, yet an ideal monetary system has yet to be identified. **PURPOSE:** To examine exercise compliance and health outcome measures associated with fixed- vs. incremental-loss monetary systems during an exercise training in a clinical population. **METHODS:** 17 male ($n=7$) and female ($n=10$), previously inactive (no planned physical activity), hyperglycemic (T2DM, $n=9$; pre-diabetes, $n=8$), adults (53±2 yrs.) completed a supervised exercise training program (3 days/wk for 8 wks). All participants started with \$48 (\$6/wk x 8 wks). For the fixed-loss group, \$2 was deducted for each missed exercise session. For the incremental-loss group, progressively more was deducted for each session missed per week: \$1 for the first, \$2 for the second, and \$3 for the third/final session of the week. Exercise compliance, body fat percentage ([BF%]) assessed via dual x-ray absorptiometry), and fitness determined by a 6-minute walk test (6MWT) were assessed before and after exercise training. Similar to cardiopulmonary rehabilitation programs, acute responses to exercise including heart rate (HR), systolic (SBP) and diastolic (DBP) blood pressure, as well as blood glucose were monitored immediately before and 5-minutes after each exercise session. **RESULTS:** Exercise compliance was similar between the fixed- vs. incremental-loss group (90±4% vs. 92±3%, $p=0.63$). No significant differences were observed between groups or in

response to exercise training for BF%. Similar improvements were observed in the 6MWT for the fixed-loss (1534±99 vs. 1799±99 ft., $p < 0.001$) and incremental-loss (1455±93 vs. 1585±93 ft., $p = 0.04$) groups. Similar reductions were also observed in average acute blood glucose response from pre to post-exercise in the fixed- (131±18 vs. 114±11 mg/dL, $p = 0.03$) and incremental-loss (152±23 vs. 132±19 mg/dL, $p = 0.01$) group. No significant differences were detected in acute response to exercise for HR, SBP or DBP. **CONCLUSION:** Regardless of loss system, modest monetary incentives appear to promote high exercise compliance that was associated with meaningful health benefits including improved fitness and blood glucose control for hyperglycemia individuals.

 (No relevant relationships reported)

PURPOSE: The purpose of this study was to investigate the effects of progressive combined exercise program on irisin, C-peptide, HOMA- β , HOMA-IR, body composition and physical fitness in obese elderly women with type 2 diabetes.
METHODS: Thirty six obese elderly women with T2DM patients (76.64 ± 6.56 years, %BF 36.09 ± 4.18, HbA1c 7.05 ± 0.85%) were randomly assigned to the combined exercise group (n = 20) and to the control group (n = 16). The 60 minute combined exercise program (outdoor walking + elastic-band resistance exercise) was performed 3 times per week for 12 weeks, and the intensity was progressively increased every four weeks (Outdoor walking RPE 11-14; Band exercise 1-4 weeks: OMNI-RES 3 to 4, 5-8 weeks: OMNI-RES 5 to 6, 9-12weeks: OMNI-RES 7 to 8).
RESULTS: There were significant time × group interactions for irisin ($p < 0.001$), C-peptide ($p = 0.002$), HOMA- β ($p < 0.001$), HOMA-IR ($p = 0.045$), fasting blood glucose ($p < 0.001$), and HbA1c ($p < 0.001$). Result of combined exercise group were as follows; percentage of body fat had significantly decreased, and irisin level had significantly increased. In addition, HbA1c and Glucose were significantly decreased to improve glycemic control, and C-peptide, CPI and HOMA- β levels were significantly increased. Fasting glucose ($r = -0.424$), HbA1c ($r = -0.351$), SBP ($r = -0.397$) and percentage of body fat ($r = -0.423$) changes level showed a negative whereas HOMA- β ($r = 0.411$) and aerobic endurance ($r = 0.355$) changes level had a positive correlation with irisin change level.
CONCLUSIONS: Combined exercise improves irisin levels and regulates percentage of body fat and blood glucose, which improves beta-cell function than non-exercise. Therefore, progressive combined exercise improves body composition, blood glucose and β -cell function by increasing irisin levels in obese elderly women with type 2 diabetes.

Ethnic Differences In Post-prandial Glycemic Control After Acute Moderate-intensity Continuous Or High-intensity Interval Exercise

Jack Alistair Sargeant¹, Charlotte Jelleyman², Matthew McCarthy¹, Joseph Henson¹, James A. King³, Kamlesh Khunti¹, Melanie J. Davies¹, Thomas Yates¹. ¹University of Leicester, Leicester, United Kingdom. ²Auckland University of Technology, Auckland, New Zealand. ³Loughborough University, Loughborough, United Kingdom.
 Email: js928@leicester.ac.uk
 (No relevant relationships reported)

PURPOSE: To examine the effects of acute continuous moderate-intensity aerobic exercise (CME) and low-volume high-intensity interval training (LV-HIIT) on glycemic control in white Europeans (WEs) and south Asians (SAs) with impaired glycemic control.
METHODS: 23 participants (WE / SA [M/F]: 13[6/7] / 10[7/3]; median (IQR): age 67 (60–68) years, BMI 30.0 (28.4–32.8) kg/m², waist circumference 100.8 (97.6–109.1) cm, HbA1c 5.9 (5.8–6.1) %) completed three 6 h trials (control [CON], CME, LV-HIIT; randomized order). Participants rested throughout, except for 35 min of CME and 25 min of LV-HIIT (closely matched for external work produced) during corresponding trials. Both CME and LV-HIIT ended at 2 h. Standardized meals were consumed at 0 and 3 h. Plasma glucose and insulin were measured at 0, 0.5, 1, 2, 3, 3.5, 4, 5 and 6 h. Data were analysed as post-exercise time-averaged area under the curve (AUC_{post}), using generalized estimating equations, adjusted for pre-exercise AUC

(also time-averaged), sex and age. Main effects of trial and ethnicity were assessed, with an interaction term fitted to explore if ethnicity modulated responses. Insulin resistance index (IRI) was calculated as $tAUC_{glu} \times tAUC_{ins}^{-1}$.
RESULTS: Glucose was unaffected (all $p \geq 0.28$), but insulin AUC_{post} was reduced in both exercise trials compared to CON (main effect $p < 0.001$; Figure 1A). Furthermore, this effect was modulated by ethnicity ($p = 0.03$), with a greater effect seen in SAs. Notably, insulin AUC_{post} was similar in both ethnicities during exercise trials, despite being higher in SAs during CON (Figure 1A). Results were similar for IRI (Figure 1B).
CONCLUSION: Despite ~30% higher post-prandial insulin responses during prolonged sitting, SAs may benefit more from acute exercise than WEs. Acknowledging that this was an acute-crossover study, these findings warrant further investigation with longer-term exercise training interventions, given the higher cardiometabolic disease risk observed in SAs.

Figure 1 – Post-exercise responses of (A) insulin and (B) insulin resistance index during each trial in each ethnicity group.

Data presented as mean (95% confidence interval); *[#] indicate significant differences from the CON trial within ethnicity group (*[#] $p < 0.05$, **[#] $p < 0.01$, ***[#] $p = 0.001$). Data for insulin resistance index presented normalised to the mean value during the CON trial in the white European group, for ease of interpretation. CME: continuous moderate-intensity aerobic exercise trial; CON: control trial; LV-HIIT: low-volume high-intensity interval training.

Motor-assisted And Functional Electrical Stimulation Cycling Impacts Postprandial Glucose In Diabetic Patients With Adl Disability

Tongyu Ma, Chong-Do Lee, FACSM, Steven Hooker, FACSM, Gabriel Shaibi, Carol Johnston, Shannon Ringenbach. Arizona State University, Tempe, AZ. (Sponsor: Chong Lee, FACSM)
 Email: tongyuma@asu.edu
 (No relevant relationships reported)

Background: Effective glucose management using exercise modalities in older patients with type 2 diabetes and activities of daily living (ADL) disabilities are unknown.
Purpose: The study investigated the acute effects of motor-assisted cycling and functional electrical stimulation (FES) cycling on the 2-h postprandial glucose responses compared with sitting control in older adults with type 2 diabetes and ADL disability.
Methods: The study used a 3×3 crossover study design. Nine participants were randomly assigned to one of the three intervention sequences: ABC, BCA, and CAB. (A, motor-assisted cycling; B, FES cycling; C, sitting control). Linear mixed models (LMM) with Bonferroni post-hoc tests were used to test the mean differences for the 2-h postprandial glucose, estimated by the area under the curve (AUC) and incremental AUC (iAUC), between intervention and control treatments after adjustment for covariates (e.g., age, sex, and race).
Results: There were significant mean differences for iAUC ($p = 0.005$) and AUC ($p = 0.038$) across motor-assisted cycling, control, and FES cycling treatments. The FES cycling had a lower mean of 2-hour postprandial iAUC as compared with sitting control (iAUC 3.98 mmol·h/L vs 6.92 mmol·h/L, $p = 0.006$, effect size [ES] = 1.72) and the motor-assisted cycling (iAUC, 3.98 mmol·h/L vs 6.19 mmol·h/L, $p = 0.0368$, ES = 1.29), respectively. The FES cycling also had a lower mean of the 2-hour postprandial AUC as compared with sitting control (AUC, 18.29 mmol·h/L vs 20.95 mmol·h/L, $p = 0.043$, ES = 0.89), but had an AUC similar to the motor-assisted cycling (18.29 mmol·h/L vs 20.23 mmol·h/L, $p = 0.183$, ES = 0.19). There were no statistical differences in iAUC (6.19 mmol·h/L vs 6.92 mmol·h/L) and AUC (20.23 mmol·h/L vs 20.95 mmol·h/L) between the motor-assisted cycling and sitting control (all $p > 0.05$).
Conclusion: Performing 30 minutes of FES cycling on a motor-assisted bike (40 Hz, 38 rpm, 25-29 mA) significantly decreased the 2-h postprandial glucose levels by 42% in older adults with type 2 diabetes and ADL disabilities. Our findings suggested that FES cycling can be a promising exercise modality for glucose management in diabetic patients with ADL disabilities.

(No relevant relationships reported)

PURPOSE: The evidence from randomised controlled trials (RCTs) and meta-analyses supports the use of exercise to manage type 2 diabetes (T2D), and most guidelines propose exercise as a cornerstone of clinical management. However, there is a paucity of evidence for how this translates to real-world practices, specifically the effectiveness of exercise in patients with T2D when delivered as part of complex health service models, rather than in tightly controlled research trials. **METHODS:** A collaboration of universities and health clinics in Australia is addressing this evidence gap by investigating the effectiveness of services provided by Accredited Exercise Physiologists on a range of outcome measures in people with T2D. The novelty of this approach is the authenticity of 1) the sample population, which excludes no one who is referred to the service; and 2) the type of intervention, which is whatever the individual clinic, clinician and/or patient deem suitable for each situation, subject to any cost constraints. This study is a preliminary analysis of the challenges encountered with this real-world research approach and of the population presenting for exercise physiology services in this context. **RESULTS:** Key challenges encountered were 1) delays in regional ethics committees, 2) participant recruitment particular to each site, 3) attrition, 4) access to medical records. Sixty-two participants (59% female, 65 ± 10 y.o., HbA1c 7 ± 1%, BP 137/77 including 23% stage 1 and 33% Stage 2 hypertension based on ACC levels) have been enrolled to date. All were on 1 or more hypoglycaemic medication, 88% were on 1 or more cardiovascular medication and 83% were on 1 or more other medication. Of those on additional medications the mean number of medications prescribed was 7.5 per person. **CONCLUSIONS:** The challenges encountered are consistent with similar approaches of translational research. The sample recruited so far is older with more comorbidity and complex polypharmacy, but has relatively good glycaemic control compared to the typical patient population studied in published RCTs. The difficulty in accrual considered alongside the patient characteristics supports the need for more focus on this type of implementation research to inform the real-world evidence for the benefits of exercise, rather than relying only on RCTs.

Glycemic Effects Of Exercise In Sri Lankans Adults With Type 2 Diabetes Mellitus

Chathuranga Ranasinghe¹, Godwin Constantine¹, Prasad Katulanda¹, Andrew Hills², Neil King³. ¹Faculty of Medicine, University of Colombo, Colombo, Sri Lanka. ²University of Tasmania, Launceston, Australia. ³Queensland University of Technology, Brisbane, Australia. (Sponsor: Cemal Ozemek, FACSM)

Email: chath_r@yahoo.com.au

(No relevant relationships reported)

The prevalence of type 2 Diabetes Mellitus (T2DM) is rising in South Asia. Although exercise training is recommended for its management, the effects of exercise training on glycemic control in Sri Lankans with T2DM has not been studied. **PURPOSE:** To examine the effects of aerobic training (AT) and resistance training (RT) on glycemic control in Sri Lankan adults with T2DM. **METHODS:** 86 Sedentary Sri Lankans (50.1±8.7 years, 53% women) diagnosed with T2DM within last 6 years were randomized into AT (n=28), RT (n=28) or control (CN, n=30). Supervised exercise training was performed for 75 minutes per session, 2 days/week for 12 weeks. RT targeted 7 (i.e., 3 upper body, 3 lower body, 1 core) exercises. AT included brisk walking, stepping and stationary cycling at an intensity of 60-75% heart rate max. Fasting blood glucose (FBG), HbA1c, and fasting insulin (FI) were measured at baseline and post intervention. **RESULTS:** Baseline mean BMI, HbA1c, FBG and FI were 26.4 kg/m²±4.0, 8.2±1.7%, 146.9 ±54.1 mg/dl and 13.3±8.5 micIU/ml, respectively. Subject characteristics were similar among groups, except the CN group had higher mean HbA1c level (8.9 ± 1.7%). Absolute mean change in HbA1c was not

significant across groups; RT 0.6 % (95% CI; 1.16% to -0.01%, p=0.8), AT 0.74 % (95% CI; 1.25% to -0.24 %, p=0.5) or CN 0.52% (95% CI, 1.1% to 0.03%, p= 0.8). Absolute mean change in FBG significantly improved in RT (-3.8 mg/dl [95% CI, 4.9 to -12.6 mg/dl; p=0.02]) and CN (25.6 mg/dl [95% CI; 48.5 to 3.0 mg/dl, p= 0.04]), but not AT (20.1 mg/dl [95% CI, 39.6 to 0.6 mg/dl, p= 0.5]). Absolute mean change in FI did not significantly increase in RT (0.2 micIU/ml [95% CI, (2.9 to -2.4 micIU/ml, p = 0.1)] or AT (0.2 micIU/ml [95% CI; 2.9 to -2.5 micIU/ml, p = 0.1]) but did in the CN group (3.0 micIU/ml [95% CI, 0.8 to -8.3 micIU/ml, p=0.00]). **CONCLUSION:** To our knowledge this is the first randomized controlled trial to study the effects of AT and RT on glycemic control in Sri Lankan diabetics. Intervention showed mixed effects in improvement in chronic glycemic control (HbA1c) and in short term glycemic control (FBG). FI did not increase in intervention groups which demonstrated reduced disease progression. Future studies with larger sample sizes are need for definitive conclusions.

510 Board #326 May 27 10:30 AM - 12:00 PM
Improvement In Insulin Sensitivity With Four Weeks Of Neuromuscular Electrical Stimulation In Overweight/obese Sedentary Adults

Michael J. Sanchez, Michelle Galvan, Isaac Gandara, Dante Nacim, Jeffrey Covington, Jason Boyle, Francisco Agullo, Kisuk Min, Sudip Bajpeyi. University of Texas at El Paso, El Paso, TX. Email: mjsanchez6@miners.utep.edu

(No relevant relationships reported)

Most U.S. adults (80%) do not meet minimum exercise recommendations by ACSM (CDC, 2015). Using an *in vitro* primary cell culture model, we and others have shown that muscle contraction induced by electrical stimulation results in increased glucose transporter 4 (GLUT4) protein, glucose uptake and mitochondrial content. Neuromuscular electrical stimulation (NMES) is a novel alternate strategy to induce muscle contraction, using electrical impulses. However, effectiveness of NMES induced muscle contraction to improve insulin sensitivity and energy expenditure is not clear.

PURPOSE: To investigate the effects of four weeks of NMES on insulin sensitivity in a sedentary overweight/obese population.

METHODS: Sedentary overweight/obese participants (n=8; age: 37.0 ± 3.6 years; BMI= 30.9 ± 1.1 kg/m²) were randomized into either a control or NMES group. All participants received bilateral quadriceps stimulation (12 sessions, 30 minutes/session, 3 times/week) either using low intensity sensory level (control) or at high intensity neuromuscular level (NMES) for four weeks (50Hz and 300µs pulse width). Insulin sensitivity was assessed by three-hour oral glucose tolerance test (OGTT) at baseline and after four weeks of NMES intervention.

RESULTS: Control and NMES group had comparable fasting blood glucose (Control 106.1 ± 3.1; NMES 107.9 ± 3.9 mg/dL; p=0.74) and glucose tolerance (Control 430.73 ± 20.23; NMES 469.97 ± 28.03 AU; p=0.30) at baseline. Four weeks of NMES resulted in significant improvement in insulin sensitivity measured by OGTT, whereas no change was observed in control group (Control 430.73 ± 20.23 to 418.36 ± 15.13 AU; p=0.62; NMES 469.97 ± 28.03 to 423.97 ± 31.53 AU; p=0.04). Additionally, blood glucose level measured after 2 hours of glucose drink consumption trended to be lower after 4 weeks of NMES treatment (154.38 ± 8.71 to 140.25 ± 9.46 mg/dL, p=0.052) whereas no change was observed in control group (151.75 ± 6.14 to 139.75 ± 9.03 mg/dL, p=0.33).

CONCLUSION: NMES is a novel and effective strategy to improve insulin sensitivity in an at-risk overweight/obese sedentary population.

Exercise Prescription Is An Effective Action To Achieve 3B Targets In T2DM

Xianbo Zhang¹, Dongni Yu¹, Xiaoxia Wang¹, Qi Pan¹, Lixin Guo¹, Zhengzhen Wang, FACSM². ¹Beijing Hospital, National Center of Gerontology, China, Beijing, China. ²Beijing Sport University, Beijing, China. (Sponsor: Zhengzhen Wang, FACSM)

Email: zhangxianbo_87@aliyun.com

(No relevant relationships reported)

PURPOSE: To explore the effects of exercise prescription on the effect of achieve blood glucose, blood pressure and blood lipid(3B) targets of T2D patients.

METHODS: T2D patients aged from 18 years to 75 years were assigned to the exercise prescription group (ExRx), 10000-steps group (Steps), or education group (Edu). CPT, anthropometric and blood test was assessed at baseline and after 12 weeks intervention in all participants. Participants were asked to achieve moderate exercise (50%-60% V_{O2}max, self-monitored heart rate) for a minimum of 30min/d, 5d/week for ExRx group, or achieve 10,000 steps a day as pedometer monitored, at least 5d/week for Steps group, or receive exercise education every 4 weeks but not make exercise records for Edu group. Follow-up was performed every four weeks. The primary outcome was the improvement of fitness and glucose control of T2D; secondary outcomes were the achievements of 3B targets of T2D.

RESULTS: A total of 298 subjects with a mean age of 55 years (154 men, 144 women) entered the final analysis. After 12 weeks of intervention, the $\text{VO}_{2\text{max}}$ were significantly increased by 2.49 ± 5.92 METs in ExRx group compared with Steps group (0.53 ± 1.23 METs) and Edu group (-0.54 ± 4.82 METs) ($P < 0.001$); FPG decreased 0.39 ± 1.79 mmol/L ($P < 0.001$), no intergroup difference; HbA1c were significantly decreased $0.37 \pm 0.92\%$ in ExRx group compared with Steps group ($0.12 \pm 1.05\%$) and Edu group ($-0.05 \pm 1.09\%$) ($P < 0.05$). After intervention for 12 weeks, the proportion of patients who achieved 3B targets increased from 10.5% to 17.0%, while $\text{VO}_{2\text{max}}$ increased 0.74 ± 3.34 METs for all participants. Participants who achieves the three targets got an improvement of 1.03 ± 3.60 METs in $\text{VO}_{2\text{max}}$ after 12 weeks intervention compared with others (0.39 ± 2.59 METs).

CONCLUSION: 12 weeks exercise intervention improved fitness and blood glucose control of T2D patients, exercise prescription is more effective than other two methods. 12 weeks exercise intervention increased the proportion of patients who achieved 3B targets from 10.5% to 17.0%, exercise prescription group increased 11.2% which was better than other two groups. Participants who achieves the 3B targets got an improvement of 1METs in $\text{VO}_{2\text{max}}$ after 12 weeks intervention. Exercise prescription is an effective action to achieve 3B targets in type 2 diabetes patients.

Association Between Physical Activity Intensity And Glucose Variability Among Athletes With Type 1 Diabetes.

Jason R. Jagers, FACSM, Kristi M. King, Timothy McKay, Kupper Wintergerst. *University of Louisville, Louisville, KY.*
 Email: jason.jagers@louisville.edu
 (No relevant relationships reported)

All children are encouraged to engage in a minimum of 60 minutes of moderate to vigorous physical activity (PA) per day. However, when it comes to the long-term health implications of daily PA, there is an added benefit for those managing type 1 diabetes (T1D). Studies have consistently shown improvements in daily glucose and hemoglobin A1c (HbA1c) for both type 1 and type 2 diabetes. A limitation with prior investigations is that they only tested this relationship in adult populations. Whether or not similar results would be observed in a pediatric population with T1D is unknown. **PURPOSE:** The purpose of this investigation was to test the relationship between glucose variability and intensity of PA and determine if duration of activity is predictive of changes in glucose variability in a sample of teenagers with T1D. **METHODS:** Data for this investigation were used from an ongoing study at a local pediatric Diabetes Center. Participants who wore a continuous glucose monitor (CGM) and Fitbit consecutively for a period of two weeks or more were included in the data analysis. Glucose variability was determined using 2-weeks of CGM data and PA intensity time was retrieved through Fitabase. Pearson's correlation and a simple linear regression were used for final analysis with a p-value of 0.05 to determine significance. **RESULTS:** Minutes of daily moderate intensity activity had a significant inverse relationship ($r = -0.59$; $p = 0.04$) with glucose variability, whereas moderate and vigorous PA (MVPA) combined showed a stronger inverse relationship ($r = -0.86$; $p = 0.03$). When placed in a simple linear regression only MVPA significantly predicted changes in glucose variability ($\beta = -0.12$, $p = 0.03$). **CONCLUSION:** These data show that not only is duration of PA an important factor when it comes to managing diabetes, but that more attention should be paid to the time spent at various intensity levels. Even though more research still needs to be completed in this area it would be of great benefit for children with T1D to incorporate an activity monitor into their daily routine to share with their diabetes care team and better understand how PA levels impact their blood glucose. Funded by Children's Hospital Foundation, Christensen Family, Norton Children's Hospital, and University of Louisville.

A-55 Exercise is Medicine®/Poster - EIM: HIIT, Exercise with the Elderly and Parkinson's Disease

Influence Of High-intensity Interval Training On Fatigue, Depression And Anxiety In People With Multiple Sclerosis

Marit Lea Schlagheck¹, Niklas Joisten¹, Annette Rademacher¹, Sebastian Proschinger¹, Max Oberste¹, Alexander Schenk¹, Jan Kool², Wilhelm Bloch¹, Jens Bans², Philipp Zimmer¹. ¹German Sport University Cologne, Cologne, Germany. ²Kliniken- Valens, Valens, Switzerland.
 (No relevant relationships reported)

Sport and Exercise have been described to promote positive effects on psychosocial symptoms of multiple sclerosis (MS) such as fatigue, depression and anxiety. However, detailed recommendations for intervention programs in the rehabilitation of MS have not been proposed yet.

PURPOSE: The present study aims to compare the influence of high intensity interval (HIIT) on fatigue, depression and anxiety in people with relapsing remitting and secondary progressive MS.

METHODS: Within the framework of a single- blinded randomized controlled trial, 73 patients with MS conducted 3x/week for three weeks either HIIT (5x1.5 minutes at 95-100% of participants' maximal heart rate (HR_{max})) or moderate continuous aerobic exercise (MC) (24 minutes continuous cycling at 65% of HR_{max}) on a bicycle ergometer. Before (t0) and after (t1) the training period, fatigue, depression and anxiety were assessed using the multidimensional fatigue scale for motor and cognitive functions (FSMC) and the Hospital and anxiety scale (HADS). Effects of within (t0 vs. t1) - and between (HIIT vs. MC, relapsing remitting type vs. secondary progressive type) - subjects have been analyzed by baseline- adjusted analysis of variance (ANCOVA).

RESULTS: At the time of allocation, 68 patients were identified to have mild fatigue (sum score ≥ 43) and were included in the analysis of FSMC. ANCOVA revealed significant time effects for the FSMC sum score ($F(1) = 7.188$, $p = .009$). While people with relapsing remitting type of MS improved in both HIIT ($p \leq 0.001$) and MC ($p = .012$), no alterations were observed for people with secondary progressive type of MS. However, neither significant group nor interaction effects were revealed for all FSMC outcomes. Regarding HADS, 38 patients with mild depression or anxiety (HADS-TS ≥ 8) at the time of allocation were analyzed. No significant time, group and interaction effect for any outcome was observed.

CONCLUSION: There are no differences in the impact of HIIT vs. MC on fatigue, depression and anxiety in people with MS. However, people with relapsing remitting MS tend to react more sensible for positive effects of aerobic exercise in general regarding fatigue than people with secondary progressive MS. Nonetheless, results need to be taken with caution, since no main effect for group and MS type was detected.

514 Board #330 May 27 9:30 AM - 11:00 AM
High-intensity Interval Training In Inflammatory Rheumatic Disease Patients: Treatment By Man Or Machine?

Håvard Haglo¹, Eivind Wang¹, Jan Hoff², Jan Helgerud². ¹Molde University College, Molde, Norway. ²Norwegian University of Science and Technology, Trondheim, Norway.
 Email: havard@treningsklinikken.no

Reported Relationships: H. Haglo: Other (please describe); My employer (Myworkout AS) is the developer of the application used in this study.

High-intensity interval training (HIIT) is documented to counteract the reduced maximal oxygen uptake ($\text{VO}_{2\text{max}}$) and poor cardiovascular health associated with inflammatory rheumatic disease (IRS). However, supervised HIIT is resource demanding.

PURPOSE: This study sought to investigate if guidance by a smartphone application (APP: Myworkout GO) could yield similar HIIT-induced effects as supervision by healthcare professionals. **METHODS:** Thirty-four adults (27 females, 50±11 yrs; 7 males, 52±10 yrs), diagnosed with rheumatoid arthritis, spondyloarthritis or systemic lupus erythematosus were randomized to a supervised group (SG) or an APP group (AG). Both groups performed 4x4 minute intervals with an intensity corresponding to 85-95% of HR_{max} twice a week for 10 weeks. Treadmill $\text{VO}_{2\text{max}}$ and health-related quality-of-life (HRQoL), measured using SF-36, was assessed before and after the exercise period. **RESULTS:** $\dot{\text{V}}\text{O}_{2\text{max}}$ increased ($p < 0.001$) in both groups, revealing

3.6±1.4 (SG) and 3.7±1.5 mL·kg⁻¹·min⁻¹ (AG) improvements, with no between-group differences apparent. Improvements in the following HRQoL dimensions; bodily pain, vitality, social functioning and emotional wellbeing were observed for both groups (all p<0.001–0.05). Again, with no between-group differences detected. **CONCLUSION:** HIIT increased $\dot{V}O_{2max}$ and HRQoL, contributing to the patients' reduced cardiovascular disease risk, improved health, performance, and enhanced quality of life. Similar improvements were observed if IRS patients were guided by healthcare professionals or an APP, suggesting that utilization of the APP may be excellent in reducing the costs of HIIT as a treatment strategy in this patient population.

**High-intensity Interval Training Reduces Symptom-
 And Disability-associated Inflammation Marker In
 Persons With Multiple Sclerosis**

Niklas Joisten¹, Jens Banski², Annette Rademacher¹, Sebastian Proschinger¹, Alexander Schenk¹, Wilhelm Bloch¹, Philipp Zimmer¹. ¹German Sport University, Cologne, Germany. ²Clinics of Valens, Valens, Switzerland.

Email: n.joisten@dshs-koeln.de

(No relevant relationships reported)

The inflammation marker neutrophil/lymphocyte ratio (NLR) receives increased attention in various diseases and can be influenced by acute exercise. In persons with multiple sclerosis (PwMS), the NLR is elevated and associated with disability and symptom severity. High-intensity interval training (HIIT) may induce larger benefits in PwMS than moderate continuous training (MCT).

Purpose: To explore acute and chronic effects of HIIT vs. MCT on NLR and cardiorespiratory fitness (chronic only) in PwMS.

Methods: An interim analysis of a randomized controlled trial comparing 3-weeks of HIIT vs. MCT during inpatient rehabilitation was conducted. 60 PwMS (mean age 49.7 yrs, EDSS 3-6) with relapsing remitting (n=38) and secondary progressive (n=22) subtype were included. The HIIT group performed 5×1.5 min intervals at 95–100% of their maximum heart rate (HR_{max}) with active breaks for 2 min in between. The MCT group exercised 24 min continuously at 65% HR_{max}. Both groups exercised 3×/week. An incremental exercise test with spirometry was conducted before and after the intervention. To assess chronic effects on NLR, blood samples were collected before (T₀) the first exercise session and after the intervention period (T₁) during resting conditions. To assess acute effects on NLR, samples were also collected immediately (T₂) and 3 hours (h) (T₃) after the first exercise session. NLR was calculated from blood panels. Baseline-adjusted ANCOVAs with Bonferroni post-hoc test were performed.

Results: Relative $\dot{V}O_{2peak}$ increased in HIIT (mean difference (MD)=2.47 mL·kg⁻¹·min⁻¹, p<.001) and MCT (MD=1.5 mL·kg⁻¹·min⁻¹, p=.004), but no group differences were found. The increase in realtive peak power was larger in HIIT than in MCT (MD=.17 watts·kg⁻¹, p=.031). NLR decreased after the intervention period (T₁) within HIIT only (MD=-.27, p=.01). NLR was greater in HIIT 3 h after the first exercise session (T₃) compared to MCT (MD=1.6, p=.05).

Conclusion: Despite the short intervention period, cardiorespiratory fitness improved in both exercise modalities, whereas HIIT may induce greater enhancements. Only HIIT chronically reduced the NLR, thereby potentially contributing to symptom alleviation in PwMS. This chronic response might be due to repetitive inflammatory states after each HIIT session as reflected by the acute effects.

**High-intensity Interval Training In Older Adults: A
 Scoping Review**

Katie Marriott¹, Andrea Petrella¹, Naron C. Boa Sorte Sliva², Robert J. Petrella, FACSM³. ¹Center for Studies in Family Medicine, Schulich School of Medicine and Dentistry, London, ON, Canada. ²School of Kinesiology, Western University, London, ON, Canada. ³Department of Family Practice and Division of Sports Medicine, University of British Columbia, Vancouver, BC, Canada. (Sponsor: Dr. Robert Petrella, FACSM)

Email: cmarriott2021@meds.uwo.ca

(No relevant relationships reported)

High-intensity interval training (HIT) is an increasingly popular form of aerobic exercise which includes bouts of high-intensity exercise interspersed with periods of rest. The health benefits and risks as well as the optimal design of HIT are still unclear. Further, most of the research on the effects and benefits of HIT has been done in young and middle-aged adults and as such, the tolerability and effects in senior populations is less well-known. **PURPOSE:** To characterize HIT research that has been done in older adults including protocols, feasibility and safety as well as to identify gaps in the current knowledge. **METHODS:** Five databases were searched with variations of the search terms, "high-intensity interval training, high-intensity exercise" and "elderly, older adults." These searches identified 3377 potential studies which were reviewed for inclusion. Studies were included if they were randomized controlled trials published

in English in or after 2009, if the mean age of a treatment group was 65 years or older, and if the exercise protocols being tested were exclusively high-intensity or high-intensity interval training. **RESULTS:** Of 3377 papers identified in the initial search, 86 met the inclusion criteria. The HIT protocols used varied widely and ranged from a single session of HIT to a year-long program. These studies included both healthy and clinical populations. The greatest number of studies examined HIT in healthy subjects, followed by subjects with cardiac or vascular disease (heart failure, coronary artery disease, hypertension), metabolic dysfunction (Type-2 Diabetes Mellitus, obesity), and chronic obstructive pulmonary disease. Sample sizes ranged from 5 to 618 with 90% of studies including less than 70 subjects. The most common primary outcomes identified in the studies included changes in cardiorespiratory fitness as well as feasibility and safety of the protocols in the target populations. **CONCLUSIONS:** With a few exceptions, most studies had small sample sizes and many included non-clinical populations. Larger studies are needed to further evaluate the clinical effects of HIT in older adults. Additionally, there is much variety in the modes of exercise as well as the HIT protocols being used. Despite this, HIT was generally reported to be well-tolerated and safe in older populations.

**Use It Or Lose It: What Happens To Bone When High-
 Intensity Exercise Ceases Or Continues?**

Belinda R. Beck, FACSM¹, Steven L. Watson¹, Benjamin K. Weeks¹, Lisa J. Weis², Kirt Myers¹. ¹Griffith University, Gold Coast campus, Australia. ²The Bone Clinic, Brisbane, Australia.

Email: b.beck@griffith.edu.au

Reported Relationships: **B.R. Beck:** Ownership/interest/stock; Owner & Director, The Bone Clinic, Australia.

The LIFTMOR trial was the first to show a high-intensity resistance and impact training program (HiRIT) was safe and efficacious for improving bone and physical function in postmenopausal women with low to very low bone mass. While results were promising, the long-term efficacy and safety of HiRIT outside an RCT setting was unknown. **PURPOSE:** The primary aim of the current study was to evaluate the effects of continuing or ceasing HiRIT on bone mineral density (BMD) and physical function of LIFTMOR trial participants. **METHODS:** We report a retrospective observational study of LIFTMOR trial participants. Three years after completion of the LIFTMOR trial, participants in the HiRIT arm of the trial underwent a single testing session. Participants were allocated to one of two groups according to either ongoing HiRIT participation (compliance >25%; HiRIT-HiRIT), or cessation of HiRIT (HiRIT-CON) after LIFTMOR. The LIFTMOR testing protocol was employed, including; BMD at the lumbar spine (LS) and femoral neck (FN), back extensor strength (BES), lower extremity strength (LES), functional reach test (FRT), timed up-and-go test (TUG), five times sit-to-stand (FTSTS) and maximal vertical jump (VJ). Data were analysed using repeated measures ANCOVA comparing final LIFTMOR outcomes to 3 year outcomes. **RESULTS:** Twenty-three women (HiRIT-HiRIT, n = 7; 64 ± 4 yr, 159.4 ± 6.5 cm, 67.0 ± 7.2 kg and HiRIT-CON, n = 16; 65 ± 4 yr, 161.8 ± 5.9 cm, 61.9 ± 9.5 kg) participated in follow-up testing 3.2 ± 0.6 yrs post-LIFTMOR. There were no characteristic differences between the follow up sample and the LIFTMOR sample at baseline. Significant ongoing gains in BMD were apparent in HiRIT-HiRIT compared with HiRIT-CON at the LS (8.63 ± 5.29% vs 2.18 ± 5.65%, p = 0.042) and FN (3.67 ± 4.45% vs 2.85 ± 5.79%, p = 0.014), while the HiRIT-CON group maintained BMD benefits from the LIFTMOR intervention. Between-group differences in functional outcomes favoured HiRIT-HiRIT but did not reach significance. No injuries were reported. **CONCLUSION:** Postmenopausal women with low bone mass continuing HiRIT over a 4 year period continued to improve bone mass, while those ceasing HiRIT maintained the gains achieved from 8 months of HiRIT 3 years previously. HiRIT exercise appears to be a highly effective therapy to reduce risk of osteoporotic fracture by improving bone mass.

**Effect Of Continuous Versus High-intensity Interval
 Training In The Management Of Adolescent Overweight**

Antonio Videira-Silva¹, Helena Fonseca². ¹University of Lisboa (Universidade de Lisboa), Lisbon, Portugal. ²Hospital de Santa Maria (University Hospital), Lisbon, Portugal.

Email: antonioascenso@campus.ul.pt

(No relevant relationships reported)

Physical activity (PA) is a widespread strategy for weight management. Yet, the majority of the adolescents with overweight present low levels of PA. PA type and structure may influence not only energy expenditure, but also PA adherence. **PURPOSE:** To analyze: a) the effectiveness of two distinct exercise protocols (continuous- CT versus high intensity interval training- HIIT) on BMI z-score (main outcome) and other anthropometric/clinical outcomes in adolescents with overweight; b) the participants' compliance with both exercise protocols. **METHODS:** Anthropometric and clinical data from 60 adolescents (Control, n=20; CT, n=21; HIIT, n=19) with overweight (BMI ≥ p85 - WHO reference) recruited for the non-

randomized controlled trial PAC-MAN (Clinicaltrials.gov/NCT02941770), were assessed at baseline and at 6 months. Participants in both exercise groups were invited to attend two exercise sessions/week (≈ 60 min/session) during six months on top of a set of appointments with a Pediatrician, Nutritionist and Exercise Physiologist. Control group participants had appointments only with a Pediatrician and Nutritionist. All groups attended three appointments (three months apart). Paired Sample *t*-tests were used to analyze outcomes variation within each group. ANOVA and Independent sample *t*-test were used to analyze differences between groups. **RESULTS:** HIIT was the only group showing a significant decrease in BMI z-score (-0.19 ± 0.23 , $p = .002$) and Waist/Height Ratio (WHtR) (-0.02 ± 0.03 , $p = .018$); and an increase in Fat-and-bone free-mass ($0.8 \pm 1.1\%$, $p = .041$) and $\dot{V}O_2$ max (148.2 ± 122.0 ml/min, $p = .001$) compared to baseline. Compared with Control and CT groups, HIIT group showed a higher decrease in BMI z-score ($d = 1.16$, $p = .004$; $d = 0.72$, $p = .029$) and WHtR ($d = 1.18$, $p = .013$; $d = 0.77$, $p = .019$); and a higher increase in $\dot{V}O_2$ max ($d = 1.47$, $p = .026$; $d = 1.07$, $p = .011$), MPA ($d = 2.10$, $p < .001$; $d = 0.66$, $p = .044$), MVPA ($d = 2.15$, $p < .001$; $d = 0.70$, $p = .031$). Time in MVPA during exercise sessions was also higher in the HIIT group compared to CT ($d = 1.46$, $p = .004$). Attendance of the exercise sessions was significantly higher among the HIIT participants (57.9 vs 38.1%). **CONCLUSION:** Compared to CT, HIIT showed to be associated with better health-related outcomes and higher compliance.

Influence Of High-intensity Training On Quality Of Life And Daily Activity Performance In Multiple Sclerosis

Sebastian Proschinger¹, Jens Bansi², Annette Rademacher¹, Niklas Joisten¹, Alexander Schenk¹, Max Oberste¹, Jan Kool², Wilhelm Bloch¹, Philipp Zimmer¹. ¹German Sport University Cologne, Cologne, Germany. ²Kliniken Valens, Valens, Switzerland.
 Email: s.proschinger@dshs-koeln.de
 (No relevant relationships reported)

Persons with multiple sclerosis (pwMS) report lower health-related quality of life (HRQoL) as compared to general and other chronic disease populations. High-intensity interval training (HIIT) has been shown to improve certain physical and cognitive measures more effectively than moderate training in pwMS. **PURPOSE:** To determine the influence of HIIT vs. moderate training over three weeks on HRQoL and motor/processing performance of activities of daily living (ADL) in pwMS with light-to-moderate disability status. **METHODS:** The intervention group (INT; $n = 36$) cycled at 95-100% of HR_{max} during 5 \times 1.5-min high-intensity intervals, whereas the control group (CON; $n = 36$) cycled for 24 minutes at 65% of HR_{max} . Performance of ADL was quantified by the Assessment of Motor and Processing Skills. Physical and mental HRQoL were assessed using the Patient-Reported Outcome Measurement Information System short form Global-10. Between-subject and within-subject effects (baseline vs. post intervention) were analyzed by ANCOVA (Bonferroni corrected). Baseline measures were used as covariates.

RESULTS: Results are presented as MEAN baseline \pm MEAN change at post. No significant group interaction for either outcome measure was observed. Physical HRQoL improved significantly in both groups (INT: 12.662 ± 1.256 [SE=.290], $p < .0001$; CON: 12.662 ± 0.773 [SE=.290], $p = .01$), whereas mental HRQoL only improved in CON (13.647 ± 1.247 [SE=.336], $p < .001$). Significant improvements in motor (INT: 1.437 ± 0.203 [SE=.075], $p = .009$; CON: $1.437 \pm .210$ [SE=.081], $p = .012$) and processing (INT: 1.111 ± 0.110 [SE=.053], $p = .042$; CON: 1.111 ± 0.145 [SE=.057], $p = .014$) performance of ADL have been observed in both groups.

CONCLUSIONS: Compared to moderate training, HIIT over three weeks does not show superior effects on HRQoL and ADL measures. However, both HIIT and moderate training seem to have profound clinical impact by improving overall HRQoL and performance of ADL in pwMS. Trial registration NCT03652519

High-intensity Interval Versus Moderate-intensity Continuous Heated Water-based Exercise On Cardiovascular Variables In Hypertensive Older Individuals

Isabela R. Marcal¹, Bianca Fernandes¹, Vanessa T. Amaral¹, Fernanda Z. Arthuso¹, Felipe B. Santinelli¹, Raphael M. Abreu², Emmanuel G. Ciolac¹. ¹São Paulo State University (UNESP), Bauru - Sao Paulo, Brazil. ²Federal University of São Carlos (UFSCar), Sao Carlos - Sao Paulo, Brazil.
 Email: isabela.marcal@unesp.br
 (No relevant relationships reported)

PURPOSE: To evaluate acute hemodynamic and autonomic responses to high-intensity interval (HIIT) vs moderate-intensity continuous (MICE) exercise in heated water-based in older hypertensive individuals. **METHODS:** 15 sedentary older hypertensives were randomized in 2:2:1 to HIIT, MICE or without exercise (CON)

sessions. Systolic/diastolic blood pressure (SBP/DBP), pulse wave velocity (PWV), endothelial function (EF) and variability of heart rate (HRV) were assessed before (pre), immediately after (post) and 45 min after intervention (rec). HIIT was consisted of warm-up (4 min), 21 min of 1 min of high-intensity alternating with 2 min of walking at moderate-intensity. MICE was performed by 4 min warm-up followed by 26 min of walking at moderate-intensity. Sessions were controlled using Rating Perceived of Exertion Scale (RPE). Two-way ANOVA (repeated measures) was used to indicate interventions differences and Bonferroni post hoc was used to identify significant differences ($p < 0.05$). **RESULTS:** No significant differences were found for PWV and EF. HRV showed an increase in the μ_{HF} (high frequency band) when compared the moments PRE vs REC within CON group (PRE: 906 ± 132 ms vs REC: 942 ± 148 ms; $p = 0.007$). Moreover, even though POST-HIIT session we found a decrease of $HF_{a,HP}$ (PRE: 413 ± 874 ms² vs POST: 272 ± 716 ms²; $p < 0.001$), during REC only the HIIT group was able to increase the $HF_{a,HP}$ index (POST: 272 ± 716 ms² vs REC: 530 ± 1336 ms²; $p < 0.001$). The changes in $HF_{a,HP}$ during REC was followed by a decreased of LF_{HP} (low frequency band) index after HIIT (POST: 49 ± 24 n.u. vs REC: 33 ± 18 n.u.; $p = 0.013$). None difference was found in pre SBP/DBP ($p > 0.05$). Although in post moment SBP was different between CON (153 ± 4) vs MICE (141 ± 6 , $p < 0.02$) and CON vs HIIT (136 ± 5 , $p < 0.001$), with no difference in DBP. For REC, only CON (131 ± 3) vs HIIT (123 ± 4 , $p < 0.02$), with no difference in CON vs MICE and MICE vs HIIT ($p > 0.05$) were founded. Only HIIT modality was able to return the SBP values to the PRE (122 ± 4 in REC moment (123 ± 4 , $p < 0.66$), but increasing in POST (136 ± 5) moment comparing with PRE ($p < 0.01$) and REC ($p < 0.02$). For DBP, all intensities increase the values in POST ($p < 0.05$) and maintain greater in REC moment comparing with pre ($p < 0.05$). **CONCLUSION:** Water-based HIIT using RPE may be a time-efficient intervention in hypertension treatment of older individuals.

 (No relevant relationships reported)

Establishing an ideal resistance training (RT) protocol for hypertensive individuals has been a challenging task, given the many variables that should be considered in these protocols. In general, the protocols established for hypertensive individuals involve the use of lower loads and a higher number of repetitions. However, recent evidence has shown that this approach might generate negative effects on cardiovascular parameters, especially in the short term, which may indicate a potential risk to participants. In contrast, the use of higher loads but with a reduced number of repetitions does not seem to cause such overload to the cardiovascular system and have been shown to promote comparable gains in variables such as strength, body composition, balance and quality of life. **PURPOSE:** Analyze the effects of different resistance training protocols with lower and higher loads on cardiovascular parameters in hypertensive women. **METHODS:** A randomized crossover design clinical trial was conducted with 20 postmenopausal hypertensive women who underwent a control session and two RT protocols involving 6 and 15 repetition maximum (RM). The cardiovascular variables were collected pre, immediately post, 1 h post, and 24 h post each protocol. Repeated-measures ANOVA was used. **RESULTS:** The HR indices were higher in 15RM protocol immediately and 1 hour after the exercise (86.55 ± 12.81 ; 75.96 ± 11.51) when compared with control (67.14 ± 7.38 ; 66.01 ± 8.88) and 6RM (78.56 ± 9.73 ; 71.29 ± 9.40) sessions ($p < 0.05$). The rate-pressure product indices that represent the myocardial workload also were higher in 15RM protocol immediately (12089.59 ± 3022.77) and persisted in 1 hour after (9947.44 ± 2184.58) the exercise when compared with control (8830.83 ± 1394.09 ; 8800.71 ± 1498.79) and 6RM (11002.58 ± 1986.82 ; 9226.33 ± 1604.68) sessions ($p < 0.05$). **CONCLUSIONS:** Performing high intensity RT with lower loads and a higher number of repetitions seems to promote higher heart rate and rate-pressure product, which may be related to an increased cardiovascular stress. Although the 6RM protocol also raises these parameters immediately after, these changes were not evident within 1 hour and may serve as an indication that the use of high loads may be safe to the cardiovascular system in hypertensive individuals.

Resistance Training And High-intensity Interval Training Improve Cardiometabolic Health In Older Adults: A Meta-analysis

Kelly A. McLeod, Jeanette M. Thom, Matthew D. Jones, Belinda J. Parmenter. *UNSW Sydney, Kensington, Australia.*
Email: k.mcleod@unsw.edu.au
(No relevant relationships reported)

PURPOSE: Older adults have an increased risk of developing cardiometabolic disease including cardiovascular disease and type 2 diabetes. Progressive resistance training (PRT) and high-intensity interval training (HIIT) individually improve cardiometabolic health (CMH) in older adults. However, whether a combination of the two prescriptions provides greater benefit is yet to be explored. We conducted a systematic review and meta-analysis of controlled trials investigating the effect of PRT, HIIT and combination PRT+HIIT (COMB) on CMH in older adults with moderate cardiometabolic risk. **METHODS:** Nine databases were searched from inception until September 2019. We included studies comparing PRT, HIIT or COMB vs usual care that reported ≥ 2 modifiable CMH risk factors. Standardized mean (SMD) and mean differences (MD) were calculated using a random-effects inverse variance model. Heterogeneity and risk of bias were assessed according to Cochrane guidelines. **RESULTS:** We analysed 451 participants from ten studies (7 PRT, n=149, 2 HIIT, n=25, 1 COMB, n=60), 40.6% male with a mean age of 67.7 \pm 1.8 years. Training ranged from 2-4 times per week for 22 \pm 16 weeks. Compared to usual care, exercise significantly improved body mass index (BMI) (MD -0.36 [-0.50, -0.22], $p \leq 0.0001$), body fat % (BF%) (SMD -0.60 [-1.13, -0.06], $p=0.03$), peak aerobic capacity (SMD 0.40 [0.13, 0.68], $p=0.004$), triglycerides (SMD -0.22 [-0.45, 0.00] $p=0.05$) and fasting blood glucose (FBG) (SMD -0.30 [-0.54, -0.05], $p=0.02$). PRT alone significantly improved BMI (MD -0.37 [-0.53, -0.21], $p=0.00001$), BF% (SMD -0.91 [-1.70, -0.13], $p=0.02$) and lean body mass (SMD 0.96 [0.05, 1.87], $p=0.04$). COMB improved triglycerides (SMD -0.44 [-0.79, -0.08], $p=0.02$) and FBG (SMD -0.41 [-0.76, -0.05], $p=0.02$). **CONCLUSIONS:** Exercise improves CMH in older adults, with PRT interventions eliciting significant improvements in body composition. COMB exercise was the only modality to improve triglycerides and blood glucose. Further research is warranted on COMB, HIIT and PRT training, focusing on volume and intensity to investigate differences in effect. More thorough CMH outcome and exercise prescriptive element reporting is warranted in order to identify optimal exercise prescription for improving CMH in older adults.

Postmenopausal Women With Low Bone Mass Enjoy Bone-targeted, High-intensity Resistance Training: LIFTMOR Trial Observations

Benjamin K. Weeks¹, Belinda R. Beck, FACSM¹, Conor Lambert¹, Lisa J. Weis², Amy T. Harding¹, Sean A. Horan¹, Steven L. Watson¹. ¹Griffith University, Gold Coast, Queensland, Australia. ²The Bone Clinic, Brisbane, Queensland, Australia.
(Sponsor: Belinda R Beck, FACSM)
Email: B.Weeks@griffith.edu.au
(No relevant relationships reported)

PURPOSE: The LIFTMOR trial improved bone and function with high-intensity progressive resistance and impact training (HiRIT) in postmenopausal women with low to very low bone mass. While efficacious in a research setting, a comprehensive evaluation of participant perception of HiRIT was required to inform implementation in the 'real world'. Therefore, the aim of the current work was to examine physical activity enjoyment, quality of life (QOL), and participant perception of the HiRIT program undertaken in the LIFTMOR trial. **METHODS:** Postmenopausal women with low bone mass were randomized to either 8 months of 30-minute, twice-weekly supervised HiRIT (n=49) or unsupervised, low-intensity, home-based exercise (CON; n=52). At baseline and follow-up, all participants completed physical activity enjoyment (PACES-8) and QOL (WHOQOL-BREF) questionnaires (Kruskal-Wallis and Friedman's test). At follow-up, 17 HiRIT and 15 CON participants completed an exit survey relating to their experiences, scored using a 5-point Likert scale. Of those, 14 participants from the HiRIT program underwent semi-structured interviews to facilitate qualitative analysis (Leximancer v4.50) of their experiences undertaking the HiRIT program. **RESULTS:** Participants who undertook the HiRIT program reported improvements in PACES-8 (3.3 \pm 1.0 vs -1.6 \pm 0.9, $p < 0.001$), and on the exit survey, HiRIT were happier with their group allocation (4.8 \pm 0.6 vs 4.0 \pm 1.2, $p=0.03$), more enthusiastic about undertaking training sessions (4.4 \pm 0.5 vs 3.7 \pm 1.1, $p=0.03$) and more likely to participate in the LIFTMOR trial again given the chance (3.8 \pm 0.9 vs 2.9 \pm 1.3, $p=0.028$), than CON ($p < 0.05$). Qualitative analysis revealed current bone health status as the most common motivator for enrolling in the LIFTMOR trial, time was an important barrier to previous physical activity participation and supervised group exercise sessions were perceived as positive. All HiRIT participants would recommend the program to a friend. No differences in QOL were observed ($p > 0.05$). **CONCLUSIONS:** Supervised HiRIT was more enjoyable than a low-intensity home

exercise program. The combination of high acceptability and the osteogenic nature of the LIFTMOR program suggests supervised HiRIT is an effective and appealing therapy for postmenopausal women at risk of fracture.

Eccentric Training To Improve/maintain Motor And Speech Function For Persons With Parkinson's Disease

Jeff Bauer, Irena Vincent, Philip Buckenmeyer, Larissa True, Alexander Generali, Olivia Trumino. *SUNY Cortland, Cortland, NY.*
Email: jeff.bauer@cortland.edu
(No relevant relationships reported)

PURPOSE: Parkinson's disease (PD) is a progressive motor disease that is typically characterized by gait, balance, and speech difficulties. This study evaluated the effectiveness of lower body eccentric training on adults with PD. It was hypothesized that completing a 24-session training protocol would maintain or improve balance, gait, and speech variables. **METHODS:** 6 male and 5 female PD volunteers (PDV) (61-78 yrs, \bar{x} = 70 yrs) completed the exercise program. All were clinically diagnosed with PD (.5 - 14 yrs since diagnosis, \bar{x} = 4 yrs) and able to walk/stand without assistance. The PDVs attended 24 biweekly training sessions, which consisted of three 45-second bouts of high-intensity lower body eccentric exercise with a 2-minute rest period between bouts. An exercise machine provided an eccentric quadriceps workout as PDVs stood with both feet on a solid platform that moved along an elliptical path. Pre- and post-exercise SWAY (30-second eyes-closed balance test) and SAW (self-paced 7-meter straight walk, turn around, and return) tasks were completed to record measures of balance and gait. Speech data were recorded at the beginning, in the middle, and at the end of the exercise program. **RESULTS:** SWAY test - Paired samples t-tests showed no significant pre/post (Session 1 to Session 24) differences for the total center of gravity path, coronal, or sagittal path length. SAW test - Paired samples t-tests showed significant pre/post (Session 1 to Session 24) improvement for Right leg cadence (RLC) ($p = .040$), Left leg cadence (LLC) ($p = 0.43$) and Right toe angle (RTA) ($p = .035$). No significant change was observed for Left toe-off angle, Right and Left leg double support time, or Right and Left leg elevation at midswing. Most PDVs produced similar respiratory, speech rate, intonation, and loudness values throughout the study, with a few producing slightly improved values. Sound production precision either remained unchanged or slightly deteriorated towards the end of the protocol. **CONCLUSIONS:** No balance or gait parameters evaluated over the duration of the study indicated a decrease in function in the 11 PDVs. RLC, LLC and RTA did show improvement. Most speech variables remained unchanged. Lower body eccentric training should be considered to maintain gait and balance functions for ambulatory adults with PD.

525 Board #341 May 27 9:30 AM - 11:00 AM

Parkinson's Disease Treatments: Treating Symptoms Through Group Power Movements Or Passive Forced Cycling

Allison Nickel, Miranda Hanson, Ella Borgerding, Max Stockwell, Lauren Johnson, Emalee Smith, Shaina Bodenhofer, Samuel Miller, Joshua Olson, Joshua Waits, Justin Geijer. *Winona State University, Winona, MN.*
(No relevant relationships reported)

Introduction: Parkinson's Disease (PD) is a neurodegenerative disease that affects motor and non-motor function due to a loss of dopamine. There are exercise interventions that have been shown to improve PD symptoms, such as passive forced cycling and group fitness classes. Passive forced cycling is a useful, non-invasive treatment for PD, and has been shown to produce similar effects to common PD medications including improvement in motor function, gait, and quality of life. The Group Fitness-Only (GFO) class is based on large body movements in order to slow the progression of PD symptoms. The purpose of this study was to determine if Forced Cycling paired with a group fitness class or the group fitness class alone was better in the symptomatic treatment of PD. **Methods:** A total of ten participants diagnosed with stage two or three PD were recruited through a local support group and a medical facility. Each participant was randomly assigned to either GFO or group fitness class paired with Forced Cycling (PFC) exercise groups. Regardless of the group, the participants were asked to attend four 60-minute exercise sessions per week for four weeks. Pre and post data were collected using the MiniBESTest and PROMIS-29 survey. **Results:** The GFO group improved their Timed Up and Go test (Pretest: 6.51 \pm 0.80, Posttest: 5.87 \pm 1.03, $p = 0.041$). The time taken to perform the TUG also improved more for the GFO group when compared to the PFC group's posttest data (Pretest: 5.87 \pm 1.03, Posttest: 8.59 \pm 1.74, $p = 0.032$). Dynamic gait sub-score improved posttest in the PFC group compared to the GFO group (Pretest: 7.8 \pm 0.8, Posttest: 9.0 \pm 0.0, $p = 0.033$). Other variables showed improvement but were not statistically significant. **Conclusion:** This pilot study suggests that strength-based group fitness classes are a part of an effective intervention for managing PD symptoms and could

be a possible supplemental treatment option for these individuals. In this study, forced cycling showed improvements in managing symptoms of PD, however, only one variable was statistically significant. Future studies with longer interventions and larger sample sizes may yield more significant improvements than this study.

Group Exercise And Over-speed Cycling Effects On Mental Health In Parkinson's Disease.

Emalee Smith, Josh Waits, Josh Olson, Shaina Bodenhofer, Samuel Miller, Ella Borgerding, Allison Nickel, Miranda Hanson, Lauren Johnson, Max Stockwell, Justin Geijer. *Winona State University, Winona, MN.*
 (No relevant relationships reported)

PURPOSE: Parkinson's Disease (PD) is a neurodegenerative disease that affects motor and non-motor function due to a loss of dopamine. Exercise has been shown to help physical and mental symptoms of PD. Over-speed cycling (OSC) involves cycling at a speed faster than the participant can actively produce. Group fitness classes (GF) for patients with Parkinson's Disease focus on dynamic movements to enhance activities of daily living. Both OSC and GF have been shown to improve PD symptoms, however, previous studies have not examined the effects of these modalities on mental health.

METHODS: Participants (n=8, mean age 73±3) diagnosed with level 2-3 PD were randomly assigned into two groups: 1) GF or 2) GF classes combined with OSC (GFC). GF was completed four times per week for one hour, for four weeks. In GFC, both the GF class and OSC was completed for one hour, two times per week for four weeks. The OSC protocol included a five minute-manual warm up each session, during the last 30 seconds participants cycled maximally. Speed of the cycle during forced exercise was determined by adding 10 RPM to the participant's maximal manual speed. After the speed was determined, participants performed the forced cycling for 55 minutes, and completed the session with a five-minute cool down. A previously validated survey was administered pre and post exercise intervention to determine scores for physical function, mental health, fatigue, sleep, ability to participate in social roles and activities, and pain.

RESULTS: All variables of the survey were recorded observing only one statistically significant change within physical function. There was a significant difference between GF and GFC when participants were asked, after the 4-week protocol, about their ability to go up and down stairs at a normal pace (5.0±0.0 vs. 4.2±0.5, p=0.024). All other variables included in the survey did not yield any significant changes during the 4-week exercise protocol.

CONCLUSIONS: The results of this pilot study suggest that mental health measures show no significant improvements or decrements in group, and between groups, following the completion of the four-week exercise programming. A larger sample size may assist in determining the impact of group fitness and forced cycling on aspects of mental health associated with PD.

Associations Between Physical Function Variables For People With Parkinson'S Disease In An Exercise Program

Amerigo Rossi, Rebecca States, Adam Marcus. *Long Island University Brooklyn, Brooklyn, NY.*
 Email: amerigo.rossi@liu.edu
 (No relevant relationships reported)

Parkinson's disease (PD) is the second-most common neurodegenerative disorder in the United States. Physical activity has been shown to improve physical function in people with PD, however the correlation between many common measures of physical function is still unclear.

PURPOSE: To evaluate the correlation between various measures of physical function among people with PD who exercised regularly.

METHODS: Eighty-three individuals with PD (67 ± 6 years old; 8 ± 6 years since diagnosis; 54% women) were tested at baseline, and every 3 months to 1 year thereafter while participating in a twice-weekly group exercise program. Participants continued in the program for up to 10 years and completed a total of 605 examinations (range: 1-29/participant) during which they were assessed for gait velocity, six-minute walk test, timed up-and-go, single leg balance, Berg Balance Scale, grip strength, 30-second chair stand, and the Motor section of the Unified Parkinson's Disease Rating Scale (UPDRS). A correlation matrix across all 8 variables was calculated using Pearson correlation coefficients with a Bonferroni-adjusted alpha level of 0.002. Correlation strength was defined as strong (abs r > 0.7), moderate (0.7 ≥ abs r > 0.5), and weak (abs r ≤ 0.5).

RESULTS: Mean (± SD) six-minute walk test was 340 ± 188 meters, timed up-and-go was 11.0 ± 4.4 seconds, and gait velocity was 115 ± 24 cm·sec⁻¹. All correlations were significant (p < 0.002). Gait velocity had a strong correlation with the timed up-and-go (r = -0.72), as well as moderate correlations with the six-minute walk test (r = 0.52), Berg Balance Scale (r = 0.52), and 30-second chair stand (r = 0.55). The timed up-and-

go had moderate correlations with 30-second chair stand (r = -0.61), and Berg Balance Scale (r = -0.61). The Berg Balance Scale also had a moderate correlation with the single leg balance test (r = 0.54) and UPDRS (r = -0.60).

CONCLUSION: Gait velocity, timed up-and-go, and the Berg Balance Scale were all correlated with at least three other variables, indicating the greatest breadth of association. Grip strength was the only variable with no moderate or strong correlations. Further research should be conducted to determine whether these correlations change for people with Parkinson's disease following exercise training.

528 Board #344 May 27 9:30 AM - 11:00 AM
Effects Of 24-week Wuqinxi Intervention On Posture Control Ability Of Patients With Parkinson'S Disease

Tian Wang, Guiping Xiao, Kuncheng Jie, Zhenlan Li, Yan Jiang, Zhen Wang, Jie Zhuang. *Shanghai University of Sport, Shanghai, China.*
 (No relevant relationships reported)

PURPOSE: This study was to determine the effects of 24-week's Wuqinxi routine on posture control ability in patients with Parkinson's disease (PD). **METHODS:** A randomized, controlled trial design was used in this study. Forty-six patients (23 women) with stage 1 through 3 Parkinson's on the Hoehn and Yahr staging scale were randomly assigned into a Wuqinxi training group or a stretching group. All participants practiced 60-minute exercise sessions twice weekly for 24 weeks. The NeuroCom Balance Manager System was used to assess Limit of Stability and Unilateral Stance. Limit of Stability (LOS) is a test that evaluates the movement of the center of gravity on a test platform to the farthest boundary that can be achieved. Limit Of Stability was performed to assess posture control ability, along with the standing time of Unilateral Stance and the Unified Parkinson's Disease Rating Scale(UPDRS)III scores before and after the 24-week exercise interventions. Mixed-model (group by time) Repeated measures ANOVAs using SPSS 24.0 were conducted to determine the differences in balance ability between the Qigong and Wuqinxi groups before and after the intervention. Statistical significance was set at p<0.05. **RESULTS:** After 24 weeks of exercise intervention, PD patients in the Wuqinxi group showed a significant increase in forward maximum excursion and endpoint excursion.(Table 1) **CONCLUSIONS:** After 24 weeks of exercise intervention, the posture control ability of patients with Parkinson's disease in the Wuqinxi group was significantly improved and it has already been appeared after the 12th week.

EFFECTS OF A 12-WEEK WUQINXI INTERVENTION ON HAND FUNCTION OF PATIENTS WITH PARKINSON'S DISEASE

Jie Zhuang¹, Tian Wang¹, Guiping Xiao¹, Zhenlan Li¹, Kuncheng Jie¹, Zhen Wang¹, Yan Jiang¹, Yong Gao², Xiangrong Shi³.
¹Shanghai University of Sport, Shanghai, China. ²Boise State University, Boise, ID. ³UNT Health Science Center at Fort Worth, Fort Worth, TX.
 Email: zhuangjiesh@163.com
 (No relevant relationships reported)

PURPOSE: This study was to compare the effects of 12-week's Wuqinxi exercise versus stretching on hand function (including hand dexterity and hand-eye coordination) in patients with idiopathic Parkinson's disease (PD).

METHODS: This study used a randomized, controlled trial design, where 46 patients (23 women) with stage 1 through 3 Parkinson's on the Hoehn and Yahr staging scale were randomly and evenly assigned into a Wuqinxi exercise group or a stretching group. All participants practiced either 60-minute Wuqinxi or stretching exercise sessions twice a week for 12 weeks. The Purdue Pegboard test (PPT) and the Soda Pop test (SPT) were performed to assess hand dexterity (timed speed and flexibility), and hand-eye coordination, respectively, before and after the 12-week exercise intervention. Mixed-model (group by time) repeated measures ANOVAs using SPSS 24.0 were conducted to determine the differences in hand function between the Wuqinxi and stretching groups before and after the intervention. Statistical significance level was set at $p < 0.05$.

RESULTS: After the 12-week's exercise intervention, the post-intervention PPT score performed by both hands was greater ($P = 0.003$) in the Wuqinxi group than the stretching group; whereas the post-intervention SPT scores were significantly increased ($P < 0.01$) for both groups through the intervention, with no group difference being observed ($P = 0.734$). (Table 1)

CONCLUSIONS: The Wuqinxi exercise routine could improve hand dexterity following the 12-week's training in patients with mild-to-moderate PD.

Table 1. Scores of PPT and SPT before vs after 12-week intervention

Items	Wuqinxi (N = 23)			Stretching Group (N=23)			P values from ANOVAs		P value from the test for Δ difference
	Baseline	12-week	Δ (change)	Baseline	12-week	Δ (change)	Group factor	Time factor	
PPT-D	12.26 \pm 2.28	12.87 \pm 2.53	0.61 \pm 1.34*	12.22 \pm 3.72	11.83 \pm 3.74	-0.39 \pm 1.62	0.408	0.868	0.048

Changes In Muscle Power After Usual Care Or Early Structured Exercise Intervention In Acutely Hospitalized Older Adults: A Secondary Analysis Of A Randomized Controlled Trial.

Mikel Izquierdo¹, Mikel L. Sáez de Asteasu¹, Nicolás Martínez-Velilla², Fabricio Zambom-Ferraresi¹, Robinson Ramírez-Vélez¹, Antonio García-Hermoso³, Eduardo L. Cadore⁴, Álvaro Casas-Herrero², Arkaitz Galbete³. ¹Public University of Navarra, Pamplona, Spain. ²Complejo Hospitalario de Navarra (CHN)-Universidad Pública de Navarra, Pamplona, Spain. ³Navarrabiomed-Biomedical Research Centre, IDISNA-Navarra's Health Research Institute, Pamplona, Spain. ⁴Universidade Federal do Rio Grande of Sul, Porto Alegre, Brazil.

(No relevant relationships reported)

PURPOSE: To assess the effects of a multicomponent exercise training intervention on dynamic and isometric maximal muscle strength of lower and upper extremities and muscle power output in acutely hospitalized older adults. **METHODS:** A secondary analysis of a single-blind randomized clinical trial in an acute care for elderly (ACE) unit in a tertiary public hospital in Navarre (Spain). 370 hospitalized patients (aged ≥ 75 years) were randomly allocated to an exercise intervention ($n = 185$) or a usual care ($n = 185$) group. The intervention consisted of a multicomponent exercise-training program performed during 5-7 consecutive days (2 sessions/day). The usual care group received habitual hospital care, which included physical rehabilitation when needed. The main endpoints were change in maximal dynamic strength (i.e., leg-press, chest-press, and knee extension exercises) and maximal isometric knee extensors and hip flexors strength from baseline to discharge. Changes in muscle power output at submaximal and maximal loads were also measured after the intervention period. **RESULTS:** The physical exercise program provided significant benefits over usual care. At discharge, the exercise group showed a mean increase of 19.6 kg (95% confidence interval [CI], 16.0, 23.2; $p < 0.001$) on the one-repetition maximum (1RM) in the leg-press exercise, 5.7 kg (95%CI, 4.7, 6.8; $p < 0.001$) on the 1RM in the chest-press exercise, and 9.4 kg (95%CI, 7.3, 11.5; $p < 0.001$) on the 1RM in the knee extension exercise over usual-care group. There were improvements in the intervention

group also in the isometric maximal knee extension strength (14.8 Newtons (N); 95%CI, 11.2, 18.5 vs. -7.8 N; 95%CI, -11.0, -3.5 in the control group; $p < 0.001$) and the hip flexion strength (13.6 N; 95%CI, 10.7, 16.5 vs. -7.2 N; 95%CI, -10.1, -4.3; $p < 0.001$). Significant benefits were also observed in the exercise group for the muscle power output at submaximal loads (i.e., 30%1RM, 45%1RM, 60%1RM, and 75%1RM; all $p < 0.001$) over usual care group.

CONCLUSIONS: An individualized, multicomponent exercise-training program, with special emphasis on muscle power training, proved to be an effective therapy for improving muscle power output of lower limbs at submaximal loads and maximal muscle strength in very old patients during acute hospitalization.

The Effects Of Power Training Frequency On Functional Performance In Healthy, Older, Untrained Women.

Konstantina Katsoulis, Catherine E. Amara. University of Toronto, Toronto, ON, Canada.

Email: dina.katsoulis@mail.utoronto.ca

(No relevant relationships reported)

Power training (PT) in older adults can improve muscle power and functional performance. The majority of studies have utilized higher intensities for training ($\geq 60\%$ of maximum strength) and have included combined results for older men and women. Less is known about the effects of low-intensity PT on muscle performance and function in older, healthy women. In addition, the dose-response of PT on power and function with 1, 2, or 3 days/week in older adults has not been determined.

PURPOSE: The purpose of this study was to investigate the impact of different weekly frequencies of low-intensity PT on muscle strength, power, and function in healthy, older, untrained women. **METHODS:** Older women ($n = 54$) were randomized to PT 1 ($n = 14$), 2 ($n = 17$), or 3 ($n = 17$) days/week or wait-control, C ($n = 15$). Participants undertook 12 weeks of PT using lower-body resistance training machines at an intensity of 40% of the 1-repetition maximum (1RM), and performed the concentric phase of the exercises 'as fast as possible'. The primary outcome was functional performance (Short Physical Performance Battery, stair climb, 30 second chair stands, and 400-meter walk) and secondary outcomes were strength (leg-press 1RM) and power (knee-extension power at 40% of maximal isometric strength). **RESULTS:** Within-group analyses (pre-post time points) indicated that strength improved in all PT groups ($p < 0.05$) with a 23.7%, 23.3%, 34.8%, and 9.8% increase from baseline for PT1, PT2, PT3 and C, respectively. Pre-post power improved significantly in PT2 and PT3 ($p < 0.05$) by 9.6% and 12.2%, respectively. For pre-post function, all PT groups improved in 3 of 4 functional tests ($p < 0.05$) with improvements ranging from 4.0 - 21.7% and with no differences observed between groups. Although the control group showed small but significant improvement in some aspects of function over the course of the study, effects sizes for all PT groups suggest small to large improvements above that observed in the controls. The large intra-individual variability in the data might have limited statistical power to detect differences between the groups. **CONCLUSIONS:** PT of 2 days/week or more is recommended for improving muscle power, however, 1 session weekly might be sufficient for improving functional performance.

Effectiveness Of Aquatic Exercise On Dynamic Balance In Older Adults: A Systematic Review And Meta-analysis

Youngwook Kim, Michael N Vakula, Eadric Bressel. Utah State University, Logan, UT.

Email: ywkimac@gmail.com

(No relevant relationships reported)

Balance and mobility impairments are the leading causes of falls in older adults. Aquatic-based exercises have been broadly practiced as an alternative to land-based exercises due to several beneficial effects. However, there has been no systematic review with meta-analysis regarding the effects of aquatic exercises on dynamic balance in older adults.

PURPOSE: To compare the effectiveness of aquatic exercises (AE) to land exercises (LE) on dynamic balance in older adults. **METHODS:** Electronic databases (PubMed, MEDLINE, CINAHL, SPORTDiscus, psycINFO), from inception to March 2019, were searched. Studies met the following eligibility criteria: Randomized controlled trials, English language, older adults aged 65 years or older, a minimum of one AE group and one LE group, at least one assessment for dynamic balance. For the meta-analysis, the effect sizes of dynamic balance outcomes were calculated using a weighted mean difference (WMD) or a standardized mean difference (SMD) and a 95% confidence interval (CI). **RESULTS:** A total of 9 trials met the inclusion criteria, and 7 studies including 328 participants (age = 69.6 \pm 6.4yr) were eligible for the meta-analysis. Exercise intervention duration and frequency varied from 4 to 20 weeks, from 2 to 5 sessions per week, from 45 to 60 min per session. The tests most used in the studies were Berg Balance Scale (BBS), Tinetti scale, gait assessment, Functional Reach Test (FRT), Timed Up and Go test (TUG), and Five Times Sit-

to-Stand test (FTSTS). The meta-analysis showed that older adults in AE groups demonstrated comparably enhanced dynamic balance compared with those in LE groups (SMD = 0.38; 95% CI, 0.16-0.60). Subgroup analysis showed that there were no differences in BBS (WMD = 1.66; 95% CI, -0.27-3.59; $P = .09$), FRT (WMD = 2.40; 95% CI, -3.38-8.18; $P = .42$), TUG (WMD = 0.98; 95% CI, -0.08-2.04; $P = .07$), and FTSTS (WMD = 2.05; 95% CI, -0.59-4.70; $P = .13$) between AE and LE groups. **CONCLUSION:** AE may have comparable effects on dynamic balance abilities in older adults aged 65 years or older when compared to LE, which implies that AE may serve as a safe low-impact alternative to LE. Older adults may participate in various physical activities in the safer aquatic environment to improve dynamic balance and possibly reduce the risk of falls.

Weekly Sedentary And Standing Time As Predictors Of Body Composition In Older Adults

Alexis Ortiz, FACS¹, Martha Acosta², Lisa Le², Kalie Pietsch², Juan Robledo². ¹University of The Incarnate Word, San Antonio, TX. ²University of Texas Health, San Antonio, TX.

Email: arortiz5@uiwtx.edu

(No relevant relationships reported)

Sedentary behavior is detrimental to body composition in older adults and a possible predictor for cardiometabolic disease. **PURPOSE:** To validate the correlation between levels of physical activity and body composition in older adults. **METHODS:** Activity levels from five days of accelerometer data of 315 subjects (mean age: 63.47 ± 5.90 years, mean BMI: 27.91 ± 4.54 kg·m⁻²; male: 155; female: 160) were retrieved from the Interactive Diet and Activity Tracking in AARP (iDATA) database from the National Cancer Institute. Subjects were also categorized into three body composition (BMI) subgroups: normal (<18.5-24.9 kg·m⁻²), overweight (25-29.9 kg·m⁻²) and obese (>30 kg·m⁻²). Average time spent (secs) in standing, sitting, lying and number of steps for each subject were measured. Descriptive statistics were performed for the entire sample and all three subcategories. Analysis of variance (ANOVA) between the three groups were performed for weekly steps and time spent standing, sitting, and lying down. An alpha level of .05 was considered statistically significant. A linear regression analysis was performed to explore the association between these variables and body composition for the entire sample. **RESULTS:** ANOVA analysis revealed statistically significant differences for time spent standing and sitting between the normal weight (standing: 26,941 ± 8,163 secs; sitting: 29,954 ± 9,197 secs) group and the overweight (standing: 22,840 ± 7,892 secs; sitting: 33,632 ± 10,630 secs) and obese (standing: 20,836 ± 7,318 secs; sitting: 34,467 ± 10,335 secs) groups. The regression analysis showed a statistically significant association ($r = .31$, $r^2 = .094$; $p < .001$) among steps, standing, sitting, and lying with the greatest contributors to the model being standing time ($p = .008$) and sitting (.042). The greater time standing indicated lower BMI, while greater time sitting contributed to greater BMI. **CONCLUSIONS:** In older adults, greater time spent standing and lower time spent sitting appears to be the greater contributors for desirable body composition. This population of adults should be encouraged to spend more time in standing activities to enhance their health and wellness for a more desired cardiometabolic profile.

The Effect Of Five-years Of Exercise On High-density Lipoprotein Cholesterol In Older Adults

Ida Berglund¹, Elisabeth Vesterbekkmo², Stian Lydersen³, Ulrik Wisløff¹, Stensvold Dorte¹. ¹K.G. Jebsen Center of Exercise in medicine at the Faculty of Medicine and Health Sciences, Norwegian University of Science and Technology, Trondheim, Norway. ²Department of Cardiology, St. Olavs Hospital, Trondheim University Hospital, Trondheim, Norway. ³Regional Center for Child and Youth Mental Health and Child Welfare, Norwegian University of Science and Technology (NTNU), Trondheim, Norway.

Email: ida.j.berglund@ntnu.no

(No relevant relationships reported)

Purpose. Dyslipidemia, is one of the major risk factors for cardiovascular disease (CVD), the leading cause of death in older adults. Aging is associated with an unfavorable change in the lipid-profile. High levels of LDL can be reduced by cholesterol lowering medications, while pharmacological treatment have not proven to be as efficient in increasing HDL as they are at decreasing LDL. Exercise is associated with lower risk of CVD and exercise is a potential approach for obtaining and/or maintaining an optimal lipid profile. However, the effects of exercise on HDL cholesterol in older adults are unclear. It has been suggested that the time-frame needed to achieve a change in lipid-metabolism is longer in older compare to younger adults. The aim of this study was to examine the effect of five-year of exercise on HDL in older adults. **Methods.** A total of 1567 individuals (790 women) were included and randomized to either 5 years of two weekly sessions of high-intensity (HIIT) (10 min warm-up followed by 4x4 min intervals at ~90% of peak heart rate) or

moderate-intensity training (MICT) (50 min of continuous work at ~70% of peak heart rate) or, to a control group (CON) that followed the national recommendations for physical activity. Serum HDL cholesterol was measured immediately using standard procedures at St.Olavs Hospital, Norway. Linear mixed models were used to determine within- and between-group differences over time. **Results.** All groups had a significant reduction in HDL after 5 years, with no between group differences. In the per protocol analysis the reduction was less in HIIT, and significantly higher than CON and MICT (mean difference of 0.05 mmol/L, $p = 0.03$ in both). **Conclusion.** Supervised exercise twice a week was not enough to hinder an unfavorable decline in HDL. However, HIIT resulted in a smaller reduction in HDL in older adults.

Is The Physical Activity Vital Sign Associated With Fall Risk In Older Adults?

Colleen Griffin Hergott, Nathan Massey, Debra A. Beazley, Lori A. Bolgla. Augusta University, Augusta, GA.

(No relevant relationships reported)

PURPOSE: ACSM Exercise Is Medicine (EIM) initiative recommends the use of Physical Activity Vital Signs (PAVS) as an objective measure to assess compliance with the Physical Activity Guidelines for Americans. While physical activity is important for overall health, it may not necessarily improve balance and reduce risk of falls. The purpose of this study is to determine the associations between PAVS and measures of fall risk.

METHODS: 65 seniors (age=81.2±8.0) participated. The PAVS was calculated in accordance with ACSM Exercise Is Medicine. Fall risk was assessed using the Activities-Specific Balance Confidence Scale (ABC), Timed-Up-and-Go (TUG), and BTrackS™ Balance Plate. A less than 68-point ABC score suggested less balance confidence and a fall risk. A greater than 12-second TUG time and greater postural sway on the balance plate (based on BTrackS normative data) suggested a fall risk. Dependent measures were dichotomized as fall risk or no fall risk. Separate point biserial correlations were conducted to determine associations between the PAVS and fall risk category for the ABC, TUG, and postural sway.

RESULTS: No significant associations existed between PAVS and ABC ($r = .23$; $p = .06$), TUG ($r = .20$; $p = .12$), or postural sway ($r = -.01$; $p = .94$).

CONCLUSIONS: Increasing physical activity levels based on the PAVS was not strongly associated with scores from commonly used fall risk assessments. This finding suggests that meeting physical activity guidelines alone may not be sufficient to reduce fall risk. While the PAVS can provide beneficial information regarding other health factors, clinicians should utilize established balance screening tools and incorporate balance exercises into physical activity prescription to reduce fall risk in older adults.

Correlation Between Age, Sarcopenia, And Length Of Stay In Preoperative Cancer Patients

Fabrice A. Voltarelli¹, Roberto Carlos Vieira-Junior, RCVJ¹, Ailton S. Machado, ASM¹, Felipe S. Boa Sorte, FSBS¹, Andrea C. Alves, ACA¹, Sérgio I. Guasque Faria, SIGF², Geovane J. Tolazzi, GJT¹, Haracelli A. Leite da Costa, HALC³. ¹Federal University of Mato Grosso, Cuiabá - MT, Brazil. ²University of Cuiabá, Cuiabá - MT, Brazil. ³Mato Grosso Cancer Hospital, Cuiabá - MT, Brazil.

Email: voltarellifa@gmail.com

(No relevant relationships reported)

PURPOSE: Data from the National Cancer Institute indicate that in Brazil (2018-2019) there should be 1.2 million new cases of cancer, and by 2025 the estimate is a 50% increase in its incidence. In this sense, researches indicate that cancer is associated with metabolic alterations, causing significant changes in body composition, which may promote muscle mass loss and, consequently, sarcopenia. The present study aimed to evaluate the correlation between age, sarcopenia, and length of stay (LS) in preoperative cancer patients (CP).

METHODS: Ninety-six CP of both sexes (53.1 ± 14.1 years old), admitted to the Mato Grosso Cancer Hospital (HCan-MT), Cuiabá, Mato Grosso, Brazil, were enrolled and performed the following evaluations: total body mass (TBM), height, BMI, and calf circumference (CC); answered a sarcopenia questionnaire (SARC-F); LS information was collected from the hospital database. The CP were divided into 2 groups according to the cutoff point of the CC measurement (indicative of sarcopenia;

men: <34 cm; women: <33 cm): non-sarcopenic (NS; 68 - 70.8%); probable sarcopenic (PS; 28 - 29.2%). Data are presented as mean \pm standard deviation and, for comparison between means, the Mann-Whitney test was applied. To verify the correlation between the variables, the Spearman correlation test was used. For all analyses, the p-value was set at 0.05. The analysis was performed using the IBM SPSS version 22.0 program (Ethics Committee Protocol Number: 87449918.5.0000.8124).

RESULTS: NS TBM (kg) (75.0 ± 16.7) was significantly higher ($p < 0.001$) if compared to PS (58.6 ± 9.1); The same occurred in relation to BMI (Kg. [m²]⁻¹) (NS: 28.3 ± 5.6 ; PS: 22.6 ± 2.8 ; $p < 0.001$). Regarding LS (days), there were no significant differences between groups (NS: 3.5 ± 3.5 ; PS: 5.2 ± 5.6 ; $p = 0.386$). There was a positive correlation ($p = 0.05$) (correlation coefficient: $p = 0.200$) between the LS and the score obtained in the SARC-F questionnaire. In addition, there was a significant positive correlation ($p < 0.001$) between the ranks of the LS and age (correlation coefficient: $p = 0.388$).

CONCLUSIONS: Take together, the results denote that sarcopenic CP, especially the elderly, presented a longer length of stay in the postoperative period.

Examination Of The Time Course Effect Of Creatine Supplementation On Acute Doxorubicin-induced Skeletal Muscle Dysfunction

Brandon C. Jones, Raquel B. Busekrus, Salaheddin Sharif, David S. Hydock. *University of Northern Colorado, Greeley, CO.*

Email: brandon.jones@unco.edu

(No relevant relationships reported)

Chemotherapy drugs such as doxorubicin (Dox) may cause skeletal muscle dysfunction, and supplementing the diet with creatine (Cr) could counteract skeletal muscle dysfunction. Very little has been done, however, exploring the time course effects of Cr on Dox-induced skeletal muscle dysfunction. **PURPOSE:** To examine the effects of Cr on skeletal muscle function 1, 3, and 5 days following Dox treatment. **METHODS:** Male rats were randomly assigned to the control group (Con), the doxorubicin group (Dox), the standard Cr diet (2% Cr for 4 weeks) and doxorubicin group (Cr1+Dox), or the Cr loading diet (4% Cr for 1 week followed by 2% Cr 3 weeks) and doxorubicin group (Cr2+Dox). After 4 weeks of feeding, Dox groups received 15 mg/kg Dox and Con received saline. At 1, 3, and 5 days post-injection, grip force and extensor digitorum longus (EDL) forces during a 100 s *ex vivo* fatigue protocol were measured. **RESULTS:** No between group differences in grip force were observed 1 day post injection, but at 3 days, a between group difference in grip force was observed ($p=0.03$) with Dox and Cr1+Dox having lower grip forces than Con (-9.8% and -10.5%, respectively, $p < 0.05$), but this difference was not observed in Cr2+Dox. A between group difference in grip force was also observed at the 5 day time point ($p < 0.0001$) with Dox, Cr1+Dox, and Cr2+Dox having lower grip force than Con (-19.9%, -37.2%, and -19.5%, respectively, $p < 0.05$). With *ex vivo* EDL function, no between group differences were observed 1 day post injection, but at day 3, EDLs from Dox generated less force than Con at the 10 s through 40 s and the 70 s through 100 s time points ($p < 0.05$), but these differences were not observed in Cr1+Dox and Cr2+Dox. At day 5, Cr1+Dox EDLs generated significantly less force than Con at every time point during the 100 s fatigue protocol ($p < 0.05$), and Cr2+Dox EDLs generated significantly less force than Con at the 10 s through 40 s time points ($p < 0.05$). **CONCLUSIONS:** Cr supplementation provided protection against Dox-induced muscle dysfunction 3 days post injection, and this protection was more evident with the Cr loading diet (Cr2). This myoprotection, however, was not observed 5 days post Dox injection suggesting that Cr's benefit may be limited to protecting against the early phases of acute Dox myotoxicity.

Phase Angle Adaptation To Exercise Training In Cancer Patients Undergoing Treatment

Nicholas Harman, Nathaniel Croteau, Reid Hayward. *University of Northern Colorado, University of Northern Colorado Cancer Rehabilitation Institute, Greeley, CO.*

(No relevant relationships reported)

Phase angle is a measure of cellular resistance and reactivity to bioelectrical impedance analysis. This measurement is useful as a marker of cell membrane integrity and is used as a prognostic marker in several clinical populations. Cancer and its related treatments impact cell membrane integrity and lead to poor cell function. Exercise is shown to increase phase angle, which is associated with lowered risk of hospitalization and cardiovascular events. However, the effect of chronic exercise training on phase angle in the cancer population is unclear. **Purpose:** To assess the effect of chronic exercise on phase angle in cancer patients who are actively undergoing chemotherapy and/or radiation. **Methods:** A total of 56 cancer patients who were actively undergoing chemotherapy and/or radiotherapy were recruited to participate in a 12 week exercise-based rehabilitation program at the University of Northern Colorado Cancer Rehabilitation Institute (UNCCRI). Each participant underwent an initial assessment of physiological parameters, including body composition and phase angle analysis

via the InBody 770 (InBody USA, Cerritos, CA). Results of this assessment were used to develop an individualized exercise prescription. Each participant received prescribed, supervised, one-on-one training from a Clinical Cancer Exercise Specialist, three times per week for one hour each session. Each session of exercise consisted of 20 minutes of aerobic training, 30 minutes of balance and resistance training, and 10 minutes of flexibility training at a low to moderate intensity. After 12 weeks, each participant underwent a follow-up assessment of physiological parameters. **Results:** After 12 weeks of exercise training, significant increases in whole body (Initial: 4.55 ± 0.72 , Follow-up: 4.68 ± 0.68 ; $p = 0.02$), right arm (Initial: 4.45 ± 0.76 , Follow-up: 4.57 ± 0.72 ; $p = 0.03$), and left arm (Initial: 4.28 ± 0.79 , Follow-up: 4.39 ± 0.75 ; $p = 0.03$) phase angle was observed. **Conclusion:** This study demonstrates that prescribed exercise training can increase phase angle in cancer survivors even while undergoing chemotherapy and/or radiation treatments. These changes may provide insight into the protective and rehabilitative benefits (e.g., cellular health, membrane integrity, disease risk) that exercise may have in this population.

(Sponsor: Claudio Battaglini, FACSM)

Email: michael.harrison@duke.edu

Reported Relationships: M.R. Harrison: Consulting Fee; Bayer, Janssen. Industry contracted research; Pfizer.

PURPOSE: Exercise training improves regional body composition in localized prostate cancer, but it is unknown if training has similar effects in advanced disease. Goals of this analysis were to determine changes in leg muscle cross-sectional area (CSA) and quality (MQ) values following home-based exercise training during metastatic castration-resistant prostate cancer (mCRPC) and to compare CSA values to healthy controls (CON).

METHODS: Sedentary mCRPC patients undergoing androgen deprivation therapy (ADT) including next generation androgen receptor signaling inhibitors ($n = 17$, age = 71 ± 8 , BMI = $32.0 \text{ kg/m}^2 \pm 6.5$) underwent CSA and MQ analyses using B-mode ultrasound for the vastus lateralis (VL) muscle before and after a 12-week home-based exercise protocol. Age- and BMI-matched CON ($n = 17$, age = 69 ± 2 , BMI = $32.8 \text{ kg/m}^2 \pm 6.5$) completed baseline scans only.

RESULTS: At baseline, VL CSA was lower in mCRPC ($9.12 \text{ cm}^2 \pm 3.15$) relative to CON ($36.55 \text{ cm}^2 \pm 7.04$, $p < 0.001$, $d = 4.95$). For mCRPC patients, the 12-week intervention did not change VL MQ, but increased CSA by 15.2% following the intervention (pre: $8.28 \text{ cm}^2 \pm 2.85$, post: 9.54 ± 3.56 , $p < 0.001$, $d = 0.39$) with no change in MQ.

CONCLUSIONS: Patients undergoing ADT for advanced prostate cancer exhibit lower muscle size compared to CON; however preliminary results suggest that home-based exercise training induces a moderate degree of regional muscle hypertrophy. The finding of regional hypertrophy is consistent with work conducted in patients with localized disease on ADT and may be an important outcome to monitor if increases in muscle CSA translate into improvements in physical function and quality of life. (No relevant relationships reported)

Adverse cardiovascular effects associated with anthracycline chemotherapy (AC) are well established, but the impact on skeletal muscle, and the ability of exercise to attenuate these effects has been poorly characterized. **PURPOSE:** To investigate the effects of structured exercise training during AC on skeletal muscle composition, strength and functional performance in women with early-stage breast cancer (BCa).

METHODS: This is a secondary and preliminary analysis of a 4-month, randomized controlled trial in which 53 women with early-stage BCa scheduled for AC (51 ± 8 years) were randomized to usual care lifestyle advice (UC, n=27) or structured, supervised exercise training (ET, n=26) consisting of moderate intensity aerobic and progressive resistance training (2/week), and high intensity interval training (1/week) during AC. Total body lean mass (LM) and fat mass (FM) (dual-energy x-ray absorptiometry), mid-thigh quadriceps muscle volume and fat-fraction (2-point DIXON MRI), muscle strength (grip strength, 1-repetition max leg press and seated row) and physical function (30 second sit to stand [30STS], 4-metre gait speed test) was assessed prior to commencing AC, and 4-weeks following the final cycle of AC (4-months). Data are presented as mean Δ or mean Δ (95% CI). **RESULTS:** Mean adherence to the exercise training was 78%. Following the intervention, ET resulted in a significant increase in mid-thigh quadriceps muscle volume [ET: +5.9%, (95% CI, 2.8, 9.0) vs UC: 0.9% (-2.2, 4.0), P=0.013] relative to UC, with no effect on fat fraction [ET: -7.9% (-22.2, 6.4) vs +1.4% (-11.9, 14.8), P=0.29]. There was no effect of ET on LM (P=0.77) or FM (P=0.28), however there was a main effect for time, with pooled results for ET and UC showing a significant increase in FM [+4.6% (0.8, 7.5), P=0.032]. Relative to UC, exercise also improved usual and fast gait speed (ET: +9.3% vs UC: -1.8%, P=0.034; ET: +9.8% vs UC: +0.6%, P=0.018 respectively), 30STS (ET: +19.4% vs UC: -0.6%, P<0.001) and upper (ET: +11.7% vs UC: -4.6%) and lower-body (ET: +14.7% vs UC: -5.2%) dynamic muscle strength (P=0.002 for both). **CONCLUSIONS:** Completing structured, multi-modal exercise training is an effective therapy for improving muscle strength, physical function and thigh muscle volume among breast cancer patients undergoing AC.

Antioxidant Supplementation Improves Neuromuscular Adaptations Induced By Strength Training In Breast Cancer Survivors

Filipe Dinato de Lima¹, Claudio L. Battaglini, FACSM², Sandro Nobre Chaves³, Lucas Ugliara³, Jonathan Sarandy³, Martim Bottaro³. ¹University Center of Brasilia - UniCEUB, Brasilia, Brazil. ²University of North Carolina at Chapel Hill, Chapel Hill, NC. ³University of Brasilia, Brasilia, Brazil.
 Email: fdinatolima@gmail.com
 (No relevant relationships reported)

Strength training (ST) and antioxidant supplementation have been used to reverse oxidative stress and muscle loss. However, in healthy subjects, the combination of ST and antioxidant supplementations hamper neuromuscular adaptations. Studies investigating the use of dietary supplementation aimed to improve adaptations to exercise training in cancer survivors are scarce. Thus, there is a need to investigate the chronic effects of ST combined with antioxidant vitamins in breast cancer survivors. **PURPOSE:** To assess the effect of antioxidant supplementation on neuromuscular adaptations induced by ST in breast cancer survivors.

METHODS: Twenty-five breast cancer survivors were enrolled in this double-blinded placebo-controlled study. Survivors were randomly assigned to one of two groups: Antioxidant (AG; n = 12; 51 ± 9.03 years; 68.08 ± 10.57kg; 1.61 ± 0.07m) or Placebo (PG; n = 13; 48.23 ± 8.34 years; 70.45 ± 9.92kg; 1.58 ± 0.05m). Both groups participated in a 10-week ST protocol with six different exercises, twice a week. AG supplemented vitamins C (500mg/day) and E (400IU/day), and PG with polydextrose (1g/day). At the beginning and at the end of training period, muscle thickness of knee extensors (MT) was measured using B-mode ultrasound. Knee extension isokinetic peak torque (PT) was measured by two sets of four maximal isokinetic knee extension at 60°/s¹. Work capacity (WC) was measured by the amount of work performed in one set of 30 maximal isokinetic knee extensions at 120°/s¹. A two-way mixed model ANOVA was used to analyze data.

RESULTS: PT increased similarly in both AG (120.54 ± 17.85 to 133.53 ± 18.91 N.m; p < 0.001) and PG (120.56 ± 23.41 to 131.95 ± 26.57 N.m; p < 0.001). WC also increased in both AG (1805.25 ± 355.25 to 2210.34 ± 344.24 J; p < 0.001) and PG (1945.65 ± 294.87 to 2187.85 ± 396.90 J; p < 0.001). However, greater increase in WC was observed in AG than in PG (F = 5.030; p = 0.035; Δ = 22.44% vs. 12.45%). MT increased in AG (31.05 ± 6.05 to 35.86 ± 5.96mm; p < 0.001) but not in PG (31.83 ± 4.86 to 33.45 ± 6.04 mm; p = 0.105).

CONCLUSIONS: Antioxidant supplementation appears to affect strength gains induced by ST similarly between AG and PG groups. However, antioxidant supplementation appears to improve muscle work capacity and the promotion of muscle hypertrophy when compared to placebo in breast cancer survivors.

 (No relevant relationships reported)

Self-monitoring is associated with successful health behavior change and improvements in relevant fitness outcomes accompanying lifestyle interventions. Although exercise consistently results in meaningful improvements in muscular strength and physical function among prostate cancer patients (PCa) undergoing androgen deprivation therapy (ADT), the extent to which exercise-related self-monitoring is linked with improvements in clinically relevant outcomes among PCa patients remains unclear. **PURPOSE:** The purpose of the single-blind, randomized controlled Individualized Diet and Exercise Adherence-Pilot (IDEA-P) trial is to evaluate the preliminary efficacy of a combined exercise and dietary (EX+D) intervention, implementing a group-mediated cognitive behavioral (GMCB) approach, relative to standard of care (SC) treatment among PCa patients undergoing ADT. In the current study, we conducted an exploratory analysis to evaluate the relationship between exercise-related self-monitoring in the EX+D intervention and change in muscular strength at 3-months post intervention. **METHODS:** A total of 32 PCa patients (M age = 65 years) on ADT were randomly assigned to the EX+D (n = 16) or SC (n = 16) interventions. Measures of 1RM chest and leg extension strength were obtained at baseline and 3-month follow-up assessments. **RESULTS:** Results from a linear regression analysis revealed that frequency of self-monitoring was not significantly associated with increased 1RM chest strength ($b = 0.52$; $SE_b = 0.551$; $r^2 = .083$; $p = 0.364$) or 1RM leg extension strength ($b = 0.234$; $SE_b = 0.716$; $r^2 = .083$; $p = 0.751$). **CONCLUSION:** Findings suggest that exercise-related self-monitoring was not significantly associated with change in upper or lower body muscular strength observed following the EX+D intervention in the IDEA-P trial. Given the importance of exercise and preservation of muscular strength for PCa patients undergoing ADT, exploring the role of exercise-related self-monitoring in future optimally-power lifestyle intervention trials is warranted.

Effect Of Different Rating Of Perceived Exertions On The Muscle Strength In Breast Cancer Survivors

Wanderson Santos, Gabriel Siqueira, Vitor Marques, Thalles Guillarducci Costa, Claudio Lira, Carlos Vieira. Federal University of Goias, Goiânia, Brazil.
 Email: wanderson.nilo@gmail.com
 (No relevant relationships reported)

PURPOSE: To evaluate the effect of resistance training (RT) with a higher rating of perceived exertion (RPE) and lower RPE on the muscle strength of upper limbs in breast cancer survivors (BCS).

METHODS: Twenty-six BCS women (age: 56.07 ± 6.94 years old; body mass: 68.32 ± 11.16 kg) undergoing hormonal therapy, performed eight weeks of RT once a week with high supervision ratio (one trainer per volunteer). RT protocol was three sets of 8 to 12 repetitions, with a 2-min rest interval between sets, until volitional muscle failure, on the bench press (BP). RPE scale (0-10) was assessed after each set. After eight weeks, the BCS were categorized into two groups using the average of RPE, lower than 7 (< 7) and higher than 7 (≥ 7). The muscle strength was assessed by the 10-repetitions maximum (10-RM) test on the BP, and then normalized by body mass (kg/BM). A repeated measurement ANOVA with the Bonferroni post hoc tests was used to examine differences between muscle strength changes.

RESULTS: After eight weeks of RT, 12 women reported RPE < 7 (6.12 ± 0.56) and 14 women reported RPE ≥ 7 (7.78 ± 0.49). There was no difference found at baseline (p = 0.23): 10-RM normalized was 0.27 ± 0.06 and 0.24 ± 0.05, for RPE < 7 and RPE ≥ 7, respectively. BCS who reported lower or higher RPE improved their 10-RM by Δ 19 ± 12 % and Δ 23% ± 14% (p < 0.0001), respectively, and no difference was found between groups (p = 0.30). **CONCLUSIONS:** The improvement in muscle strength of BCS seems is not related to higher or lower RPE, both levels of effort generated similar gains. Suggesting that RPE is not the main factor for improving muscle strength in this population. Further studies analyzing the differences between upper and lower RPE in upper muscle strength are needed.

(No relevant relationships reported)

PURPOSE: Previous work showed that cancer patients with spinal metastases classified as stable (i.e. with low fracture risk) benefit from isometric exercises for the paravertebral muscles concomitant to palliative radiotherapy in terms of bone density and pain. In this exploratory randomized controlled trial we investigated whether paravertebral muscle training is safe and feasible also in patients with spinal metastases classified as unstable (i.e. with high fracture risk).

METHODS: Sixty cancer patients with unstable spinal metastases (Taneichi score $\geq D$) were randomized to an intervention group (INT, n=27 starters) or a control group (CON, n=29 starters). INT received 15 min of 1:1-supervised isometric exercises ("all fours", "plank", "swimmer", and a standing exercise with an elastic band) daily on 10 \pm 2 days of radiotherapy and continued home-based on 3 days/week for 3 months. CON received muscle relaxation. Adverse events and adherence (primary endpoints), strength, pain and quality of life (secondary endpoints) were assessed.

RESULTS: In 41% of patients, exercises were modified because of pain or immobility. There were no training-related adverse events. During radiotherapy, 67% of patients in INT and 55% of patients in CON attended $\geq 80\%$ of the planned training sessions. During home-based training, 64% of patients in INT performed $\geq 80\%$ of the planned training sessions. Plank position holding time (strength) increased by 24 \pm 28 s in INT and dropped by 2 \pm 34 s in CON by the end of radiotherapy (p=0.01). There were no differences between groups for pain or quality of life (p>0.05).

CONCLUSIONS: The described or individually modified isometric exercises for the paravertebral muscles are safe and in about 2/3 of cancer patients with unstable spinal metastases feasible when introduced 1:1 and continued home-based. To investigate potential benefits, larger studies powered for patient reported outcomes and clinical endpoints are needed.

(No relevant relationships reported)

INTRODUCTION: There are gaps in our knowledge about differences in arterial stiffness (AS) and cardiorespiratory fitness (CRF) in adults with and without Down syndrome (DS).

PURPOSE: To describe and compare AS and CRF in adults with DS versus adults without DS.

METHODS: Fourteen adults with DS (27±5 yrs) and 14 adults without DS (27±5 yrs) participated in this study. An informed consent and a health screening questionnaire was completed by each participant and/or legal guardian. After familiarization, participants rested lying for 5-10 minutes before the measurements were taken. Brachial and central systolic and diastolic blood pressure (BSP; BDP; CSP; CDP), central augmented pressure (AP), augmentation index (AIx), AIx normalized at 75 beats/min (AIx@75) and AS (carotid-femoral pulse wave velocity (cfPWV)) were measured by using the SphygmoCor Xcel device (SphygmoCor XCEL, AtCor Medical). To assess the CRF, all participants performed a maximal treadmill test. Respiratory gas-exchange was measured breath-by-breath with an automatic gas analysis system (Metasys TR-plus, Brainware SA, La Valette, France).

RESULTS: Non-DS participants were taller and had a lower BMI than the DS group (all $p < .05$). The CRF of the DS group was lower than the non-DS group (VO_2 peak = 29.4±6.3 vs. 51.5±11.3 ml/kg/min; $p < .001$). Non-significant differences were found for BSP/BDP (DS = 116.31 ± 10.9/68.4 ± 9.3 vs. Non-DS = 123.43 ± 8.8/71.6 ± 6.6 mmHg; all $p > .050$); CSP/CDP (DS = 103.6 ± 8.5/61.1 ± 9.3 vs. Non-DS = 107.0 ± 7.6/71.6 ± 6.6 mmHg; all $p > .050$) and cfPWV (DS = 5.5 ± .6 vs. Non-DS = 5.8 ± .7 m/sec; $p = .191$). The AP (DS = 6.4 ± 2.7 vs. Non-DS = 1.8 ± 3.2 mmHg; $p = .002$); AIx (DS = 18.1 ± 6.3 vs. Non-DS = 4.9 ± 10.3; $p = .001$) and the AIx@75 (DS = 12.3 ± 8.8 vs. Non-DS = -1.6 ± 11.7; $p = .002$) were significantly higher in the DS group.

CONCLUSIONS: Despite having lower CRF and higher BMI, adults with DS presented similar values of central and peripheral blood pressure than the Non-DS group. Nevertheless, the DS group showed higher AP, AIx and AIx@75 values, which may be due to a higher aortic wave reflection and arterial stiffness. **Partially supported by:** MINECO (DEP2017-86862-C2-1-R) & FPCEE Blanquerna (APR- FPCEE19/20).

Evaluation Of 3D Body Imaging To Estimate Percentage Body Fat In Older Adults

James E. Stampley¹, Samantha Kennedy², Matthew C. Scott¹, Brett Davis¹, Heather Quiariarte¹, Neil Johannsen¹, Steven B. Heymsfield², Frank Greenway², Guillaume Spielmann¹, Brian A. Irving, FACSM¹. ¹Louisiana State University, Baton Rouge, LA. ²Pennington Biomedical Research Center, Baton Rouge, LA.
 Email: jstamp5@lsu.edu

(No relevant relationships reported)

Aging is often associated with adverse changes in body composition that contribute to the development of age-related cardiometabolic and geriatric disorders. Although Dual Energy X-ray Absorptiometry (DXA) remains the gold-standard for assessing body composition, 3D body imaging is emerging as cost-effective, noninvasive, user-friendly alternative. However, the validity of 3D body imaging to assess percentage body fat in older adults is unknown.

PURPOSE: This study examined the association between percentage body fat estimated by 3D body imaging vs. DXA (criterion) in inactive older adults.

METHODS: The present analyses included data from 17 (12F, 5M and 13 White, 4 Black) older (X±SD; 71±4) adults that were participating in an ongoing exercise

intervention (REALPA). Participants completed a DXA using a Hologic Horizon A and 3D body imaging using a Fit3D to estimate whole-body percentage fat. Paired t-test were performed to assess mean differences between the two methodologies. Linear regression models were used to determine the association between the two methodologies. Finally, Bland-Altman plots were used to assess level of agreement between the two methodologies.

RESULTS: The mean percentage body fat measured by Fit3D was significantly lower than DXA (34±6% vs. 38±8%, $p < 0.01$). There was a strong positive correlation between the percentages body fat measured by the Fit3D and DXA methods ($r = 0.72$, $P = 0.001$). The mean difference (limits of agreement) between the Fit3D vs. DXA for percentage body fat was -3.8% (-14.5%, 6.7%). Finally, the Bland-Altman analysis revealed that the Fit3D over estimates percentage fat at lower percentages and under estimates percentage fat at high percentages.

CONCLUSION: Although the percentage body fat measured by the Fit3D was highly correlated with those measured by DXA (criterion), the Fit3D tended to produce lower percentage body fats than the DXA. The presence of measurement bias also suggests that the Fit3D measurements may not be interchangeable with those obtained from DXA in older adults. Future research is necessary to optimize the validity of the Fit3D to estimates of percentage body fat in older adults.

This study was supported by the NIH 5R21AG058181-02.

Relative Intensity-associated Cadence (steps/min) Thresholds In 61-85 Year Olds, The Cadence-adults Study

Cayla McAvoy¹, Christopher Moore², Elroy Aguiar³, Marcos Amalbert-Birriel⁴, Tiago Barreira⁵, Stuart Chipkin⁴, Scott Ducharme⁶, Zachary Gould⁴, Colleen Chase⁴, John Schuna, Jr.⁷, John Staudenmayer⁴, Catrine Tudor-Locke, FACSM¹. ¹University of North Carolina - Charlotte, Charlotte, NC. ²University of North Carolina, Chapel Hill, NC. ³University of Alabama, Tuscaloosa, AL. ⁴University of Massachusetts - Amherst, Amherst, MA. ⁵Syracuse University, Syracuse, NY. ⁶California State University Long Beach, Long Beach, CA. ⁷Oregon State University, Corvallis, OR. (Sponsor: Catrine Tudor-Locke, FACSM)

Email: cmcavoy1@uncc.edu

(No relevant relationships reported)

A cadence of 100 steps/min has been associated with absolutely-defined moderate intensity (3 metabolic equivalents [METs; where 1 MET = 3.5 mL O₂/kg]) in young and middle-aged adults. However, less is known about how cadence corresponds with relative intensity indicators, especially in older adults. **PURPOSE:** To investigate cadence thresholds associated with the lower thresholds of relatively-defined indicators of moderate intensity provided in the 2011 ACSM Position Stand (i.e., 40-59% of heart rate reserve [%HRR], 64-76% of maximum heart rate [%HRmax], and a Borg scale rating of perceived exertion [RPE] of 12-13) in healthy older adults. **METHODS:** Ninety-eight older adults (mean [SD]; age = 72.6 [7.0] years, BMI = 25.9 [3.5] kg/m²) completed a progressive treadmill walking protocol consisting of 5-minute bouts separated by 2-min rests increasing from 0.5 to 6.0 mph in 0.5 mph increments. The protocol concluded following the bout during which the participants naturally selected to jog or run, reached 75% age-predicted HRmax, or reported a Borg scale RPE >13. Cadence was calculated by dividing directly observed step counts by bout duration (5 min). Heart rate (HR) was measured using a chest-worn Polar HR monitor, and HR was averaged over the final 2-min of each bout. HRmax was estimated using the standard equation of 220 - age. Intensity indicators were analyzed using Receiver Operating Characteristic (ROC) curves and optimal cadence thresholds associated with moderate intensity were determined using Youden's Index. **RESULTS:** The cadence threshold associated with 40% HRR was 103 steps/min (sensitivity = 78%, specificity = 75%, area under the ROC curve [AUC] = 0.83), and that associated with 64% HRmax was 104 step/min (sensitivity = 66%, specificity = 75%, AUC = 0.77). Additionally, an RPE ≥12 was associated with a cadence threshold of 101 steps/min (sensitivity = 63%, specificity = 73%, AUC = 0.79). **CONCLUSION:** Cadence thresholds of 100 - 104 steps/min were associated with relative indicators of moderate intensity in ostensibly healthy older adults. These results are consistent with the commonly reported heuristic (i.e., practical, rounded, evidence-based) threshold of 100 steps/min associated with absolutely-defined moderate intensity walking in healthy adults.

Relationship Between Fitness Age And Face Age Amongst An Older Adult Population
 MaryBlake Williams. *University of North Carolina Wilmington, Wilmington, NC.* (Sponsor: Athanasios Jamurtas, FACSM)
 Email: maryblake.williams@gmail.com
(No relevant relationships reported)

PURPOSE: To determine the relationship between Fitness Age and Face Age amongst a sample of older adults. **METHODS:** Sixty participants (38 females; 22 males; Age = 82.7 ± 5.7 yrs; Height = 163.3 ± 8.3 cm; Body Mass = 72.4 ± 15.0 kg; Body Fat = 34.2% ± 8.9%) participated in the five-part fitness assessment to obtain a Fitness Age (FITA). Face Age (FACEA) was derived from a single high-resolution digital photograph using a proprietary algorithm based on machine learning to derive a perceived age in years from the face. Pearson product-moment correlation coefficient was used to assess the relationships between FITA and FACEA. **RESULTS:** Data revealed no significant correlation between FITA and FACEA for males ($r = .418, p = .053$). There was a significant positive correlation between FITA and FACEA for females ($r = .531, p = .001$). **CONCLUSIONS:** There was no relationship between FITA and FACEA amongst the male participants. Female participants, however, who had poorer fitness levels (higher FITA) subsequently appeared facially older (higher FACEA) when compared to their chronological age. Despite these mixed findings, more research is deemed necessary in this nascent field of research.

Preliminary Investigations Into Muscle Recovery Following Exercise-induced Muscle Damage Between Younger And Older Males
 Yvoni Kyriakidou, Carly Wood, Isabella Cooper, Evangeline Tanner, Bradley Elliott. *University of Westminster, London, United Kingdom.*
 Email: y.kyriakidou@westminster.ac.uk
(No relevant relationships reported)

Unaccustomed resistance exercise is associated with reductions in muscle force output, avoidance of repeated loading, pain and an inflammatory response. Whilst well defined in the literature in healthy younger populations, research into older individuals is lacking. **PURPOSE:** Examine muscle function, recovery and inflammatory response following an unaccustomed exercise-induced muscle damage protocol (EIMD) in younger and older males. **METHODS:** Healthy younger ($n = 7, 27.3 \pm 3.5$ years) and older ($n = 5, 62.6 \pm 2.1$ years) males provided written informed consent, performed a unilateral eccentric exercise protocol (7 sets of 10 repetitions, leg press machine). Venous plasma was collected for creatine kinase (CK), tumour necrosis factor (TNF)- α and interleukin (IL)-6 prior to EIMD, immediately after EIMD, and at 1, 2, 24, 48, and 72 hours post-EIMD. Maximal voluntary isometric contraction (MVIC), peak power and perceived muscle soreness were assessed at all time points except 1 and 2 hours post-EIMD. **RESULTS:** Significant difference in CK was found between younger and older group at 72 hours post-EIMD ($p = 0.042$), with older showing a greater increase in CK (pre- vs 72h post-EIMD) compared to the younger group (165.7% vs 107.3%, respectively). Post EIMD, older group TNF- α concentrations were significantly increased relative to pre-EIMD in comparison to the younger group ($p = 0.042$). IL-6 did not differ between younger and older groups at any time point (each $p < 0.05$). A significant main effect for time was observed for MVIC ($p = 0.005$), with both groups showing a reduction in leg strength immediately post-EIMD. The main effect comparing the two groups MVIC was also significant ($p = 0.005$). The younger group had significantly higher power output than the older group ($p = 0.001$). No difference in perceived muscle soreness was observed at any time point. **CONCLUSIONS:** The older group had greater change in muscle damage and inflammatory response following EIMD, suggesting a blunted resolution relative to the younger group. As older individuals respond to EIMD in a different manner than younger people, prior research into recovery from EIMD in younger, primarily athletic populations, cannot be extrapolated into older populations.

(No relevant relationships reported)

Purpose In order to establish standards for cardiorespiratory fitness (CRF; peak $\dot{V}O_2$), peak heart rate (HR) and peak oxygen pulse (O_2 -pulse, a surrogate for stroke volume), we collated percentile data from maximal exercise testing from a sample of sedentary, overweight and obese adults in North Carolina. A second objective was to describe the relative role of declines in peak HR and peak O_2 -pulse in the overall decline in CRF that occurs from ages 45-69 years. **Methods** A total of 669 sedentary adults, ages 45-69, with BMI 25-35 kg/m² from the three STRRIDE clinical trial cohorts were included in the analysis. All three cohorts used the same graded maximal treadmill test. Peak $\dot{V}O_2$ was determined by the greatest two consecutive 15-sec collection periods. O_2 -pulse was calculated as: peak $\dot{V}O_2$ (mL/min) / peak HR (beats per min). Only subject's data with peak RER ≥ 1.00 were included in the registry. Sex-specific percentile data for each half-decade of age are shown in **Table 1** (only $\dot{V}O_2$ Peak data shown below) **Results** When assessing trends across the 25 year age range, we observed a 20.6%, 14.3% and 11.6% decrement in peak $\dot{V}O_2$ (mL/kg/min), peak HR and peak O_2 -pulse from the youngest to oldest women. In men, the magnitude of these trends across 25 years was slightly less, with 15.1%, 12.6% and 7.2% decrements in peak $\dot{V}O_2$ (mL/kg/min), peak HR and peak O_2 -pulse. In both women and men, the age-dependent decrements in peak HR were greater than the decrements in peak O_2 -pulse. The trend for decrement in the weight-independent absolute peak $\dot{V}O_2$ (L/min) was 24.1% in women and 19.7% in men across the 25-year period. **Conclusion** This CRF registry represents sedentary, overweight or obese adults in North Carolina. As a majority of Americans are sedentary and have an elevated BMI, these data are also likely representative of the U.S. population. Further, these data suggest that the age-dependent decrements in peak HR play a greater role than the loss of stroke volume in the decrease of CRF with age.

Table 1. STRRIDE Cardiorespiratory Fitness Data Registry by Percentiles of Peak $\dot{V}O_2$

Percentiles	10	25	50	75	90
Women Age 45 – 49.9 (N=58)	17.9	19.8	23.6	25.8	27.9
Women Age 50 – 54.9 (N=91)	18.9	20.9	22.5	25.4	27.1
Women Age 55 – 59.9 (N=84)	18.0	20.5	23.0	25.6	27.8
Women Age 60 – 64.9 (N=60)	15.8	18.1	21.0	22.7	24.4
Women Age 65 – 69.9 (N=40)	15.0	16.7	18.8	20.1	21.7
Men Age 45 – 49.9 (N=50)	22.9	27.6	31.0	33.3	37.1
Men Age 50 – 54.9 (N=67)	21.2	24.7	28.6	31.8	36.3
Men Age 55 – 59.9 (N=60)	20.7	24.0	27.3	30.6	33.5
Men Age 60 – 64.9 (N=68)	19.9	23.8	26.1	29.4	31.2
Men Age 65 – 69.9 (N=48)	19.6	22.9	26.2	29.4	30.5

Does Carbohydrate Mouth Rinsing Affect Six Minute Walk Test And Blood Glucose Responses In Older Adults?
 Elizabeth S. Evans¹, Joshua Boyle¹, Matthew R. Braswell¹, Terrence Brophy¹, G Keith Harris², Ruth H. Watkins², Stephen P. Bailey, FACSM¹. *¹Elon University, Elon, NC. ²North Carolina State University, Raleigh, NC.* (Sponsor: Stephen P. Bailey, PT, PhD, FACSM)
 Email: bevans12@elon.edu
(No relevant relationships reported)

Carbohydrate mouth rinsing (MR) prior to exercise can improve performance in endurance and power activities in young physically active populations. Carbohydrate MR may also improve impulse and power during the sit-to-stand maneuver in healthy older adults; however, its effect on functional aerobic endurance and underlying physiological mechanisms are not well established. **PURPOSE:** To determine if carbohydrate MR affects six-minute walk test (6MWT) distance and blood glucose responses in healthy older adults. **METHODS:** 26 participants (12 males, 14 females) age ≥ 70 years completed the 6MWT during two testing sessions under two MR conditions: a 6.4% maltodextrin (MDX) condition and a placebo (PLAC) condition. Participants and researchers were blinded to MR contents, and MR administration was counter-balanced. Prior to testing, participants refrained from food and drink (except water) for 4 hours, as well as exercise, caffeine, and alcohol for 12 hours. Testing

sessions occurred at the same time of day, separated by at least 48 hours. Participants held the MR in their mouth for 20 seconds, returned it to a vial, and immediately completed the 6MWT. Total distance walked and rating of perceived exertion (RPE) during the 6MWT were compared between MR conditions using paired sample t-tests. Blood glucose and lactate levels were compared pre- and post-6MWT and between MR conditions using 2x2 repeated measures ANOVAs. **RESULTS:** Total distance walked and RPE were similar between MR conditions (481 ± 79 m vs. 485 ± 70 m, $p = 0.33$ and 11 ± 3 vs. 11 ± 3 , $p = 0.62$). Blood glucose did not significantly differ according to MR condition or time (100 ± 16 mg/dL and 102 ± 17 mg/dL for the MDX condition pre- and post-6MWT; 105 ± 26 mg/dL and 104 ± 26 mg/dL for the PLAC condition pre- and post-6MWT, $p = 0.16$ - 0.49). Blood lactate significantly increased pre- to post-6MWT, but did not significantly differ according to MR condition (1.4 ± 0.5 mmol/L and 2.7 ± 0.9 mmol/L for the MDX condition pre- and post-6MWT; 1.4 ± 0.4 mmol/L and 2.6 ± 1.1 mmol/L for the PLAC condition pre- and post-6MWT; $p < 0.01$ - $p = 0.99$). **CONCLUSION:** Carbohydrate MR may not significantly impact functional aerobic performance in older adults. Continued research into the clinical relevance of pre-exercise MR in older adults, including the use of other variations of gustatory stimuli, is warranted.

Differences In Left Ventricular Twist In Elite Short And Long Distance Swimmers

Katharine D. Currie¹, Jonathan A. Hamil¹, Alexandra M. Coates², Christian P. Cheung², Trevor J. King², Margo M. Mountjoy, FACSM², Jamie F. Burr². ¹Michigan State University, East Lansing, MI. ²University of Guelph, Guelph, ON, Canada. Email: curriek4@msu.edu

(No relevant relationships reported)

Exercise-induced cardiac remodeling is influenced by sport-specific exercise characteristics, such as the isometric and isotonic components of the activity. Differences in cardiac dimensions and left ventricular (LV) systolic and diastolic function have been observed between short- (SS) and long-distance (LS) swimmers. Intensity and duration specific adaptations in LV mechanics may help to explain these differences in global function. **PURPOSE:** To examine whether there are event-specific differences in LV twisting mechanics between elite SS and LS athletes. **METHODS:** Data were collected during the 2019 FINA World Championships. SS were identified as competing in pool events ranging from 50-400m; LS were identified as open water swimmers competing in events 5-25 km. Fourteen SS (7 males; 23 ± 4 years; 100% identified as white) and 14 sex, age and ethnicity matched LS were selected for comparison. Echocardiography was performed in the left lateral decubitus position following 10 minutes of rest. Parasternal short axis images at the level of the mitral valve and apex were analyzed using speckle-tracking software and post-processed in custom software to normalize the temporal sequence of heart rate. **RESULTS:** Data are presented as mean \pm SD for LS vs. SS. Athletes had a similar body surface area (1.92 ± 0.15 vs. 1.94 ± 0.18 m², $P=0.76$), resting heart rate (52 ± 10 vs. 54 ± 8 bpm, $P=0.54$), years of event-specific training (11 ± 6 vs. 14 ± 5 years, $P=0.21$), and weekly training duration (25 ± 5 vs. 22 ± 5 hours/week, $P=0.15$). Peak LV twist (13.8 ± 3.5 vs. 12.7 ± 5.0 deg, $P=0.49$) and peak LV twist normalized to LV length (1.7 ± 0.5 vs. 1.6 ± 0.6 deg/cm, $P=0.67$) were similar between groups. Time to peak LV twist (94 ± 4 vs. 98 ± 4 % systole, $P=0.006$) and time to peak LV untwisting rate (9 ± 4 vs. 12 ± 3 % diastole, $P=0.03$), were faster in LS, while time to peak twisting rate was also trending to be faster in LS (56 ± 9 vs. 62 ± 10 % systole, $P=0.06$). **CONCLUSION:** In swimming, event distance appears to influence the temporal sequence of LV mechanics at rest with faster twisting and untwisting rates occurring in swimmers who train and compete in longer-distances. The relationship between these observations and global systolic and diastolic function warrants investigation.

Cardiac Remodeling Following High Intensity Exercise Training In A Preclinical HCM Mouse Model

Jonathan J. Herrera¹, Kate Szczesniak¹, Danielle L. Szczesniak¹, Rose-Carmel Goddard¹, Jaime Yob², Jil C. Tardiff³, Sharlene Day². ¹University of Michigan, Ann Arbor, MI. ²University of Pennsylvania, Philadelphia, PA. ³University of Arizona, Tucson, AZ.

Email: jonjoe@med.umich.edu

(No relevant relationships reported)

Participation in high intensity exercise for individuals with hypertrophic cardiomyopathy (HCM) remains controversial. Retrospective data has suggested that HCM patients who participate in lifetime vigorous exercise can have favorable cardiac remodeling that resembles that which occurs in healthy athletes. Cardiac hypertrophy is highly variable in HCM patients and may mask physiologic hypertrophy induced by exercise. **PURPOSE:** Evaluate the effects of high intensity interval training (HIIT) on cardiac hypertrophy in a preclinical transgenic cardiac troponin T delta160E (TG) HCM mouse model. **METHODS:** C57BL/6J non-transgenic (NTG) (n=6 F, n=5 M) and TG (n=4 F, n=8 M) mice (13-16mos) underwent a translationally parallel cardiac rehabilitation HIIT protocol. One treadmill training bout included 4-4 minute high intensity intervals (~80% preVO₂ max speed) interspersed by 5-3 minute recovery intervals (~50% preVO₂ max speed) for 31 total minutes. Exercise compliance was measured as percent of total training time completed. Bouts were repeated 3 times/wk for 10wks. Pre and post HIIT murine echocardiography (ECHO) was recorded and analyzed by a blinded technician. Unpaired and paired t-tests were used for data analysis. **RESULTS:** Training compliance between TG and NTG did not differ (921.90 min \pm 4.24 , 99.13% vs 928.95 min \pm 1.05 , 99.90% ; $p=0.14$). Pre and post HIIT left ventricular (LV) mass was significantly greater in both NTG (Mean difference & SEM: 23.04 mg, 6.23 ; $p=0.0042$) and TG (Mean difference & SEM: 17.56 mg, 6.31 ; $p=0.019$) mice. Body weights measured prior to pre and post HIIT ECHOs did not differ in NTG (Mean difference & SEM: 0.473 g, 0.8370 ; $p=0.585$) or TG (Mean difference & SEM: 1.354 g, 0.819 ; $p=0.129$) mice. **CONCLUSION:** In a preclinical HCM mouse model that doesn't demonstrate pathologic hypertrophy, HIIT training resulted in LV hypertrophy in both NTG and TG mice. Our data provides initial evidence that high intensity exercise training may result in physiologic hypertrophy. Biochemical analyses are underway to elucidate the underlying type of cardiac remodeling.

Naltrexone, Opioid Antagonist, Decreases Left Ventricular Function At Rest And Following Acute Exercise In Mice.

Sophie B. Green¹, Candace Longoria², Sara C. Campbell, FACSM², John J. Guers¹. ¹Rider University, Lawrenceville, NJ. ²Rutgers University, New Brunswick, NJ.

(No relevant relationships reported)

Naltrexone (NTX) is an opioid receptor blocker which can be prescribed for weight loss. To augment the effects of NTX on weight reduction, exercise (EX) is recommended as an adjacent therapy. There is prior evidence that NTX may interfere with the psychological benefits of EX. Despite a working knowledge of how NTX influences the psychological dynamics of EX investigations into how opioid receptor blockade may alter left ventricular function (LVF) following EX is lacking. **PURPOSE:** To determine the effect of NTX on LVF following EX in a rodent model. **METHODS:** Male 8 wk C57-BL6 mice were divided into 4 groups: control (CON), exercise (EX), naltrexone (NTX), exercise with naltrexone (EX+NTX). Mice that underwent EX performed 50 mins of forced swimming following a week of familiarization. NTX or saline was given (i.p., 4 mg/kg), 15 min prior to EX or 65 min prior to echocardiography (ECHO). Mice were anesthetized using isoflurane (4-5% for induction; 0.5-2.0% for maintenance of anesthesia). Fur was removed from the anesthetized animal with nair and echo gel was applied. LVF was assessed by ECHO using a VisualSonics Vevo 2100 ultrasound. LV internal dimensions (LVID) were measured in systole and diastole using Vevo 2100 for calculations. LV systolic function was estimated from LV dimensions by the cubed method. Results were quantified using a one-way ANOVA with a Tukey Post-HOC. **RESULTS:** Heart rate was elevated ($p<0.05$) in the EX group when compared to CON (CON = 275 ± 12 vs. EX = 360 ± 30 bpm; $n=8-9$). This effect was abolished with the addition of NTX (EX vs. EX-NTX = 275 ± 36 BPM). Stroke volume (SV), was reduced in the NTX group compared to CON and EX ($p<0.05$), exercise mediated increase in SV was attenuated with pre-treatment of NTX (CON 128.8 ± 15.0 , EX 147.4 ± 7.5 , EX+NTX 14.3 ± 17.7 , NTX 76.9 ± 19.0 ml; $n=7-8$). Cardiac output was

reduced in NTX group when compared to EX and CON ($p < 0.05$), NTX+EX was also lower ($p < 0.05$) than the EX group (CON 35.4 ± 4.3 , EX 52.5 ± 2.5 , EX+NTX 29.4 ± 6.5 , NTX 19.2 ± 4.5 L/min; $n = 7-8$).

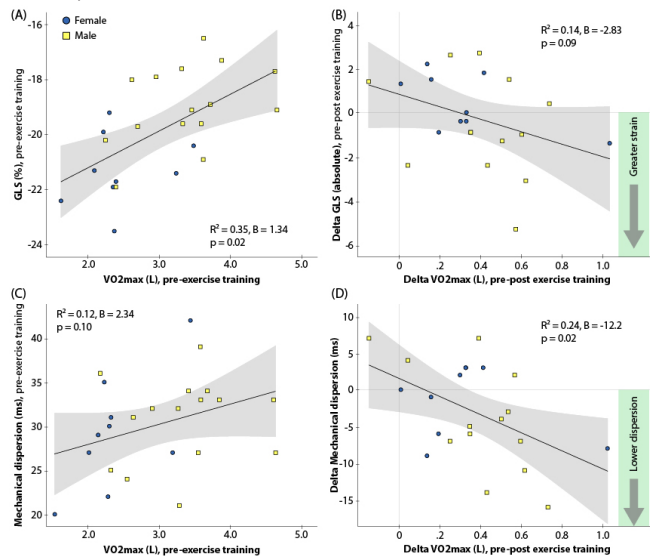

CONCLUSION: To our knowledge, this is the first study to examine the effects of NTX on LVF following acute exercise in a mouse model. These data suggest that NTX diminishes LVF following exercise. Being that exercise is a frontline therapy for weight loss the addition of NTX may alter LVF and ultimately negatively affect exercise recovery.

Effects Of Very Low Volume, High-intensity Interval Training On Left Ventricular Volume And Systolic Function

Kristofer Hedman¹, Meriam Astrom-Aneq¹, Eva Nylander¹, Karin Bouma², Mirko Mandic², Eric Rullman². ¹Linköping University, Linköping, Sweden. ²Karolinska Institutet, Stockholm, Sweden. (Sponsor: Jonathan Myers, FACSM)
Email: kristofer.hedman@liu.se
(No relevant relationships reported)

PURPOSE: It is unknown whether exercise training of extremely low volume and high intensity is enough to elicit measurable changes in cardiac dimensions or function at rest. **METHODS:** Healthy, young subjects not performing regular training were recruited for six weeks of supervised exercise training, three times per week. Each of the 18 sessions consisted of three 30 seconds all-out sprints on a bicycle ergometer (breaking force 7.5% of the subject's body weight), separated by two minutes of low intensity cycling. A maximal cardiopulmonary exercise test (CPX) and an echocardiographic examination (echo) at rest were performed before and the week after the last session. Left ventricular (LV) and left atrial (LA) volumes were determined with 4-D echo. LV systolic function was measured as ejection fraction (LVEF), global systolic longitudinal strain (GLS, 2-D speckle tracking), and mechanical dispersion (MD, standard deviation of time to peak systolic strain in all 17 LV segments). **RESULTS:** Twenty eight subjects (27 ± 5 yrs, 16 male) performed all sessions and pre- and post echo. VO_{2max} , determined in 27 subjects, increased from 3.0 ± 0.8 L/min to 3.4 ± 0.8 L/min post-training (mean +14%, $p < 0.001$). LV end-diastolic volume and LV stroke volume were similar pre-/post training (112 ± 20 vs 115 ± 24 mL, $p = 0.29$; 65 ± 13 vs 66 ± 3 mL, $p = 0.64$), as was LA end-systolic volume (47 ± 9 vs 51 ± 15 mL, $p = 0.26$). LVEF and GLS were similar pre-/post training (58 ± 5 vs 58 ± 6 %, $p = 0.89$; -20 ± 2 vs -20 ± 2 %, $p = 0.60$) while MD decreased from 30 ± 6 to 27 ± 7 ms, $p = 0.042$. There was a significant association between the decrease in MD and increase in VO_{2max} as well as between baseline GLS and VO_{2max} (figure 1). **CONCLUSIONS:** Less than five minutes of high-intensity exercise training per week for six weeks increased VO_{2max} , but not LV or LA volume at rest. Interestingly, LV longitudinal shortening was more synchronous following training, proportional to the increase in VO_{2max} , which could indicate a more efficient LV contraction.

Time-frequency Analysis Of The Seismocardiogram

William J. Armstrong, Western Oregon University, Monmouth, OR.
(No relevant relationships reported)

PURPOSE: The present study compares the features of the seismocardiograph (SCG) resolved in the time-frequency domain to the features of a single-lead electrocardiogram (ECG). **METHOD:** SCG and ECG signals were obtained from the combined measurement of ECG, breathing and seismocardiogram (CEBS) database. Baseline signals (b001 to b020) were selected from the data base and trimmed to include a minimum of ~10 beats (range: 8-12 beats; 50,000 samples). The analyzed data included lead II ECG with a bandwidth between 0.05 Hz and 150 Hz and SCG acquired using a triaxial accelerometer with a bandwidth between 0.5 Hz and 100 Hz, sampled at 5000 Hz. Time values for the peak P- and T-waves and the Q, R, and S of the ECG were identified and recorded. The SCG was subjected to an adaptation of the von Tscharny intensity analysis for accelerometry ($r = 1.959$, $q = 1.45$, scale = 1.0), and total intensity (sum of the intensities over the set of $J = 11$ Cauchy wavelets for each sample in time) was calculated. The peaks (P1 & P2) and valleys (V1 & V2) of the total intensity for each cardiac cycle (10 per sample) were determined and compared to the ECG. Correlation coefficients were determined and P1-P1 and R-R intervals were compared using a paired t-test in R. Statistical significance was set at an alpha-level of 0.05. **RESULTS:** Correlations were consistently strong among the variables (range: 0.971 to 0.999). There were no significant differences between the rate intervals for P1-P1 and R-R ($p = 0.60$). **CONCLUSION:** This preliminary analysis suggests that the SCG intensity analysis may be a suitable alternative when EMG signals are not feasible. Visual analysis and these results suggest that SCG intensity provides reliable heart rate data and may offer further insight into the nature of the cardiac cycle (e.g., pre-ejection period, left ventricular ejection time, etc.), however, the CEBS database lacked data (e.g., heart sounds) that would permit more thorough analyses. Additional study is, therefore, warranted.

602 Board #7 May 27 1:00 PM - 3:00 PM

Importance Of Frequency In Volume Matched Exercise On Heart Rate Variability In Type 2 Diabetes

Charlotte Bjoerk Ingul, Michael Shelver, Norwegian University of Science and Technology, Trondheim, Norway.
Email: charlotte.b.ingul@ntnu.no
(No relevant relationships reported)

Type 2 diabetes mellitus is associated with a decrease in heart rate variability (HRV), which reflects autonomic nervous system modulation of cardiac activity and is associated with increased mortality. HRV variation is the time interval between consecutive heartbeats. Nighttime HRV provides a more unambiguous measurement of changes in the autonomic nervous systems regulation.

PURPOSE: To compare two volume and intensity matched exercise protocols with different frequencies in individuals with T2D and to investigate the effects on HRV. **METHODS:** 54 subjects with T2D were recruited and randomly assigned to either a high-frequency high-intensity interval training protocol (HF, $n = 29$) (10-minute high frequency, 12 sessions per week) or a low-frequency high-intensity interval training protocol (LF, $n = 25$) (30-minute low frequency, 4 sessions per week). Both groups were matched for volume and intensity, and the study participants exercised for 120 minutes a week for 12 weeks. 24-hour time-domain HRV measurements were selected for analysis. Aerobic capacity (VO_{2peak}) and glycosylated hemoglobin (HbA1c) were also measured. **RESULTS:** HRV improved only in the LF group, with a significant decrease in nighttime heart rate and an increase in nighttime HRV (rMSSD, root mean square of differences between NN intervals) (Table). Both the HF and LF group significantly improved aerobic capacity by 9% (3.0 ml, baseline 33.2 ml/kg/min) and 10% (3.3 ml, baseline 32.1 ml/kg/min), respectively, with no significant difference between groups. A significant decrease of 5% in HbA1c was observed in the LF group only ($p = 0.001$). **CONCLUSION:** Longer, less frequent exercise training seems to be more effective in improving heart rate variability, and glycemic control in type 2 diabetes provided this is at a frequency of at least four times a week. This finding might be associated with enhanced cardiovascular health in a population with an elevated risk of cardiovascular morbidity and mortality.

Nighttime Heart Rate Variability in type 2 diabetes after an exercise intervention						
	Baseline High-frequency training	Post intervention High-frequency training	P-value	Baseline Low-frequency training	Post intervention Low-frequency training	P-value
Night heart rate (beats/minute)	61±10	61±7	0.40	69±11	64±10	0.005
Night HRV rMSSD (ms)	29±13	35±17	0.36	27±13	32±17	0.02

PO₂-dependent Changes In Contractility And Mitochondrial Activation In Single Myofibers From Young And Old Mice

Leonardo Nogueira, Kristoffer Svensson, Simon Schenk, Michael C. Hogan, FACSM. *University of California San Diego, La Jolla, CA.* (Sponsor: Michael C. Hogan, FACSM)
 Email: lnogueira@ucsd.edu
(No relevant relationships reported)

Aging shows muscle contractile and mitochondrial dysfunctions, as well as muscle hypoxia. **PURPOSE:** To investigate how aging affects contractile function during fatigue and contraction-induced mitochondrial activation at near-physiological oxygen tensions (PO₂). **METHODS:** Flexor digitorum brevis muscles were dissected from young (4-mo old, YM) and old (21-25 mo-old, OM) C57BL/6J mice. Single myofibers were perfused with Tyrode's solution (22°C), pre-equilibrated with 5% or 1% or 0% O₂, which produced an extracellular PO₂ of ~40, or 10, or 3 Torr, respectively. To measure fatigue resistance, myofibers (n=5 for YM and OM) were repetitively contracted (100 Hz) with progressive increases in train frequency each 2 min until fatigue (30% of initial tension) at 5% O₂. The myofibers rested for 1h, perfused with 1% O₂, and the previous contractile protocol was repeated. To measure NAD(P)H changes during contractions, myofibers (n=4 for YM and OM) were equilibrated at 5% O₂, then at 1% O₂, and then at 0% O₂, with 1h rest between conditions. For each PO₂ condition, myofibers contracted repetitively for 2 min at a fixed train frequency (0.5 trains per second). **RESULTS:** At 5% O₂, time to fatigue was significantly higher in myofibers from OM (509 ± 93 sec) vs YM (207 ± 38 sec, p<0.01). At 1% O₂, time to fatigue was not different to 5% O₂ in YM (4 ± 11% decrease, p=0.87), but showed a trend to be decreased in OM (16 ± 7% decrease, p=0.06). Relaxation time (½RT) at 5% O₂ was higher in OM (122 ± 17 ms) compared to YM (77 ± 4 ms, p<0.05) before fatiguing contractions, but showed a similar slowing in relaxation at fatigue (103 ± 30 vs 117 ± 33% increase, respectively, p>0.05). At 1% O₂, ½RT was further increased at fatigue (154 ± 39%) compared to 5% O₂ (p<0.05) in YM. ½RT changes with fatigue were not different in OM at 1% O₂ (151 ± 31 %) vs 5% O₂ (p>0.05). Contractions produced a transient (for ~30-40 s) increase in NAD(P)H fluorescence in YM at 5% O₂, which was enhanced at 1% and at 0% O₂. However, the increase in fluorescence at 1% O₂ was minimized in OM. **CONCLUSION:** These data suggest that myofibers from old mice have a higher fatigue resistance during repetitive contractions under "near-physiological" PO₂ conditions, although mitochondrial NAD(P)H responses were lower and relaxation was slower in aged myofibers. **FUNDING:** NIAMS AR069577

Skeletal Muscle Cells Derived From Old Donors Show Mitochondrial Fragmentation And Decreased Oxygen Consumption Rates

Jose A. Arevalo, Marvin L. Miller, Jose Pablo Vazquez-Medina, George A. Brooks, FACSM. *University of California, Berkeley, Berkeley, CA.*
 Email: josearevalo@berkeley.edu
(No relevant relationships reported)

With age, skeletal muscles lose their oxidative capacity and have a reduced mitochondrial fusion leading to fragmentation. These phenomena can lead to a reduction in oxygen consumption, atrophy, and an increased risk of developing age-related diseases such as sarcopenia. Skeletal muscle cells derived from humans can be used to investigate these physiological capacities in primary culture. **PURPOSE:** Investigate mitochondrial morphology and maximal oxygen consumption rates (OCR) of skeletal muscle cells derived from healthy young and old men. **METHODS:** Primary skeletal muscle cells derived from the Rectus abdominis muscle of healthy active eighteen and sixty-nine year old men (SKM18M and SKM69M, respectively) were obtained from Cook MyoSite Inc. (Pittsburgh, PA). Cells were stained with MitoTracker Red (Cell Signaling; Danvers, MA) and mitochondria morphology was observed using a Zeiss LSM 710 AxioObserver confocal scanning microscope (Carl Zeiss; White Plains, NY). The mitochondrial network was analyzed using the Mitochondrial Network Analysis tool in ImageJ (MiNA, FIJI) to estimate

mitochondrial footprint from a binarized image. Oxygen consumption rates were measured in intact cells using Seahorse Cell Mito Stress Tests on a XFp extracellular flux analyzer (Agilent Technologies; Santa Clara, CA). **RESULTS:** Primary cells derived from the young donor (SKM18M) had a larger mitochondrial footprint, longer branch length, and a greater number of network branches compared to SKM69M (Footprint: 34.65 ± 25.30 vs. 11.64 ± 9.53 μm²; Branch Length: 20.59 ± 7.23 vs. 12.10 ± 6.84 μm; Network: 17.25 ± 0.16 vs. 7.67 ± 4.97 counts). SKM18M also showed higher Basal and Maximal OCR compared to SKM69M (Basal: 38.78 ± 8.34 vs. 12.82 ± 2.07; Maximal: 60.09 ± 10.84 vs. 20.52 ± 2.36 pmol/min/protein). **CONCLUSIONS:** We observed differences morphologically and metabolically between the primary skeletal muscle cells derived from young and old donors. These preliminary results give us an insight into human skeletal muscle-derived cellular physiological capacity. Technology to observe human muscle mitochondrial fragmentation in vitro will help us elucidate the effects of aging on skeletal muscle mitochondrial fragmentation and loss of metabolic flexibility in aging.

The Impairment Of Oxidative Metabolism After 10-day Of Bed Rest Is Upstream Of Skeletal-Muscle Mitochondria

Lucrezia Zuccarelli¹, Benedetta Magnesa¹, Cristina Degano¹, Marina Comelli¹, Mladen Gasparini², Giorgio Manfredelli³, Mauro Marzorati³, Irene Mavelli¹, Andrea Pilotto¹, Simone Porcelli³, Letizia Rasicca³, Bostian Šimunič⁴, Rado Pišot⁴, Marco Narici⁵, Bruno Grassi, FACSM¹. ¹Università degli Studi di Udine, Udine, Italy. ²Splōšna Bolnišnica Izola, Izola, Slovenia. ³Institute of Biomedical Technologies, National Research Council, Milano, Italy. ⁴Institute of Kinesiology Research, Science and Research Centre, Koper, Slovenia. ⁵Università di Padova, Padova, Italy.
(No relevant relationships reported)

PURPOSE: Exposure to microgravity, as simulated by bed rest (BR), leads to an impairment of oxidative metabolism. The sites of this impairment are still debated. Aim of this study was to identify markers of impaired oxidative metabolism along the O₂ pathway, from ambient air to skeletal muscle mitochondria, following 10 days of BR.

METHODS: Measurements were carried out on 10 recreationally active young males (age 23 ± 5 years [mean±SD]) before (PRE) and after (POST) 10 days of horizontal BR. Pulmonary O₂ uptake (V̇O₂) and other respiratory, cardiovascular and skeletal muscle variables were determined during an incremental exercise on a cycle ergometer. Peripheral vascular and endothelial functions were evaluated by the blood flow response (Doppler ultrasound) in the femoral artery during 1-min passive leg movement (PLM). Mitochondrial respiration was evaluated by high-resolution respirometry on permeabilized vastus lateralis fibers obtained by biopsy.

RESULTS: Peak V̇O₂ was lower (P=0.001) in POST (41.5 ± 6.5 ml·kg⁻¹·min⁻¹) vs. PRE (44.5 ± 7.4). The area under the blood flow vs. time curve during PLM was lower (P=0.038) in POST (274 ± 233 mL) vs. PRE (427 ± 291). Skeletal muscle citrate synthase activity, an estimate of mitochondrial mass, was not different (P=0.115) in POST (131.2 ± 15.9 U·mg⁻¹·protein) vs. PRE (137.9 ± 18.8). Maximal ADP-stimulated mitochondrial respiration (66.4 ± 17.5 pmol·s⁻¹·mg⁻¹ wet weight [POST] vs. 72.3 ± 14.0 [PRE], P=0.127) and oxidative phosphorylation coupling efficiency (respiratory control ratio, 4.10 ± 1.19 [PRE] vs. 3.59 ± 1.11 [POST], P=0.443) were not affected by BR. **CONCLUSIONS:** These preliminary data suggest that the whole-body impairment of oxidative metabolism during exercise, following 10 days of horizontal BR, is associated with an impairment of peripheral vascular and endothelial functions, whereas mitochondrial volume and respiratory function are unaffected. Data related to several other markers (pulmonary function, cardiac output, submaximal exercise tolerance, skeletal muscle fractional O₂ extraction, skeletal muscle V̇O₂ recovery kinetics, mitochondrial respiration sensitivity to submaximal [ADP]) are yet to be analyzed. Funding: ASI, MARS-PRE Project, n. DC-VUM-2017-006

Effect Of Endurance Exercise On Localization Of Myoglobin In Mitochondria In Muscle

Rikuhide Koma¹, Tsubasa Shibaguchi¹, Claudia Pérez López¹, Thomas Jue², Kazumi Masuda¹. ¹Kanazawa University, Kanazawa, Japan. ²University of California Davis, Davis, CA.
 Email: higasiyamadamasi@gmail.com
(No relevant relationships reported)

Purpose: Mitochondria play a principal role for metabolism and have a primary role in regulating respiration in myocytes. Recently, we have shown that the muscle-specific protein myoglobin (Mb) interacts with complex IV to augment mitochondrial respiratory capacity in skeletal muscles. However, the precise mechanism for the Mb-mediated upregulation remains unclear. The present study has focused on effect of the endurance training (eTR) on Mb within the mitochondria. **Methods:** Wistar male

rats aged 10-week, were subjected to eTR sessions for 4 weeks (25 m/min X 60 min X 5-day/week, n=6). Muscle specimen from the deep portion of m. Gastrocnemius was taken and homogenized. Crude mitochondria were isolated by differential centrifugations and washed with the mitochondrial isolation buffer. The isolated mitochondria were treated with proteinase K (PK), osmotic shock (OS), and SDS (or TrX) in order to digest proteins on the outer membrane and in the intramembrane. The final samples were subjected to SDS-PAGE and immunoblotting using antibodies to localize the proteins in the mitochondria. **Results:** The eTR increased VDAC-I and COX-IV around +80~130% as compared with non-exercise control ($p<0.05$). Mb increased by +50% ($p<0.05$). Western blotting analysis revealed that the PK digested Tom20, and Tom20 band intensity decreased with the amount of PK used. PK treatment, however, did not affect Mb found in the mitochondrial fraction. Combining treatment with PK, OS and SDS (or TrX) allowed immunoblotting detection of the mitochondrial proteins localized in specific regions of the mitochondria. Mb was detected with either PK or OS treatment. But it cannot be detected with a combined PK+OS treatment, suggesting that Mb associated with the inner membrane (intramembrane side, not matrix side) of the mitochondria. The Mb content inside the mitochondria in eTR rat was similar with that in the control muscles (n.s). **Conclusion:** The present results suggest that Mb in muscle cells localizes both in the cytosol and in the mitochondrial intermembrane space. Although eTR elevates mitochondrial volume and Mb content but does not change Mb content in the mitochondria. Therefore, the observation might imply that the dynamic flux of Mb from cytosol to mitochondria has greater importance than just the amount found in the mitochondria

skeletal muscle fat oxidation in healthy humans and to what extent exercise regulates ETF remains largely unknown. **PURPOSE:** To determine the relationship between skeletal muscle ETF protein abundance and mitochondrial fat oxidation capacity in healthy adult humans at rest and after acute aerobic exercise. **METHODS:** Sedentary lean adults (n=14 [10F/4M], age 28 ± 7 years, BMI 22.2 ± 2.1 kg/m²) completed two studies involving 1-hour of cycle ergometry (65% $\dot{V}O_{2max}$) or sedentary rest in a randomized cross-over design. Vastus lateralis muscle biopsies were collected at rest and 15 minutes after exercise. High-resolution respirometry was performed on isolated mitochondria using palmitoyl-carnitine (lipid substrate, ETF-linked) and glutamate-succinate (non-lipid substrate, N and S-linked). ETF protein abundance and methylation status were determined via western blot. **RESULTS:** Exercise did not alter ETF-linked oxidative phosphorylation or leak respiration compared to rest. Acute exercise did not stimulate N or S linked respiration states. Oxidative phosphorylation was lower for ETF substrates ($p<0.0001$), but with greater electron leak to H_2O_2 , than N or S substrates ($p<0.0001$). Acute exercise did not alter protein abundance of ETF-beta subunit or trimethylation ($p=0.41$ and 0.28 , respectively). **CONCLUSION:** Moderate intensity aerobic exercise did not alter mitochondrial respiration for either lipid or non-lipid substrates. ETF proteins did not undergo acute regulation to a single session of aerobic exercise. The lower capacity for lipid oxidation indicates factors upstream to ETF may regulate muscle lipid oxidation to acute exercise.

Vastus Lateralis Muscle Oxygenation Measured By Near-infrared Spectroscopy During Voluntary Isometric Leg Extension Muscle Actions
 Marni E. Shoemaker, Zachary M. Gillen, Nicholas A. Bohannon, Sydney M. Gibson, Joel T. Cramer, FACSM. *University of Nebraska-Lincoln, Lincoln, NE.*
(No relevant relationships reported)

Purpose: Examine vastus lateralis muscle tissue oxygenation measured by near-infrared spectroscopy (NIRS) during submaximal (10-90%) and maximal voluntary isometric contractions (MVIC) of the leg extensors.

Methods: Ten healthy, active males (age: 23 ± 1 y, mass: 84.5 ± 4.5 kg, stature: 181.4 ± 2.5 cm) performed three, 5-s MVICs and nine, 5-s submaximal isometric step muscle actions at 10 – 90% of the MVIC in 10% increments (randomly-ordered). Bipolar surface electromyography (EMG) and NIRS were used simultaneously to record muscle activation and muscle tissue oxygenation, respectively, from similar adjacent locations of the vastus lateralis muscle. The following four variables from the NIRS device were quantified for 0.5-s epochs during the isometrics force plateaus: concentration changes ($\Delta \mu M$) in oxygenated hemoglobin (Hb) + myoglobin (Mb) (oxy[heme]), deoxygenated Hb + Mb (deoxy[heme]), total Hb + Mb (total[heme]) and tissue saturation index (StO_2 , %). Difference EMG amplitude values were calculated for the same 0.5-s epochs and normalized to the MVIC. B-mode ultrasound was used to measure muscle and subcutaneous adipose tissue thicknesses.

Results: The sample demonstrated homogenous muscle thickness (range = 3.8 – 5.6 cm) and subcutaneous adipose thickness (0.3 – 0.6 cm). MVIC torque values ranged from 129 – 308 Nm. As expected, EMG amplitude increased incrementally from 10% to 100% MVIC ($p<0.001-0.021$). Oxy[heme] and total[heme] decreased incrementally from 10% to 80% MVIC ($p<0.001-0.05$), while deoxy[heme] did not change ($p=0.897$), from 10% to 100% MVIC. StO_2 remained unchanged from 10% to 60% MVIC ($p=0.406-0.992$), then decreased incrementally from 60 to 100% MVIC ($p=0.001-0.039$).

Conclusions: Despite systematic decreases in vastus lateralis blood diffusion (total[heme]) from 10% to 80% MVIC, muscle perfusion (deoxy[heme]) remained unchanged across the force spectrum. Interestingly, vastus lateralis tissue oxygen saturation remained intact from 10% to 60% MVIC, but then systematically decreased to 100% MVIC from 71% saturation to 64% saturation. These findings suggest that non-fatiguing submaximal isometric leg extension muscle actions from 10% to 60% MVIC may allow for a steady maintenance of oxygen saturation, which is decreased at higher force production.

Skeletal Muscle Mitochondrial Plasticity is Reduced in Liver Transplant Recipients Echevarria CE, Abdul-Mateen S, Shen S, Blalock M, Bhati C, Siddiqui MS, Kirkman DL

PURPOSE Sarcopenic obesity is a hallmark of liver transplant recipients, of which the mechanisms are not yet fully understood. Decline in mitochondrial plasticity could play a mechanistic role in muscle wasting, loss of strength, and increased adiposity via impaired energy substrate utilization. The purpose of this study is to determine if skeletal muscle mitochondrial plasticity is reduced in liver transplant (LT) recipients. **METHODS** In this prospective cohort study, 15 LT patients (Mean \pm SD; Age: 58 ± 10 years; months since transplant: 55 ± 81 months) and 10 age matched healthy controls (Age: 55 ± 4 years), underwent assessment of mitochondrial oxidative capacity of the wrist flexor muscle group. Near infrared spectroscopy coupled with repeated, transient arterial occlusions, measured the recovery kinetics of oxygen consumption following a 10 second bout of hand grip exercise. Post exercise metabolic recovery rate constant was calculated and reported as an index of mitochondrial oxidative capacity. **RESULTS** Post exercise metabolic recovery rates were significantly greater in LT recipients (Mean \pm SEM; Recovery Time Constant: 72 ± 7 s) compared to HC (51 ± 4 s; $p=0.03$) indicative of diminished mitochondrial plasticity in this patient cohort (Figure 1). **CONCLUSION** Skeletal muscle mitochondrial plasticity is reduced in LT patients compared to matched healthy controls. Further investigations are warranted to determine the role of mitochondrial dysfunction in the development of sarcopenic obesity and frailty following LT.

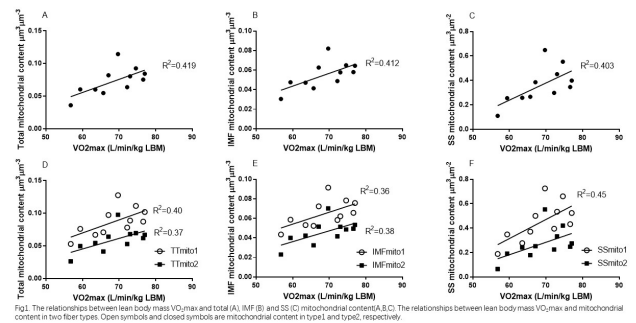

Fig 1. The relationships between lean body mass VO_{2max} and total (A), IMF (B) and SS (C) mitochondrial content (A, B, C). 611 Board #8 May 27 1:00 PM - 3:00 PM The Associations Of Mitochondrial Content And Maximal Oxygen Uptake

Yiheng Liang¹, Rasmus Jensen², Guoqiang Geng¹, Junqiang Qiu¹, Niels Ortenblad², Joachim Nielsen². ¹Beijing Sport University, Beijing, China. ²University of Southern Denmark, Odense, Denmark.

(No relevant relationships reported)

Introduction The purpose of this study was to explore the relationship between human fiber type specific mitochondria volume density and VO_{2max} . **Methods** Eleven recreational active subjects (VO_{2max} mean 4.54 ± 0.58 L/min) reported to lab for a progressive ergometer cycle test to estimate VO_{2max} . Ten muscle fibers were obtained in each 9 biopsies in vastus lateralis from each of the 11 subjects. In each fibers, 24 images were obtained in a randomized systematic order, thus 528 fibers and 13968 images were analyzed. Point counting was used to estimate intermyofibrillar (IMF) mitochondrial content as a volume density and subsarcolemmal (SS) mitochondrial content as a volume per fiber surface. Total mitochondrial content were obtained by recalculating the SS subfraction to myofibrillar volume density. Fibre type was determined by z-disk widths. Lean body mass (LBM) was determined by DXA. All data are presented as means \pm SD. Associations was evaluated using Pearson's correlation coefficient. **Results** The total, IMF and SS mitochondrial content in type 1 are $0.087 \pm 0.021 \mu m^3/\mu m^2$, $0.065 \pm 0.014 \mu m^3/\mu m^2$, $0.451 \pm 0.159 \mu m^3/\mu m^2$, respectively, and in type 2 are $0.059 \pm 0.018 \mu m^3/\mu m^2$, $0.046 \pm 0.012 \mu m^3/\mu m^2$, $0.271 \pm 0.129 \mu m^3/\mu m^2$, respectively. Total mitochondrial volume content was a strong predictor of VO_{2max} per LBM. Further, IMF mitochondrial content is a better predictor of a subject's VO_{2max} per LBM than SS mitochondrial content. The fiber type specific correlations revealed that, total, IMF and SS in different fiber types are associated with VO_{2max} per LBM, except SS mitochondrial content in type 2 is not associated (Fig1). **Conclusion** There is a strong correlation between mitochondrial content and VO_{2max} per LBM, however, VO_{2max} and relative VO_{2max} are not associated with mitochondrial content. Also, there is a clear correlation between total and IMF mitochondrial content and VO_{2max} per LBM in both type 1 and type 2 fibers, whole this was only the case for SS in type 1 fibers.

613 Board #1 May 27 1:00 PM - 3:00 PM Associations Of Muscle Strength And Genetic Predispositions To High Blood Pressure With Mortality And Cardiovascular Disease Outcomes: Findings From The Uk Biobank Project

(No relevant relationships reported)

PURPOSE: High blood pressure (BP) is a heritable risk factor for cardiovascular diseases (CVD). Whether muscle strength, a modifiable environmental trait, is associated with risk of mortality and CVD independently of genetic risk for high BP is unknown. The purpose was to investigate the associations of genetic risk for high BP and muscle strength with mortality from all causes and CVD, and incidence of myocardial infarction (MI) and stroke. **METHODS:** This study is based on data from UK Biobank, a prospective cohort containing >500,000 adults aged 40-69 years. We included 304,020 individuals of European ancestry without 2nd-degree genetic relatedness and prevalent CVD at baseline. Polygenic risk scores (PRS) for high BP were determined by averaging the standardized calculated risk scores for systolic BP (using 274 single-nucleotide polymorphisms [SNPs]), diastolic BP (278 SNPs) and pulse pressure (231 SNPs). Muscle strength was assessed through grip strength tests. The average grip strength values from both hands were divided by measured fat-free mass. Independent and stratified associations were estimated using Cox regression. **RESULTS:** Compared with the bottom muscle strength tertile, hazard ratios of the top tertile were 0.72 (95% Confidence Interval: 0.69-0.76) for all-cause mortality, 0.66 (0.59-0.75) for CVD mortality, 0.84 (0.78-0.90) for MI, 0.81 (0.74-0.89) for stroke, 0.79 (0.72-0.88) for ischemic stroke and 0.80 (0.67-0.96) for hemorrhagic stroke after adjusting for confounders and PRS. Higher PRS was associated with higher hazards of each disease outcome. At all tertiles of genetic risk for high BP, higher muscle strength was associated with lower hazard of mortality due to all causes and CVD (except at low genetic risk), MI, stroke, ischemic and hemorrhagic stroke (except for high muscle strength at medium genetic risk), compared with low muscle strength: no additive and multiplicative interactions detected. **CONCLUSION:** Individuals with higher levels of muscle strength have lower rates of mortality from all causes and CVD, and incidence of MI and stroke, independent of genetic risk for high BP. Increased muscle strength is, in general, protective against mortality and CVD in the whole population including those at increased genetic risk for high BP.

Association Of Knee Extensor Strength With Prevalence Of Type 2 Diabetes Among Japanese: A Cross-sectional Study

Takahisa Ohta¹, Junzo Nagashima², Takeshi Yoshihisa², Yasunori Imagawa², Nobuyoshi Ono², Wataru Fukuda², Susumu S. Sawada, FACSM³, Hiroyuki Sasai⁴, Kazushige Sasaki¹, Naokata Ishii¹. ¹The University of Tokyo, Tokyo, Japan. ²Yokohama Sports Medical Center, Yokohama, Japan. ³Waseda University, Saitama, Japan. ⁴Tokyo Metropolitan Institute of Gerontology, Tokyo, Japan.

(No relevant relationships reported)

Low hand grip strength is known to be an independent risk factor for developing type 2 diabetes. However, the relationship between the strength of lower limb muscles such as knee extensors and the prevalence of type 2 diabetes remains unclear among Japanese adults. **PURPOSE:** To investigate the relationship between knee extensor strength and prevalence of type 2 diabetes among Japanese adults.

METHODS: This cross-sectional study was conducted in 6227 Japanese male [age: 49.7 (16.0) years, mean (standard deviation)] and 7790 Japanese female [age: 50.4 (14.6) years] who had undergone medical checkup and physical fitness tests voluntarily from 1998 to 2018 at a preventive medical center. Participants completed a maximal voluntary knee extension test, a medical examination, and lifestyle questionnaires. Knee extensor strength, expressed as knee joint torque per body weight (Nm/kg), was measured at 60 degrees/s with an isokinetic dynamometer. Type 2 diabetes was defined as having at least one of the following criteria; fasting plasma glucose ≥ 126 mg/dL, hemoglobin A1c $\geq 6.5\%$ (NGSP) and self-reported physician diagnosis. All participants were divided into quartile according to knee extensor strength. Odds ratios and 95% confidence intervals for having type 2 diabetes were obtained by using logistic regression models. The models were adjusted for age, systolic blood pressure, current smoking status, alcohol intake, and body mass index.

RESULTS: Of the participants who had complete data, 720 males (11.6%) and 505 females (6.5%) had type 2 diabetes. Using the lowest quartile of knee extensor strength as reference, odds ratios and 95% confidence intervals for the highest quartile were 0.71 (0.59- 0.86) for overall (p for trend < 0.001), 0.64 (0.51- 0.82) for male (p for trend <0.001), and 0.75 (0.55- 1.01) for female (p for trend =0.036).

CONCLUSIONS: Our results suggest an inverse relationship between knee extensor strength and prevalence of type 2 diabetes among Japanese adults. Further cohort studies are warranted to investigate longitudinal associations between lower limb muscle strength and type 2 diabetes.

Muscle Strength Moderates The Harmful Relationship Between Abdominal Obesity With Health Variables Among Adults

Tiago Rodrigues de Lima¹, David Alejandro González-Chica², Diego Augusto Santos Silva¹. ¹FEDERAL UNIVERSITY OF SANTA CATARINA, Florianópolis, Brazil. ²The University of Adelaide, Adelaide, Australia.
Email: tiagopersonaltrainer@gmail.com

(No relevant relationships reported)

PURPOSE: Clinical variables are usually altered among individuals with abdominal obesity (AO). However, few population-based studies have investigated whether clinical variables are improved according muscle strength (MS) levels in adults with AO or without AO. We investigate whether MS levels moderates the relationship between AO with clinical variables among adults.

METHODS: Cross-sectional population-based study comprising 862 adults (39.3 \pm 11.4 years, 46.4% men) from Florianópolis, Southern Brazil. MS was assessed by handgrip strength. Clinical variables investigated as outcomes were systolic (SBP) and diastolic blood pressure (DBP), carotid intima-media thickness (IMT), high sensitive C-reactive protein (hs-CRP) levels, lipid and glucose metabolism markers. Multiple linear regression adjusted for confounding factors was used.

RESULTS: Higher levels of MS were related to lower levels of IMT, hs-CRP, triglycerides, insulin resistance (HOMA-IR) and higher HDL cholesterol (HDL) among male (p<0.05 in both cases). Among female, to have higher levels of MS was associated with lower levels of SBP, DBP, IMT, hs-PCR, glycated hemoglobin (HbA1c), HOMA-IR and higher HDL (p<0.05). Reduced IMT was observed in male with AO who presented higher MS levels (p<0.05). Among female with AO, lower levels of SBP, HbA1c, HOMA-IR, and higher levels of HDL and IMT were identified in those with higher MS levels (p<0.05).

CONCLUSIONS: MS levels moderated the harmful relationship between AO with clinical variables in male and female.

The Independent And Combined Effects Of Aerobic Physical Activity And Muscular Strengthening Activity On All-Cause Mortality: An Analysis Of Effect Modification By Race-Ethnicity

William Boyer¹, James Churilla, FACSM², Amy Miller¹, Trevor Gillum¹, Marshare Penny¹. ¹California Baptist University, Riverside, CA. ²University of North Florida, Jacksonville, FL.
(Sponsor: James R. Churilla, FACSM)
Email: wboyer@calbaptist.edu

(No relevant relationships reported)

The relationship between aerobic physical activity (PA) and all-cause mortality risk is well documented. However, the combined effects of sufficient aerobic PA and muscular strengthening activity (MSA) on all-cause mortality risk need further exploration. Moreover, the 2018 PA guidelines committee report suggests that effects of race-ethnicity on this relationship need to be examined. **PURPOSE:** To examine the independent and joint relationship between meeting the current aerobic PA and MSA recommendations and all-cause mortality while considering potential effect modification by race-ethnicity. **METHODS:** This study sample (n=14,384), included adults (20-79 years of age), who participated in the 1999-2006 NHANES. Participants self-reported participation in aerobic PA (leisure-time, transportation, household) and MSA. PA was categorized into 6 categories based around the 2018 PA guidelines: category 1 (no aerobic PA and no MSA), category 2 (insufficiently active and no MSA), category 3 (active and no MSA), category 4 (no PA and meeting the MSA recommendations), category 5 (insufficiently active and meeting the MSA recommendations), and category 6 (meeting both the aerobic and MSA recommendations). All-cause mortality was the dependent variable. Race-ethnic groups examined included non-Hispanic White (NHW), non-Hispanic Black (NHB) and Mexican American (MA). Cox-proportional hazard models were used for the total sample and for individual race-ethnicity estimates. **RESULTS:** A significant interaction was found between aerobic PA and race-ethnicity (p=0.0001) and MSA and race-ethnicity (p=0.0005). Significant risk reductions were found for categories 2,3 and 6 among NHW (cat 2: HR 0.76, 95% CI 0.64-0.91; cat 3: HR 0.63, 95% CI 0.52-0.74; cat 6: HR 0.58, 95% CI 0.44-0.76) and NHB (cat 2: HR 0.63, 95% CI 0.52-0.74; cat 3: HR 0.51, 95% CI 0.41-0.65; cat 6: HR 0.54, 95% CI 0.38-0.77). Among MA, only those meeting both guidelines had significant reductions in all-cause mortality risk (HR 0.54, 95% CI 0.32-0.92). **CONCLUSIONS:** In support of the most recent PA guidelines, participation in sufficient volumes of both aerobic PA and MSA lead to significant reductions in risk for all-cause mortality across race-ethnic groups. The positive effects of aerobic PA alone seem to be isolated to NHW and NHB.

Weakness May Cause Mortality In Older Americans: A Matched Cohort Analysis

Ryan McGrath¹, Brian Clark², Kyle Hackney¹, Donald Jurivich³, Brenda Vincent¹, Lindsey Dahl³, Mark Peterson, FACSM⁴.
¹North Dakota State University, Fargo, ND. ²Ohio University, Athens, OH. ³University of North Dakota, Grand Forks, ND. ⁴University of Michigan, Ann Arbor, MI.

(No relevant relationships reported)

Muscle weakness has been implicated with early mortality; however, quantifying the extent of this association with a carefully matched not weak and strong control will help to better establish the impact of weakness on premature death. **PURPOSE:** We utilized a propensity cohort analysis in a national sample of older Americans for this study to determine if persons who were weak had a higher risk for early mortality compared to a not weak or strong control group. **METHODS:** Data from 19,729 Americans aged at least 50 years from 2006-2014 waves of the Health and Retirement Study were analyzed. Handgrip strength was measured with a hand-grip dynamometer. Men with handgrip strength <26 kilograms were considered weak, ≥ 26 kilograms were considered not weak, and ≥ 32 kilograms were considered strong. Women with handgrip strength <16 kilograms were classified as weak, ≥ 16 kilograms were classified as not weak, and ≥ 20 kilograms were classified as strong. The National Death Index and postmortem interviews determined date of death. The greedy matching algorithm was used to separately match the weak cohort 1:1 to a 1) not weak control cohort, and 2) strong control cohort on several influential covariates. Kaplan-Meier estimators examined survival probabilities and Cox models determined the association between weakness and time to mortality for each of the matched pairs. **RESULTS:** Of the 1,077 weak and not weak matched pairs, 401 weak (37.2%; mortality rate per 1,000 person years: 90.6) and 296 not weak (27.4%; mortality rate per 1,000 person years: 57.8) older Americans died over an average 4.4 \pm 2.5 year follow up. There were 392 weak (37.0%; mortality rate per 1,000 person years: 89.6)

and 243 strong (22.9%; mortality rate per 1,000 person years: 46.7) persons that died over a mean 4.5±2.5 year follow up from the 1,057 weak and strong matched pairs. Those in the weak cohort had a 1.40 (95% confidence interval (CI): 1.19-1.64) and 1.54 (CI: 1.30-1.83) higher hazard for mortality relative to older Americans in the not weak and strong control cohorts, respectively. **CONCLUSION:** Our findings may indicate a causal association between muscle weakness and mortality in older Americans. Healthcare providers should include measures of handgrip strength as part of routine health assessments and discuss the health risks of weakness with their patients.

Association Between Silent Lacunar Infarcts And Muscle Strength: The Bunkyo Health Study

Yuki Someya, Yoshifumi Tamura, Hideyoshi Kaga, Satoshi Kadowaki, Daisuke Sugimoto, Ruriko Suzuki, Shigeki Aoki, Nobutaka Hattori, Yumiko Motoi, Kazunori Shimada, Hiroyuki Daida, Shuko Nojiri, Ryuzo Kawamori, Hirotaka Watada. *Juntendo University, Tokyo, Japan.*

(No relevant relationships reported)

Silent lacunar infarcts by definition, lack clinically overt stroke-like symptom, are occasionally found by brain magnetic resonance imaging (MRI) scan in asymptomatic elderly individuals. A previous study revealed that more than 25% of elderly people have silent lacunar infarcts. The main risk factors for lacunar infarcts and stroke were reported as aging, hypertension, and smoking. While a recent study showed that low muscle strength is also a risk factor for cerebrovascular events, it remains unclear whether low muscle strength is a risk factor for silent lacunar infarcts. **PURPOSE:** To investigate the association between muscle strength and silent lacunar infarcts in the elderly people living in urban community. **METHODS:** This study included 1,536 elderly people without past history of cerebral vascular events, aged 65-84 years living in an urban area of Tokyo, Japan (Bunkyo Health Study). All participants underwent brain MRI scan and silent lacunar infarcts were defined as the presence of 1 or more lacunar infarcts. Isokinetic muscle strength of knee extensors was evaluated at angular velocity of 60 degree per seconds using dynamometer. Subjects was categorized tertiles (high, medium, and low) by muscle strength, and compared the prevalence of silent lacunar infarcts. **RESULTS:** Mean age of subjects was 73.0±5.4 years old and 58.9% were female. Two hundred fifty-two (16.4%) subjects were diagnosed as silent lacunar infarcts, and the subjects categorized as lower muscle strength showed higher prevalence of silent lacunar infarcts (high: 12.3%, medium: 17.7%, and low: 19.3%, p for trend 0.003), while skeletal muscle indices among the groups were similar. After multivariate adjustment by age, sex, body mass index, smoking status, physical activity, hypertension, diabetes, and dyslipidemia, the trend was still significant and the odds ratio for having silent lacunar infarcts was significantly higher in the lowest muscle strength tertile compared to the highest tertile [High: 1.00 (reference), medium: 1.42 (95%CI: 0.98-2.04), Low: 1.48 (1.02-2.14), p for trend 0.043]. **CONCLUSIONS:** In the elderly people living in urban community, lower muscle strength of knee extensors was associated with higher prevalence of silent lacunar infarcts independent of other established risk factors.

Genetic Risk, Muscle Strength And Stroke Risk

Youngwon Kim¹, Stephen J. Sharp², Semi Hwang¹, Shan Luo¹, Shiu Lun Au Yeung¹, Craig C. Teerlink¹. ¹The University of Hong Kong Li Ka Shing Faculty of Medicine, Hong Kong, Hong Kong. ²University of Cambridge School of Clinical Medicine, Cambridge, United Kingdom.

Email: youngwon@hku.hk

(No relevant relationships reported)

PURPOSE: Little is known about whether the beneficial impacts of increased muscle strength are consistent across all levels of genetic predispositions to stroke. The purpose was to examine whether the associations between muscle strength and stroke are independent of or vary by genetic risk for stroke.

METHODS: We included 312,398 individuals of European ancestry in UK Biobank (a prospective cohort of >500,000 adults aged 40-69 years) who had no stroke at baseline and genetic relatedness. Genetic risk was assessed using polygenic risk scores, calculated by multiplying the sum of risk-increasing alleles at a given locus by the known effect estimates. Muscle strength was assessed through grip strength tests via a hand dynamometer. Values from both hands were averaged, then divided by fat-free mass. The outcome variables included incidence of overall ($n=3,356$), ischemic ($n=2,632$) and hemorrhagic ($n=861$) stroke over 9-year median follow-up. Overall, stratified and joint associations were estimated using Cox regression. **RESULTS:** Compared with the bottom tertile of muscle strength, hazard ratios [95% confidence interval] of stroke were 0.88 [0.81-0.95] and 0.80 [0.73-0.87] for the middle and top tertiles of muscle strength, respectively, after adjusting for confounders and genetic risk; higher levels of genetic risk were independently associated with higher hazards of stroke. Hazard ratios of stroke for the top muscle strength tertile were 0.82

[0.69-0.96], 0.78 [0.67-0.91] and 0.81 [0.70-0.93] at low, medium and high genetic risk, respectively: no evidence of additive and multiplicative interactions detected. Compared with the reference category of high muscle strength and low genetic risk, there was an increased hazard of stroke for individuals who had medium or high genetic risk combined with low or medium muscle strength, but not for those who had medium genetic risk but high muscle strength. Similar associations were observed for ischemic and hemorrhagic stroke, although for hemorrhagic stroke, confidence intervals were wider and inconclusive for some of the associations.

CONCLUSIONS: Higher muscle strength was associated with lower risk of stroke, independently of genetic risk for stroke. The increased genetic risk of overall and ischemic stroke was partly attenuated through increased muscle strength.

Acute Perceptual Responses To Individual And Group-based High-intensity Interval Exercise In Girls

Jeanette M. Ricci¹, Todd A. Astorino, FACSM², Katharine D. Currie¹, Karin A. Pfeiffer, FACSM¹. ¹Michigan State University, East Lansing, MI. ²California State University - San Marcos, San Marcos, CA.

(No relevant relationships reported)

Vigorous-intensity physical activity (PA), such as high-intensity interval exercise (HIIE), elicits greater health benefits than moderate-intensity PA. However, predictors of PA adherence such as affect and enjoyment are rarely assessed during HIIE in children. **PURPOSE:** To compare girls' acute perceptual responses to different types of HIIE, treadmill-based (TM) and body-weight resistance exercise circuit (CIRC), and to CIRC performed in a small group setting. **METHODS:** Fifteen active girls (age = 9.2 ± 1.1 years) completed a graded exercise test to determine maximal aerobic speed (MAS). TM and CIRC were performed on separate days (randomized and counterbalanced), and then CIRC was completed in a small group (group CIRC). TM required eight 30s sprints at 100% MAS with 30s of active recovery at 40% MAS; whereas, CIRC consisted of 2 sets of 4 exercises performed 'all out' for 30s with 30s of active recovery. Perceived exertion (RPE 0-10), affective valence (Feeling Scale, -5 to +5), and exercise enjoyment (facial scale, 1-4) were recorded at pre-exercise, 38%, and 75% of protocol completion, and post-exercise. Participants also completed surveys encompassing exercise enjoyment (PACES, 16-80) and positive and negative affect (10-item PANAS) prior to the exercise test and 15 minutes post-exercise.

RESULTS: RPE increased significantly during exercise ($P<0.001$), yet there was no time by protocol interaction ($P=0.12$). Affective valence and enjoyment were unchanged during exercise ($P>0.05$) and similar between protocols ($P>0.05$). Mean affective valence and exercise enjoyment at post-exercise were equal to 3 ± 2 and 3 ± 1 (TM) respectively, 3 ± 2 and 3 ± 1 (CIRC), and 4 ± 2 and 4 ± 1 (group CIRC). Mean exercise enjoyment (PACES) at baseline was equal to 69 ± 10 and did not significantly change post-exercise, and there was no change in positive or negative affect ($P>0.05$). **CONCLUSION:** Despite an exercise-induced increase in RPE, affect and enjoyment were unchanged during all protocols, suggesting that HIIE did not elicit unfavorable perceptual responses in individual and small-group settings. A possible explanation for our findings is our use of relatively brief work intervals and a lower volume exercise protocol compared to previous HIIE studies.

623 Board #2 May 27 1:00 PM - 3:00 PM

JOINT-, CONTRACTION-TYPE, AND CONTRACTION-VELOCITY SPECIFIC DIFFERENCES IN MUSCLE STRENGTH OF LOWER EXTREMITY IN CHILDREN

Krista Casazza, Marzouq Almutairi, Sydney Watkins, Roshita Rathore, Harshvardan Singh. UAB, Birmingham, AL.

Email: kristac@uab.edu

(No relevant relationships reported)

PURPOSE: Concentric and eccentric muscle contractions produce dynamic movements requisite for activities of daily living (e.g. walking, running, and jumping). The purpose of this study is to examine joint-, contraction-type, and contraction-velocity specific differences as a function of lower extremity muscle strength in children. Methods: Thirteen children (male = 5, female = 8; age = 11.2 ±

1.1 years) participated in our cross-sectional study. After a familiarization session, participants performed randomized unilateral isometric (ISO), concentric (CON) and eccentric (ECC) muscle strength testing of the non-dominant knee extensors and ankle plantarflexors in a seated position at 120°/s and 180°/s on Biodex. Obtained peak torques were normalized to body mass. Differential muscle strengths were also calculated [D1 = (ECC120-CON120)_{knee}; D2 = (ECC120-CON120)_{ankle}; D3 = (ECC180-CON180)_{knee}; D4 = (ECC180-CON180)_{ankle}]. We used separate within repeated measures ANOVA to calculate muscle strength differences. Paired t-tests were used to compare the differential muscle strength (D1 vs D2; D3 vs D4). Results: No difference was noted between ISO and CON. However, ISO and CON were lower than ECC muscle strength at 120°/s and 180°/s (P < 0.01) at the knee and ankle. No difference was noted between D1 and D2 but D4 was significantly lower than D3 (P = 0.009). Conclusion: Irrespective of contraction velocity and the body sites, children display greatest muscle strength for ECC relative to CON or ISO which is site-dependent. Whether this is dictated by maturation associated site-specific neuromuscular inhibition remains to be investigated.

Relationship Between Deep Squat And Joint Range Of Ankle Motion In Young Female Hockey Players

Sandra L. Prieto¹, Juan C. Mazza, FACSM², Raul R. Festa², Maria B. Pasquali³. ¹National University of Colombia, Bogotá DC, Colombia. ²Biosystem Institute Sports Sciences, Rosario, Argentina. ³National University of Rosario, Rosario, Argentina. (No relevant relationships reported)

BACKGROUND: The “Deep Squat” (DS) is a qualitative functional test that integrates muscle strength, neuromuscular control, mobility and joint stability. This test has been frequently used to identify risk of musculoskeletal injury in varied populations. The active joint range of motion (AROM) is the arc of mobility that an individual performs during a voluntary movement, measured objectively by goniometer. **PURPOSE:** Identify the relationship between the DS and the AROM of the ankle measured by goniometer in young female hockey players who belong to *Gimnasia Esgrima Rosario Club*. **METHODS:** Twenty young and healthy female hockey players (age: 16.12 ± 1.16 years; Weight: 57.40 ± 6.32 Kg; Height: 161.42 ± 6.14 cm), participated in this study. Asymptomatic subjects were included, with no history of lumbar spine, hip, knee or ankle injuries. The functional DS test was measured by goniometer in angular degrees of movement for knee flexion, and three bilateral tests for the AROM of dorsiflexion of the ankle (a- Bipedal position with partial load; b- Seated with knee flexed at 90°; and c- Seated with knee at 0° of flexion). The Intraclass Correlation Coefficient (ICC: 0.832-0.993) and the Standard Error of Measurement (SEM: 0.803-0.971) were established by analysis of variance one way for each variable measured. We have applied matched t-test differences to determine statistical differences (SD) between dominant and non-dominant leg at p<0.05. Correlations were calculated through Pearson coefficient (r) between DS and right and left AROM mean values. **RESULTS:** No significant differences (ns) were found for dominant and non-dominant leg. Low correlation was found for dorsiflexion in bipedal position with partial load (r = 0.48; p <0.05) and seated with knee flexed at 90° (r = 0.39; p = 0.09 ns). However, a moderate correlation was found between the goniometric measurement of DS and dorsiflexion in the seat with 0° knee flexion (r = 0.61; p <0.01). **CONCLUSION:** Based on the results, we conclude that the DS measured objectively by goniometer has a moderate r with dorsiflexion seated with knee at 0° of flexion (gastrocnemius muscle length test). Therefore, in this sample, the DS test could be influenced by other determinants factors different from mobility, as they are the muscle strength, neuromuscular control and joint stability.

Association Between Strength Fitness And Gross Motor Function In Children: A Us National Study

Zezhao Chen¹, Jingyuan Zhu¹, Suda Xu², Weimo Zhu, FACSM¹. ¹University of Illinois at Urbana Champaign, Urbana, IL. ²Parkland College, Champaign, IL. Email: zezhao.chen86@gmail.com (No relevant relationships reported)

Zezhao Chen¹, Jingyuan Zhu¹, Suda Xu² & Weimo Zhu, FACSM¹ ¹University of Illinois at Urbana Champaign, Champaign, IL. ²Parkland College, Champaign, IL
 It was believed that children with better motor function and skills will be likely more physically active. Yet, contribution of fitness, especially muscular strength, to children’s motor function and skill has not been well understood. **Purpose:** To examine the relationship between core and upper-body strength and gross motor function in children using a US national sample. **Methods:** Three data sets in the 2012 National Youth Fitness Survey (NNYFS) were merged: Test of Gross Motor Development – Second Edition (TGMD-2), modified pull-up, and plank. TGMD-2 total score (TGMD-2 TS) was calculated by adding “Local

motor subtest raw score” and “Object control subtest raw score” together. Descriptive statistics and correlations of TGMD-2 TS, “# of correctly completed modified pull-ups (M-Pull-up)”, and “# of seconds planks position is held (Planks)” were computed using the 2012 NNYFS data.

Result: A total of 6375389 of boys and 6134317 of girls who aged between 3 and 5 yr. old participated in 2012 NNYFS, and their performances (M±SD) in gross motor function and fitness, as well as their correlations (r), are summarized below:

	Boy			Girl		
Age (yr.)	3	4	5	3	4	5
TGMD-2 TS	37.8814.79	49.8515.95	60.5515.29	34.259.46	50.5012.60	60.0113.16
M-Pull-up			2.082.75			2.282.92
Plank	10.286.29	15.7014.87	24.6123.52	12.8910.02	21.9419.25	28.5521.38
r, TGMD-T vs. Plank	0.07	0.12	0.38	0.3	0.38	0.56
r, TGMD-T vs. M-Pull-up			0.43			0.25
r, M-Pull-up vs. Plank			0.35			0.30

Conclusion: As children become older, core and upper-body strength seems playing a positive impact on children’s gross motor function in both boys and girls.

The Pedi-CHAMP Agility Test: Completion Rates For Typically Developing Children Aged 5 To 17yrs

Kirsten Tulchin-Francis, Wilshaw Stevens, Anthony Anderson, Kelly Jeans. Texas Scottish Rite Hospital for Children, Dallas, TX. Email: Kirsten.Tulchin-Francis@tsrh.org Reported Relationships: K. Tulchin-Francis: Ownership/interest/stock; Maxim Integrated.

The Comprehensive High-Level Activity Mobility Predictor (CHAMP) was developed to assess the rehabilitation and performance in active military service-members who sustained traumatic injury. A pediatric version of this 4-part agility test (the Pedi-CHAMP) has been adapted for use in children aged 5 to 17 years. The Pedi-CHAMP consists of a) 30sec single limb stance (SLS) on each leg, b) a modified Edgren Side-Step Test (Edgren) consisting of 3 continuous repetitions of side-step movements in each direction over a 4m course c) an L-test (10m forward, 10m side-step in each direction, 10m backwards) and d) the Illinois Agility Test (IAT) triple shuttle run with directional weaving on the second pass.

PURPOSE: To assess the completion rate of each portion of the Pedi-CHAMP in typically developing children aged 5 to 17 years.

METHODS: With IRB-approval, 1,093 children (574 females, average age 11.0±3.9yrs (range 5.0-17.9yrs) were tested and included for analysis. Each participant was given two attempts to complete each portion of the test. If one attempt was unsuccessful or disqualified based on performance, a third attempt was offered. Participants were grouped by age (rounded down to the nearest year) and sex (male/female). A complete test was noted if the participant was able to follow directions and did not demonstrate any performance deemed to disqualify the trial (missed end line/ cone, failed to maintain proper body position during side step, etc.)

RESULTS: All participants were able to follow the directions and perform the SLS test. It should be noted, however, that 29% were not able to maintain balance for 30 secs on one or both legs. The SLS rate of completion was higher in girls than boys for children aged 5 to 11 years. The overall completion rates for the modified Edgren and L-test tasks were 93% and 92%, respectively. Similar trends between sexes were seen for both tests, with completion rates improving from 74% (Edgren) and 69% (L-Test) in children aged 5yrs to <90% by 8yrs of age. The Illinois Agility Test (IAT) had an overall completion rate of 99%, with all age-sex groups achieving at least 92% completion.

CONCLUSION: The Pedi-CHAMP is a 4-part agility test that can be successfully administered in typically developing children aged 5 to 17yrs.

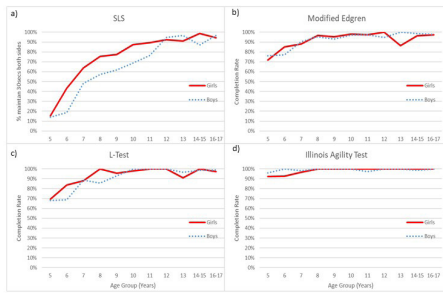

Figure 1. a) Percentage of participants who were able to maintain single limb balance for 30secs on each side; b-d) Completion rates for the modified Edgren, L-Test and Illinois Agility tests. Data for N=1,089 participants grouped by age and gender.

Effects Of Aerobic Training With Different RPEs To Double Poling Performance In Adolescent XC Skiers
 Rasmus Pind, Priit Purge, Evelin Mäestu, Eno Vahtra, Jarek Mäestu. *University of Tartu, Tartu, Estonia.*
 Email: rasmus.pind@ut.ee
 (No relevant relationships reported)

Cross-country (XC) skiers frequently perform low intensity training sessions to improve their endurance capacity or for recovery from hard sessions. It is well known that exercise performed below a certain threshold intensity, adaptational responses will only occur after a certain duration. Rating of perceived exertion (RPE) scale may be helpful to identify reference markers for intensity-duration relationship. Such reference markers, especially during low intensity trainings, could help to improve exercise training in XC skiers' performance.

PURPOSE: To investigate adaptation of low intensity sessions, by means of session RPE (sRPE) in two groups of adolescent XC skiers with different RPEs on double poling performance after 1-week pre-competitive season training camp. **METHODS:** Thirteen national level XC skiers (13.4±1.9 yrs; VO_{2max} 51.2±8.0 ml·min⁻¹·kg⁻¹) participated in a 1-week camp in preparatory period. Pre- and post-camp double poling performance was measured with incremental exercise test on the ski ergometer. All XC skiers trained with the same training program. Based on the athletes' RPE values they were divided into two groups. Group1, who rated their trainings lighter and a Group2 who rated trainings harder compared to the median rating of all trainings. **RESULTS:** After excluding the intensive training session, Group1 average RPE rating was significantly higher compared to Group2 (3.09±0.90 vs 4.94±1.84, respectively) and total sRPE was also higher in Group2 compared to Group1 (4010±765 vs 2499±193 AU, respectively), while total training time was not different (796±41 vs 786±55 min, p<0.05). No significant differences were found in time spent in different HR zones between the two groups. Progression in ski ergometer performance in Group1 was 10.0% (ES=0.18, small), while in Group2 the progression was 12.0% (ES=0.39, moderate). **CONCLUSION:** Despite training with similar training plan, adolescent XC skiers experience training load differently. This leads to differences in performance changes, highlighting the importance of individual volume-intensity description. Supported by NRC Grant no. PUT1395G.

The Relationship Between Core Strength And Sportive Performance In Adolescent Female Soccer Players
 Ceyda Sevinc¹, Nevin Ergun, FACSM². ¹Hacettepe University, Ankara, Turkey. ²Sanko University, Gaziantep, Turkey.
 Email: ceydasarial@gmail.com
 (No relevant relationships reported)

PURPOSE: The effect of the strength of the core muscles on the sportive performance is still a controversial issue. At the same time, there is very little research on female soccer players on this topic. The aim of this study was to search the relationship between core strength and sportive performance in adolescent female soccer players. **METHODS:** Thirty-six (mean age 16.5±1.1 years, BMI: 20.3±2.1 kg/m²) woman soccer players were included in this study. Core strength was evaluated by isokinetic dynamometer at the velocity of 60°/s and front abdominal power test. In the assessment of the sportive performance vertical jump test, 20 m sprint test and T-test were used. Spearman and Pearson correlation tests were used to compare the correlation between core strength and sportive performance.

RESULTS: The correlation between isokinetic flexor muscle strength at 60°/s velocity and vertical jump peak power (r = .643, p<.05); 20 m sprint performance (r = -.629, p<.05); T test performance (r = -.510, p<.05) were determined. The correlation between isokinetic extensor muscle strength at 60°/s velocity and vertical jump peak power (r = .657, p<.05); 20 m sprint performance (r = -.714, p<.05); T test performance (r = -.442,

p<.05) were determined. The correlation between front abdominal power test and vertical jump peak power (r = .737, p<.05); 20 m sprint (r = -.683, p<.05); T test (r = -.574, p<.05) were determined.

CONCLUSIONS: Core strength was correlated with sportive performances of adolescent female soccer players. The relationship between core strength and sportive performance tests reveals the importance of trunk strength in improving sportive performance. For this reason, we recommend that athletes' training programs should include exercises improving trunk strength. In addition to this, athletes should be informed about core strength's importance by physiotherapists or coaches.

Us Children Became Heavier And Unfit To Make Another Pull-up Test Failing
 Weimo Zhu, FACSM, Jin Yan. *University of Illinois at Urbana-Champaign, Urbana, IL.*
 Email: weimozhu@uiuc.edu
 (No relevant relationships reported)

PURPOSE: Since too many children and youth, especially girls, cannot perform a single chin-up, a modified pull-up (M-Pull-Up) test was developed (Pate et al., 1987), in which a test taker only pulls up only partial his/her body weight, and was used in the 2nd National Children and Youth Fitness Study (NCYFS II) in 1987. This study was to determine if M-Pull-Up could still eliminate the "zero score" problem for the current children population.

METHOD: The modified pull-up data of 6-9 yr. old (N = 4678) from the 2012 NHANES National Youth Fitness Survey (NNYFS, N= 494), were compared with the modified pull-up data from NCYFS II. Statistics, including median, interquartile range, cumulative frequency distributions for scores from 0 to 10, and correlations, were used for the analyses.

RESULTS: Between 1987 and 2012, 6-9 yr. children, on average, got slightly shorter (boys = -0.05 cm, girls = -0.2 cm), heavier (Weight: boys = +5.19 kg, girls = + 4.13 kg; BMI: boys = +1.31, girls = +1.14), less # of pull-ups (boys = -4.75, girls = -5). The "zero score" rates (%) in 1987 for 6-, 7-, 8-, 9-yr.-old boys were 7.16, 5.11, 2.60, and 2.61, respectively and for 6-, 7-, 8-, 9-yr.-old girls were 9.41, 6.29, 5.69, and 5.92, respectively; the corresponding "zero scores" rates in 2012 were increased to 22.86, 6.45, 16.67, and 26.92 for boys, respectively and to 19.67, 30.65, 21.43, and 30.00 for girls, respectively.

CONCLUSION: The US children became heavier and less fit, which made another easier pull-up test failing.

B-14 Free Communication/Slide - All in the Wrist: Development and Application of Methods for Wrist-worn Devices

Deep Learning Approach To Recognize Physical Activity Type From Wrist-worn Tri-axial Accelerometer
 Mamoun T. Mardini¹, Subhash Nerella¹, Duane B. Corbett¹, Amal Wanigatunga², Todd Manini, FACSM¹. ¹University of Florida, Gainesville, FL. ²Johns Hopkins, Baltimore, MD.
 Email: malmardini@ufl.edu
 (No relevant relationships reported)

PURPOSE: Wrist accelerometers for assessing physical activity type and intensity are rapidly growing with the advent of smartwatch technology in both public and research arenas. There is a necessity to enhance the accuracy of the wrist models in estimating hallmark measures of physical activities. The purpose of this study is to compare the performance of conventional machine learning and deep learning networks in recognizing physical activity type and estimating energy expenditure using raw data from wrist-worn tri-axial accelerometer.

METHODS: Participants (95 women and 46 men, aged 20-89 yrs) performed a battery of 31 typical daily activities in a standardized laboratory setting (e.g. washing dishes, walking) while a tri-axial accelerometer collected data at 100 Hz on the right wrist. A portable metabolic unit was worn to measure metabolic intensity (ml/min of oxygen consumption) that was expressed as a relative metabolic equivalent (MET=(ml/kg/min)/3.5). Deep learning networks comprising of convolutional neural networks

(CNN) and long-short-term memory (LSTM) were used to extract spatial and temporal representations from the raw accelerometry data. These representations were used to estimate energy expenditure and to recognize physical activity type. As a comparison, random forest algorithm was also used to estimate energy expenditure and recognize activity type from seven time and frequency domain features extracted from the raw data.

RESULTS: Deep learning networks resulted in high performance in recognizing physical activity type and estimating energy expenditure. The balanced accuracy was: 88%, 93%, and 92% for recognizing locomotor, lifestyle and sedentary activities, respectively. Random forest resulted in a slightly lower accuracy for the same set of tasks (78%, 91%, and 86%). The root mean square error for estimating energy expenditure using deep learning networks was slightly lower at 0.74 compared to 0.78 using random forest.

CONCLUSIONS: Deep learning models built using raw data from wrist-worn accelerometer data outperformed conventional machine learning algorithms such as random forest. These results show the efficacy of deep learning in extracting representation from the raw data without the need to relying on first creating a feature set that requires domain expertise.

A Novel Method To Estimate Free-living Physical Behaviors From A Wrist-Worn ActiGraph™ Accelerometer

Greg J. Petrucci, Jr., Robert T. Marcotte, Melanna F. Cox, Patty S. Freedson, FACSM, John Staudenmayer, John R. Sirard, FACSM. *University of Massachusetts, Amherst, MA.* (Sponsor: John R. Sirard, PhD., FACSM)
 Email: gpetrucci@umass.edu

(No relevant relationships reported)

BACKGROUND: Despite the proliferation of body-worn sensors to assess physical behaviors (e.g. physical activity and sedentary behavior; PBs), processing accelerometer data collected from free-living (FL) individuals remains a challenge.

PURPOSE: To develop a method to estimate FL PBs from wrist-worn ActiGraph accelerometer count data.

METHODS: Forty-nine participants (X +/- SD age:20.4±1.3 yrs, 45.8% male) wore an ActiGraph wGT3X-BT on their non-dominant wrist during four, 1-hour FL sessions. Sessions were video-recorded and coded using a direct observation (DO) system that provided criterion measures, including intensity category. All steps in the novel method were developed using a subset (n=44) of participants and tested on the remaining (n=5). The first step identifies inactive bouts (e.g. sedentary and standing behaviors) using a vector-magnitude threshold, chosen via a grid-search to maximize the positive predictive value (PPV) of inactive classification. The second step uses statistical features of the count data and bout length (seconds) as inputs to random forest models to estimate active (light, moderate, vigorous) vs inactive periods. Percent agreement between criterion-measured (DO) and method estimated PB was evaluated using second-by-second data. Gini impurity index was used to measure the importance of statistical features used as inputs to the random forest models.

RESULTS: The first step identified a vector magnitude threshold that resulted in a PPV 95.71% for inactive classification. In the holdout sample, steps 1 and 2 correctly classified 84.1% of inactive and active bouts. Gini impurity index revealed that bout length (seconds) was most important among statistical features.

CONCLUSIONS: The new method performed well at estimating FL PBs from wrist-worn ActiGraph accelerometer counts. Future work should investigate how to improve method estimates using PB bout duration and other novel accelerometer statistical features. Supported by NIH NIDDK 1R01DK110148

A Method To Estimate Free-living Behaviors Using High-frequency Wrist Accelerometer Data

Robert T. Marcotte, Greg J. Petrucci, Melanna F. Cox, Patty S. Freedson, FACSM, John W. Staudenmayer, John R. Sirard, FACSM. *University of Massachusetts Amherst, Amherst, MA.* (Sponsor: John R. Sirard, FACSM)
 Email: rmarcotte@umass.edu

(No relevant relationships reported)

PURPOSE: To develop a novel method to estimate free-living sedentary behavior and activity intensity using high-frequency wrist accelerometer data. **METHODS:** Forty-nine participants (mean ± SD; age: 20.4±1.3 yrs, 45.8% male) completed four, 1-hour sessions of free-living behaviors in home, school, community, and exercise environments. Each session was video-recorded (DO) and participants wore an ActiGraph wGT3X-BT (AG) accelerometer on the non-dominant wrist. Videos were coded for whole body movement, contextual activity type, and activity intensity from the Compendium of Physical Activities (e.g. walking, shopping, 2.8 METs). The novel two-step method (SojWrist) first segments AG data into bouts, or “sojourns”, of inactivity (i.e. sedentary and standing behaviors) or activity using an acceleration

standard deviation threshold and random forest model. The second step estimates the intensity of inactive (sedentary, light) and active (light, moderate, vigorous) sojourns. Separate inactive and active sojourn RF models were fit to estimate intensity using bout duration and time- and frequency-domain AG signal characteristics. A 90-10 sample split was used for SojWrist development (N = 44) and cross-validation (N=5). Percent agreement between DO and SojWrist was evaluated at each step using second-by-second data. **RESULTS:** In the cross-validation sample, 91.8% [95%CI: 87.0%, 96.5%] of inactive and active periods were classified correctly from step 1 of SojWrist. After step 2, overall percent agreement between DO and SojWrist was 86.9% [95%CI: 78.9%, 95.0%] across all intensity categories (Table). **CONCLUSION:** The new SojWrist performed well at estimating free-living activity intensity categories from a wrist worn accelerometer. Future work should strive to improve method performance for predicting activity intensity categories and test validity on a diverse, independent, free-living sample. Supported by NIH NIDDK 1R01DK110148

Does Heart Rate Improve Prediction Of Oxygen Uptake From Hip Or Wrist Accelerometer Output In Adults With Down Syndrome?

Slater H. Richardson, Caleb S. McCreary, Poram Choi, Supreeta Ghosh, Stamatis Agiovlasis, FACSM. *Mississippi State University, Mississippi State, MS.* (Sponsor: Dr. Stamatis Agiovlasis, FACSM)
 Email: shr83@msstate.edu

(No relevant relationships reported)

Heart rate (HR) may improve the prediction of the rate of oxygen uptake (VO₂) from accelerometer output, but this has not been examined in adults with Down syndrome (DS). Addressing this issue may have implications for accelerometer-based measurement of physical activity and sedentary behavior in adults with DS. **PURPOSE:** To examine if HR improves VO₂ prediction from hip- and wrist-accelerometer output in adults with DS. **METHODS:** Sixteen adults with DS (10 men; age 31 ± 15 years) performed 12 tasks including physical activities and sedentary behaviors. VO₂ was measured with portable spirometry (K4b², Cosmed) and accelerometer output (Vector Magnitude [VM] with a hip- and a wrist-worn accelerometer (wGT3X-BT, Actigraph). We used multi-level regression to predict VO₂ from VM alone and VM and HR together. We evaluated prediction accuracy with the absolute percent error and Bland-Altman plots. Analyses were run separately for hip and wrist accelerometer VM. **RESULTS:** Both hip- and wrist-derived VM significantly predicted VO₂ (p <0.001; R² = 0.74 and 0.49 for hip and wrist model, respectively). HR significantly contributed to both models (p <0.001; R² = 0.73 and 0.55 for hip and wrist model, respectively). For hip data, absolute error did not differ significantly between the model with VM alone and the model with VM and HR (24 ± 27 and 26 ± 27%, respectively; p = 0.15). For wrist data, absolute error was higher for the model with VM alone than the model with VM and HR (43 ± 39 and 37 ± 38%, respectively; p = 0.017). Bland-Altman plots indicated zero mean error for all models and limits of agreement were wider for wrist- than hip-models. For hip-models, limits of agreement were similar between VM alone and VM and HR (-5.6 to 5.6 and -5.8 to 5.6 ml kg⁻¹ min⁻¹, respectively). For wrist-models, limits of agreement were somewhat wider for VM alone than VM and HR (-7.9 to 7.6 and -7.4 to 7.1 ml kg⁻¹ min⁻¹, respectively). **CONCLUSION:** Inclusion of HR does not improve prediction of VO₂ from hip-accelerometer VM in adults with DS. HR may slightly improve prediction of VO₂ from wrist-accelerometer VM. Overall, hip-accelerometer VM is better than wrist-accelerometer VM at prediction of VO₂ during physical activities and sedentary behaviors in adults with DS. Supported by NIH Grant R15HD098660

Sedentary Time And Markers Of Physical Function In Those With Established Type 2 Diabetes

Joseph Henson¹, Andrew Hall², Thomas Yates¹, Emma Baldry², Emer Brady¹, Charlotte L. Edwardson¹, Alex V. Rowlands¹, Melanie J. Davies². ¹University of Leicester, Leicester, United Kingdom. ²University Hospitals of Leicester, Leicester, United Kingdom.

Email: jjh18@le.ac.uk

(No relevant relationships reported)

PURPOSE: An accelerated ageing process places those with type 2 diabetes mellitus (T2DM) at risk of physical functional impairments at a younger age. Although the importance of moderate-to-vigorous physical activity (MVPA) is acknowledged, emerging research suggests that sedentary time may be also important. Therefore, the aim was to examine cross-sectional associations between device-assessed sedentary time and markers of physical function in a population with T2DM and to determine whether associations were modified by the recommended levels of MVPA.

METHODS: Participants with T2DM (>6months), aged 18-75 years were recruited as part of an ongoing, cross-sectional study (CODEC) conducted in the Midlands, UK. Participants were asked to wear an accelerometer (GENEActiv, ActivInsights Ltd, Kimbolton, UK) on their non-dominant wrist for 7 days to quantify habitual levels of sedentary time and MVPA. Generalised linear models examined the associations between sedentary time, the short physical performance battery (SPPB), the sit-to-stand 60 second test (STS60) and 4 metre timed walk. Interaction terms determined whether results were consistent across MVPA categories (active [$>150\text{min/wk}$ of MVPA] vs. inactive [$<150\text{min/wk}$ of MVPA])

RESULTS: 621 participants had valid accelerometer and physical function data (age 63.6±8.4 years, 34.5% female, BMI=31.0±5.0kg/m²). Following adjustment for various covariates, including age, sex, ethnicity, medication and MVPA, sedentary time was detrimentally associated with SPPB score, STS60 reps and walk time. When results were stratified by MVPA (active (24.5%) vs. inactive (75.5%)), each 60 minutes of sedentary time was associated with a 0.3 lower SPPB score (p=0.020), 1.4 fewer STS60 reps (p=0.016) and 0.2s longer walk time (p=0.043) in the inactive group only. No significant associations were found in the active group.

CONCLUSION: Sedentary time is adversely associated with markers of physical function, but associations were only present in those individuals who do not meet current physical activity recommendations for health. Along with promoting MVPA, future therapeutic interventions that focus on reducing sedentary time in those with T2DM and impaired physical function may be warranted in inactive individuals. Agreement Between Fitbit And Actigraph Estimates Of Physical Activity In Young Children

Michael D. Schmidt, Stephen Rathbun, Zhixuan Chu, Benjamin D. Boudreaux, Lindsay Hahn, Kyle Johnsen, Sun Joo Ahn.

University of Georgia, Athens, GA.

Email: schmidt@m@uga.edu

(No relevant relationships reported)

Commercial wearables are used to track physical activity (PA) levels in children and as tools for increasing PA participation in youth. However, few studies have examined the agreement between commercial and research grade devices in assessing PA in children.

PURPOSE: To compare estimates from a wrist-worn Fitbit Flex 2 to a waist-worn Actigraph GT9X Link in elementary school children. **METHODS:** Forty children aged 6-10 years wore a Fitbit Flex 2 (on non-dominant wrist) and an Actigraph GT9X Link (on waist) for up to two weeks while school was in session. Children were instructed to wear the Fitbit continuously and to wear the Actigraph during all waking hours. Parents were given wear reminders via text each morning. For each device, an adapted Choi algorithm was used to flag non-wear periods (defined as ≥ 90 minutes of continuous 0 step values). Steps and intensity-specific estimates of daily PA from each device were averaged across time periods when both devices were worn simultaneously, and estimates were compared using days with 10+ h of concordant wear and using all available data. **RESULTS:** Across 91 days with concordant device wear of 10+ h, Fitbit estimates were 25% higher for steps (Mean±SD = 10318±3846 steps) and 44% higher for vigorous intensity PA (16.2±22.1 min) compared to the Actigraph GT9X Link (8260±3614 steps; 11.3±15.9 min). In contrast, Fitbit estimates of moderate intensity PA (26.8±21.1 min) were 20% lower than Actigraph estimates (33.3±24.3 min). Pearson correlations between device estimates were higher for steps (r=0.62) than for moderate (r=0.55) or vigorous (r=0.28) intensity PA. Similar patterns were observed when all available concordant data were analyzed (n=377 days), with the Fitbit recording 20% more steps, 28% less moderate PA, and 36% more vigorous PA than the Actigraph. **CONCLUSIONS:** Wrist-worn consumer wearables may produce higher estimates of steps and vigorous intensity PA, and lower estimates of

moderate intensity PA, in elementary school children. Absent additional evidence, consumers and researchers should be cautious when using wrist-worn consumer devices to assess absolute levels of PA in youth.

Do GPS Capable Fitness Watches Accurately Measure Exercise Distances?

David Q. Thomas, FACSM, Adam Jagodinsky, Delaney Mahoney, Ryan Schwerzler, Tessa Gridley, Catherine Guiffre.

Illinois State University, Normal, IL.

(No relevant relationships reported)

Fitness watches have become popular for assessing activity habits. Manufacturers of GPS capable activity monitors claim their devices provide valid and reliable measures of distances traveled. **PURPOSE:** To determine if six popular physical activity watches provide accurate measures of GPS recorded distances. **METHODS:** An Apple Watch (AW), Fitbit Ionic (FI), Fitbit Versa (FV), Garmin Vivosport (GVS), Garmin Vivoactive 3 (GVA), and a Garmin ForeRunner 35 (GF) were all tested on indoor and outdoor oval tracks, an outdoor walking trail and a zig-zag pattern course. Twenty trials were performed on each course by the same researcher. An industrial TR 88016 FX Series collapsible measuring wheel established actual distance (200 m). Two watches were worn at the same time on the left arm. Each watch was set to walking and their GPS signal was turned on and connected. Distance measured by the wheel and each watch was recorded. Means, standard deviations, and percent relative error were calculated for the GPS distance of each watch. **RESULTS:** For the outdoor trail condition, the results showed distances ranging from 180.0 to 204.4 m (FI: 180.2 m, 10.4%, FV: 186.6 m, 7.6%, GVA: 200.7 m, 4.0%, AW: 201.1 m, 4.2%, GVS: 204.4 m, 4.8%, GF: 204.4 m, 4.4%). For the zig-zag course condition, the range was from 184.2 to 204.4 m (GVS: 184.2 m, 4.1%, GF: 189.0 m, 6.0%, FI: 189.8 m, 5.6%, FV: 197.9 m, 4.0%, AW: 197.9 m, 4.0%, GVA: 204.4 m, 4.1%). For the outdoor track, the range was from 179.3 to 204.4 m (FV: 179.3 m, 10.8%, AW: 189.8 m, 5.6%, FI: 195.5 m, 4.8%, GVS: 200.3 m, 4.0%, GVA: 202.8 m, 4.0%, GF: 204.4 m, 4.1%). For the indoor track, the range was from 164.2 to 169.0 m (FI: 164.2 m, 18.3%, AW: 169.0 m, 16%). All Garmin devices failed to record an indoor measurement. **CONCLUSIONS:** The least and most accurate measurements for each condition were: trail (FI and GVA), zig-zag (GVS and FV), outdoor track (FV and GVS) and indoor track (FI and AW), respectively. The Garmins were the most accurate for the outdoor track with all exhibiting a 4.0% error. Indoor, all devices were less accurate. Only AW and FI had functioning GPS indoor and showed their most error in this setting. Caution must be used when relying on physical activity monitors if accuracy is desired in measuring distance via GPS.

Calibrating Physical Activity And Sedentary Behavior For Wrist-worn Accelerometry In Women 60 Years And Older

Kelly R. Evenson, FACSM¹, Fang Wen¹, Chongzhi Di², Andrea Z. LaCroix³, Cora E. Lewis⁴, Michael J. LaMonte, FACSM⁵, I-Min Lee, FACSM⁶, Eileen Rillamas-Sun², Lesley Fels Tinker², David M. Buchner, FACSM⁷. ¹University of North Carolina - Chapel Hill, Chapel Hill, NC. ²Fred Hutchinson Cancer Research Center, Seattle, WA. ³University of California - San Diego, San Diego, CA. ⁴University of Alabama - Birmingham, Birmingham, AL. ⁵University at Buffalo - SUNY, Buffalo, NY. ⁶Harvard Medical School, Boston, MA. ⁷University of Illinois at Urbana-Champaign, Champaign, IL.

(No relevant relationships reported)

PURPOSE: While emerging approaches for defining physical activity and sedentary behavior using accelerometry exist, cutpoint-based definitions remain a frequent convention. We explored whether a calibration study could contribute to wrist-worn accelerometer count cutpoints among women ≥ 60 years.

METHODS: Women (n=199) 60-91 years wore an ActiGraph GT3X+ accelerometer on their left wrist while performing eight structured activities. Intensity was continuously measured using an Oxycon portable indirect calorimeter. Accelerometer data were analyzed in 15-second epochs with both normal and low frequency extension (LFE) filters. Receiver operating characteristic (ROC) curves were used to calculate cutpoints for sedentary behavior, light (low and high), and moderate to vigorous physical activity (MVPA) using vertical axis and vector magnitude (VM) counts. Cutpoints were selected that balanced the number of false positives and false negatives using three different classifications: one based on specific activities and two based on measured metabolic equivalents (e.g., 1 MET=3.0 or 3.5 ml/kg/min). Area under the ROC curves (AUC) were interpreted as excellent (0.90-1.00), good (0.80-0.89), fair (0.70-0.79), poor (0.60-0.69), or failure (≤ 0.59).

RESULTS: Average VM counts/15-sec varied by activities: 76 watch DVD, 675 assemble puzzle, 836 mopping, 1875 wash/dry dishes, 2180 laundry, 570 walk

1.5 mph, 637 walk 2.0 mph, 1132 walk 2.5 mph, and 1094 400 meter walk. Of the three cutpoint classifications, activity types performed best based on sensitivity and specificity. Using the normal filter, the AUC was good for sedentary cutpoints (vertical axis 0.88; VM 0.88), but was fair to poor for light high intensity (vertical axis 0.74; VM 0.64) and failed for MVPA (vertical axis 0.50; VM 0.50). Findings were similar when using the LFE filter, with only sedentary results indicating good to excellent results (vertical axis 0.90; VM 0.89).

CONCLUSION: This approach provided useful sedentary but not physical activity indicators for wrist-worn accelerometry counts. Further research is needed to understand whether wrist-worn accelerometry can accurately measure higher intensity physical activity in older adults.

B-15 Free Communication/Slide - Clinical Exercise Testing

640 May 27 1:00 PM - 1:15 PM Calf Muscle Oxygenation Limits Maximal Respiratory Performance During Incremental Walking Test In Obese Children

Louis Toulouse¹, Patrick Mucci², Pierre Morel¹, Christophe Aron³, Gautier Zunquin⁴. ¹Université du Littoral Côte d'Opale, Dunkerque, France. ²Université de Lille, Lille, France. ³Hôpital Maritime de Zuydcoote, Zuydcoote, France. ⁴Université Pau Pays de l'Adour, Anglet, France.
Email: louis.toulouse@etu.univ-littoral.fr
(No relevant relationships reported)

PURPOSE: To study the interrelationship between respiratory and muscle haemodynamic responses during an incremental exercise in overweight children and confirm the limitations clinically observed that lead to the premature termination of an aerobic fitness test.

METHODS: Twenty-four overweight children (12 girls and 12 boys) performed a progressive maximal treadmill test during which the slope increases every minute. Changes in muscle oxygen (O_2) supply were continuously assessed using near-infrared spectroscopy. Pulmonary gas exchanges and heart rate (HR) were measured. For each participant, changes in deoxyhemoglobin level ($\Delta[Hb]$) in the medial head of the gastrocnemius muscle were expressed as a function of time, then as a percentage of peak of oxygen uptake (VO_2 peak). The influence of the sex, BMI and maturation on breakpoint in muscle desoxyhemoglobin (BP_{Hb}) was assessed with linear model effects.

RESULTS: Girls reach lower VO_2 peak than boys ($p = 0.07$). A BP_{Hb} occurred during the test in 9 girls and 6 boys and was strongly correlated with VO_2 peak ($r = 0.80$, $p < 0.001$). Expressed as a percentage of maximal theoretical value, HR peak tended to be higher in non BP_{Hb} (94.7 ± 5) than in BP_{Hb} (89.9 ± 8) participants ($p = 0.1$). Current data suggests that a lower maturation and lower BMI are the two main factors that delay the onset of BP_{Hb} .

CONCLUSIONS: Oxygenation of the calf muscle could limit maximal respiratory performance during an incremental walking test with a slope, especially in prepubere obese children who have lower BMI. Muscle limitations should be considered when choosing a protocol to assess VO_2 peak in this population.

641 May 27 1:15 PM - 1:30 PM High Peak Exercise Blood Pressure In Athletes Is Proportional To Exercise Capacity.

Email: kristel.janssens@baker.edu.au
(No relevant relationships reported)

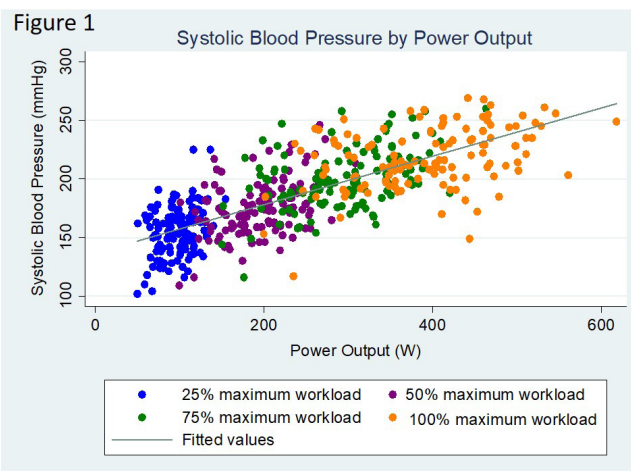

An abnormal blood pressure (BP) response to exercise is an important physiological variable associated with a risk of sub-clinical hypertension. Reference values are poorly defined and lack contextualization to physiological demands that can be obtained among very active populations.

PURPOSE: To assess the relationship between systolic BP (SBP) and workload and to determine reference values of SBP response to exercise in endurance athletes.

METHODS: We recruited 123 current and former endurance athletes (76% male), aged 16-80 years. BP was measured every 2 min during a maximal bicycle cardiopulmonary exercise test using a TangoM2 automated BP monitor. Relationship between SBP measured at 25%, 50%, 75% and 100% of maximum workload and power output during exercise were determined by linear regression analysis using STATA software.

RESULTS: SBP increased from 128 ± 13 mmHg in males (age 40 ± 18 years) and 116 ± 12 mmHg in females (age 35 ± 14 years) to peak 223 ± 27 mmHg and 203 ± 19 mmHg, respectively ($P < 0.0001$). The majority of participants demonstrated an exaggerated SBP response to exercise (72% of males and 82% of females) as defined by the American Heart Association guidelines. There was a strong correlation between power output and SBP ($r^2 = 0.67$, $P < 0.001$, Figure 1). Males achieved $123 \pm 18\%$ and females $134 \pm 26\%$ of their predicted VO_2 max ($P < 0.01$). There was no statistical difference in exercise SBP response according to age or BMI. Gender and hypertensive medication did have a statistically significant, but weak correlation to SBP ($P < 0.01$ and $P < 0.001$ respectively $r^2 = 0.03$ for both).

CONCLUSION: High SBP values are observed in athletes at peak exercise, frequently exceeding 'normal value' definitions. However, SBP increases can be explained by the supra-normal exercise capacity, thus, should be considered in the context of exercise capacity.

$r^2 = 0.67$, $p < 0.001$

642 May 27 1:30 PM - 1:45 PM Aerobic Fitness Is Related To Sports Participation In Children With Congenital Heart Disease

Astrid-Marie De Souza¹, Kathryn Armstrong¹, Nicholas Tran², Kaelan C. Naylor², Hilary V. Romans¹, James E. Potts¹, Martin C. K. Hosking¹, David C. Clarke³. ¹BC Children's Hospital, Vancouver, BC, Canada. ²Simon Fraser University, Burnaby, BC, Canada. ³Simon Fraser University, Vancouver, BC, Canada.
Email: adesouza2@cw.bc.ca
(No relevant relationships reported)

Purpose: Underlying structural lesions in congenital heart disease (CHD) result in differences in anatomy and physiology that may affect peak aerobic capacity (VO_{2peak}). The relationship between sports participation and VO_{2peak} is unclear in these patients. The aim of this study was to determine if children with CHD who participated in sports had a higher VO_{2peak} than those who did not.

Methods: Two-year, single-centre, retrospective review (May 2016-November 2018). Fifty-eight CHD patients were included based on diagnosis: 9 aortic valve disease; 13 coarctation; 6 Ross procedure; 20 tetralogy of Fallot, and 10 transposition of the great arteries. Sports participation was assessed by an ACSM Clinical Exercise Physiologist at the time of testing and categorized into 3 groups: 0-1 day/week; 2-3 days/week; ≥ 4 days/week. A validated institutional treadmill protocol (BCCH) was used. The criteria for a maximal test included: VO_2 plateau, respiratory exchange ratio > 1.0 , and/or a peak heart rate > 200 bpm. VO_{2peak} Z-scores¹, gas exchange threshold (GET) and O_2 Pulse were calculated. Data are reported in frequency tables and as medians and interquartile ranges. Kruskal-Wallis and Mann Whitney U tests were used to test for group differences. $P < 0.05$ was considered statistically significant.

Results:

	Sports Participation			P
	0-1 day/week n=17	2-3 days/week n=30	≥4 days/week n=11	
Age (years)	15.6 (13.5,17.8)	15.5 (13.7,17.2)	15.0 (14.0,16.1)	NS
VO _{2peak} (mL/min/kg)	30.3 (27.8,39.6)	39.9 (34.6,48.1)	44.7 (41.3,51.5)	<0.001
VO _{2peak} Z-Score	-1.89 (-2.37,-1.16)	-0.84 (-1.28,-0.30)	-0.78 (-0.88,0.05)	0.002
%VO _{2peak} @ GET	52 (45,65)	61 (45,69)	57 (44,65)	NS
O ₂ Pulse (mL/beat/kg)	0.16 (0.14,0.21)	0.20 (0.19,0.25)	0.23 (0.21,0.28)	0.004

Those who participated in sports 2-3 days/week or more had a significantly higher VO_{2peak}, VO_{2peak} Z-score, GET and O₂ Pulse than those with 0-1 day/week (Table 1). There were no differences between those who participated in sports 2-3 days/week compared to ≥4 days/week. VO_{2peak} was similar between CHD cohorts (p=0.21). Conclusions: VO_{2peak} is higher in those who participate in sports compared to those who do not. It is unclear whether those who have a higher VO_{2peak} are more inclined to participate in sports or whether sports participation leads to a higher VO_{2peak} these CHD patients. The role of exercise rehabilitation in the 0-1 day/week group needs to be explored.

Symptom And Physiological Response To Exercise Following Concussion

David R. Howell¹, Danielle Hunt², Stacey E. Aaron³, J Andrew Taylor³, William P. Meehan, III³, Can Ozan Tan³. ¹Children's Hospital Colorado, Aurora, CO. ²Boston Children's Hospital, Boston, MA. ³Spaulding Rehabilitation Hospital, Cambridge, MA. (Sponsor: Louis Osternig, PhD, ATC, FACSM)
Email: David.Howell@CUAnschutz.edu

(No relevant relationships reported)

Exercise can exacerbate concussion symptoms, even when symptom are not apparent at rest. Whether this relates to a physiologic response to exercise remains unknown. **PURPOSE:** To examine symptom and physiologic responses to a stationary bike exercise protocol among participants with concussion and uninjured controls. **METHODS:** 32 concussed individuals (age=16.9±2 years; 50% female; 12.4±5 days post-injury) and 22 healthy controls (age=18.3±2 years; 59% female) completed a modified YMCA branching exercise protocol. After warmup (3 mins; 50 watts), participants progressed to Stage 1 (3 mins; 100 watts). Stage 2 was based on Stage 1 HR (2 mins; 175 watts if <60% age predicted HR; 150 watts if 60-70% age predicted HR; 125 watts if >70% age predicted max HR). Stages 3-5 lasted 2 mins, and increased by 50 watts/stage. Stopping criteria were symptom worsening (visual analog scale [VAS, 0 - 100] change>30) or 85% age-predicted HR. We assessed changes (end - baseline) for VAS, HR, systolic/diastolic blood pressure (SBP/DBP), rating of perceived exertion (RPE), carbon dioxide output (VCO₂), respiratory exchange ratio (RER), and oxygen consumption (VO₂). **RESULTS:** The concussion group reported significantly higher symptom severity at rest than controls (21.0±19.6 vs. 5.6±5.6; p=0.002). Resting HR (63.4±9.8 vs. 64.6±7.3) and protocol duration (11.3±2.0 vs. 11.5±1.3 minutes) were similar between groups. 22% of concussed participants stopped due to symptom exacerbation. Symptom change was not significantly different between groups (VAS= 10.4±16.1 vs. 4.7±11.2; p=0.18). The control group had significantly larger increase in DBP than the concussion group (6.1±5.7 vs. 1.4±4.8; p=0.003). VAS change was significantly associated with HR change among concussed (β=-0.45; 95% CI=-0.87, -0.02; p=0.04) and control groups (β=0.67; 95% CI=0.18, 1.17), and for control subjects, VAS change was associated with RPE (β=2.9; 95% CI=0.55, 5.22; p=0.02) and SPB (β=-0.73; 95% CI= -0.97, -0.48; p<0.001) changes. **CONCLUSIONS:** Using a branching bike-based exercise protocol, most participants achieved 85% age-predicted maximum HR, rather than symptom exacerbation. The amount of symptom provocation between groups was similar. Greater HR changes during exercise were associated with greater symptom provocation independent of group.

644 May 27 2:00 PM - 2:15 PM

VO₂/WR Slope And HR/VO₂ Slope Predict Major Adverse Events In Patients With Severe Heart Failure

Stephan Mueller¹, Jeffrey W. Christle², Kegan J. Moneghetti², Myriam Amsallem², Martin Halle¹, Francois Haddad², Jonathan Myers, FACSM³. ¹Klinikum rechts der Isar, Technical University of Munich, Munich, Germany. ²Stanford University, Stanford, CA. ³Veterans Affairs Palo Alto Health Care System, Palo Alto, CA.

Email: stephan.mueller@mri.tum.de

(No relevant relationships reported)

In chronic heart failure (CHF), cardiopulmonary exercise testing (CPET) yields key prognostic parameters. In addition to peak oxygen uptake (peakVO₂), ventilatory efficiency (VE/VCO₂ slope) and exercise oscillatory ventilation (EOV), other parameters such as oxygen pulse [O₂-pulse; VO₂/heart rate (HR)] kinetics are considered of clinical interest. However, the prognostic value of O₂-pulse kinetics in CHF has not yet been thoroughly examined. **Purpose:** The purpose of this study was to determine whether impaired O₂-pulse kinetics and associated parameters including VO₂ as a function of work rate (VO₂/WR slope) and HR/VO₂ slope predict major adverse events in patients with CHF. **Methods:** O₂-pulse kinetics was classified as 1) continual rise; 2) plateau; and 3) decrease. To evaluate the hazard ratio and significance of the optimal cutoffs for VO₂/WR slope and HR/VO₂ slope we used a two-fold cross-validation process. Kaplan-Meier curves and univariate as well as multivariate cox regressions were used to compare time to the composite outcomes of all-cause death, heart transplantation (HTx) and left ventricular assist device (LVAD) implantation between groups. **Results:** 242 patients (55±13 years, 78% male, 50±15% of predicted peakVO₂) with CHF were included in the study. During the mean follow-up of 27.5±23.3 months, 112 patients (46%) had an event (50x LVAD, 39x HTx, 23x death). Neither an O₂-pulse plateau (43%) nor a decrease (7%) distinguished patients with and without events. However, VO₂/WR and HR/VO₂ slopes were significant univariate predictors (p<0.001) of the outcomes (Fig.1). In the multivariate analysis, peakVO₂, VO₂/WR slope and EOV [hazard ratios (95% CI): 2.06 (1.20-3.54), 2.03 (1.21-3.38) and 1.65 (1.11-2.45), respectively] remained significant independent predictors (p<0.05). **Conclusion:** VO₂/WR slope and HR/VO₂ slope during CPET appear to be of potential benefit for predicting outcomes in patients with CHF, whereas O₂-pulse kinetics did not.

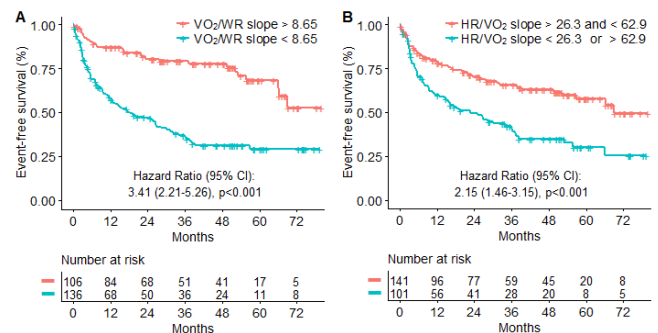

Fig.1: Kaplan-Meier curves and results of the univariate cox regression analysis [hazard ratio (95% confidence interval)] of (A) VO₂/WR slope and (B) HR/VO₂ slope

Optimal Distance For Normal Gait Speed Testing

Rosalba Saavedra, Brian Bischoff, Steven Kim, Eric Martin. California State University, Monterey Bay, Seaside, CA.

(Sponsor: Kent Adams, FACSM)

Email: rsaavedra@csumb.edu

(No relevant relationships reported)

PURPOSE: Walking speed tests are valid tools for predicting functional independence outcomes, however research has not yet agreed on their predictive ability for cardiovascular disease events. There are a range of distances used for walking speed tests, which generates a gap in knowledge and questions the test's accuracy and clinical significance. The purpose of the current study was to determine an optimal distance to calculate gait speed that can be used to standardize walking tests in clinical settings. **METHODS:** Participants walked at their normal gait speed for 20m through Brower timing gates set up at the starting line and at 5m, 10m, and 20m. Speeds from 0-5m, 5-10m, and 10-20m were compared using a linear mixed effect model. **RESULTS:** The average speed for 0-5m segment was 1.361 m/s, 5-10m was 1.449 m/s, and the 10-20m average speed was 1.467 m/s. Comparing 0-5m to 5-10m, the estimated difference was 0.088 m/s with a 95% CI between 0.062-0.079 m/s with a

p-value < 0.0001. Comparing 0-5m to 10-20m, the estimated difference was 0.106 m/s with a p-value of <0.0001. The estimated 5-10m to 10-20m difference was 0.018 m/s with a p-value of 0.18.

CONCLUSIONS: The most efficient distance to measure gait speed is between 5-10 meters of a 15 meter walk test to provide room for acceleration and deceleration. Using a walk speed test under 5 meters is not advised because people are still accelerating and have not achieved stable speed.

The Predictive Value Of The Sf-36 Questionnaire In Determining CPET Performance In Patients With ME/CFS

Jeffrey Cournoyer¹, Elizabeth Balbin¹, Precious Leaks-Gutierrez², Fanny Collado², David Freeman², Arnaldo Tercero², Nancy Klimas¹. ¹Nova Southeastern University, Miami, FL. ²Miami Veteran's Affairs Hospital, Miami, FL.
Email: jcournoyer@nova.edu

(No relevant relationships reported)

Introduction

Patients diagnosed with Myalgic Encephalomyelitis (ME/CFS) tend to have difficulties with higher-intensity exercise, and usually show diminished maximal exercise capabilities when compared to their sedentary healthy counterparts (sHC). Thus, it is important to find new ways to identify patients most at risk for diminished exercise performance as soon as possible.

Purpose

The present study seeks to determine the predictive validity of the Short Form Health Questionnaire (SF-36) and its subscales as a non-exercise component in patient evaluation.

Methods

18 male patients diagnosed with ME/CFS (Age: 39.2 ± 12.8 years) and 18 male sedentary healthy controls (Age: 39.9 ± 13.4 years) were asked to fill out the SF-36 health survey before participating in a symptom-limited maximal exercise test (CPET). CPET was performed on a cycle ergometer, and initial resistance was set at 30 Watts with a 30 Watt increase every 2 minutes. Subjects were asked to maintain a cycling cadence of 60-70 RPM for as long as possible, or until they experienced any of the predetermined symptoms. Maximal exercise data and veniality efficiency measures were recorded and used in correlative analyses.

Results

Significant differences were observed between ME/CFS and sHC in all relevant subscales of the SF-36 ($p < 0.005$ in all cases). The Physical Functioning, Vitality and Physical Health subscales were all positively correlated with maximal oxygen uptake ($\text{VO}_2 \text{ Max}$) in the ME/CFS group ($r = 0.67$, $p < 0.005$; $r = 0.59$, $p < 0.05$; and $r = 0.65$, $p < 0.005$ respectively), but showed poor correlations in the sHC group ($r = 0.28$, $p = 0.24$; $r = 0.16$, $p = 0.51$; $r = 0.11$, $p = 0.65$ respectively). Although there were significant differences in VE/VCO_2 slopes between the groups ($p < 0.05$), neither group showed strong correlations between and subscales and ventilatory efficiency.

Conclusions

The SF-36 and its subscales showed strong correlations with maximal exercise performance in subjects diagnosed with ME/CFS. These results were not observed in sHC, possibly due in part to the large percentage of "perfect" scores recorded in this group. While the SF-36 did not show any significant correlations with inter-test ventilatory efficiency measures, it might still hold some value in predicting outcomes of maximal CPETs in subjects with diminished exercise capacity.

Serial Assessment Of The Cardiorespiratory Fitness Vital Sign: Prognostic Significance One Year Post Cardiac Rehabilitation

Cemal Ozemek, FACSM¹, Deepika Laddu¹, Trina Hauer², Codie Rouleau², Tavis Campbell³, Stephen Wilton³, Sandeep Aggarwal⁴, Leslie Austford², Tamara M. Williamson³, Hongwei Liu², Daniele Chirico², Ross Arena, FACSM¹. ¹University of Illinois Chicago, Chicago, IL. ²TotalCardiology Research Network, Calgary, AB, Canada. ³University of Calgary, Calgary, AB, Canada. ⁴TotalCardiology Rehabilitation, Calgary, AB, Canada.

Email: ozemek@uic.edu

(No relevant relationships reported)

Cardiorespiratory fitness (CRF) consistently demonstrates robust prognostic value in apparently healthy individuals and in those at risk for or diagnosed with one or more chronic conditions. While CRF at baseline and immediately following cardiac rehabilitation (CR) hold prognostic value, little is known about the significance of serial CRF assessments over a prolonged period. **PURPOSE:** Assess the prognostic utility of serial CRF assessments in patients completing CR.

METHODS: 3,185 patients (mean age = 62 ± 10 years, 82% male) with cardiovascular disease (CVD) that were referred to and completed a 12-week exercise-based CR program were included. All patients completed a symptom-limited treadmill exercise test at baseline, immediately following CR and at 1-year follow-up. Peak metabolic equivalents (METs) were determined at each exercise test from treadmill speed and grade. The difference between peak METs at baseline and immediately post CR and between baseline and 1-year post CR were also calculated. Patients were subsequently tracked for all-cause mortality.

RESULTS: 206 subjects died during the tracking period (mean tracking = 79 ± 34 months). Peak METs at baseline (Mean = 7.7 ± 2.0 METs, HR: 0.66, 95% CI: 0.62-0.71, $p < 0.001$), immediately following CR (Mean = 8.7 ± 2.0 METs, HR: 0.65, 95% CI: 0.60-0.69, $p < 0.001$) and 1-year post CR (Mean = 8.6 ± 2.2 METs HR: 0.65, 95% CI: 0.61-0.69, $p < 0.001$) were all significant predictors of survival. The mean change in peak METs from baseline to immediate post CR (0.88 ± 1.4 METs) and from baseline to 1-year post CR (0.88 ± 1.3 METs) was significant ($p < 0.001$). However, only the change in peak METs from baseline to 1-year post CR was a significant predictor of survival (HR: 0.73, 95% CI: 0.66-0.80, $p < 0.001$).

CONCLUSIONS: The current findings again demonstrate the prognostic significance of the CRF vital sign in patients with CVD undergoing CR. Our results indicate continued serial assessment of the CRF, in this analysis 1-year following completion of CR, provides important prognostic information. In particular, maintenance of CRF improvement following CR over the long-term is clinically important and should be monitored.

The Impact Of Placebo Caffeine Dose On Cognitive Performance And Endurance Running In Recreational Athletes.

Ben Desbrow¹, Chris Irwin¹, Nathan Delang¹, Gregory R. Cox². ¹Griffith University, Gold Coast, Queensland, Australia. ²Bond University, Gold Coast, Queensland, Australia. (Sponsor: Louise Burke, FACSM)

Email: b.desbrow@griffith.edu.au

(No relevant relationships reported)

PURPOSE: A caffeine-mediated dose-response placebo effect has previously been observed in trained cyclists. The current study aimed to determine if perceived caffeine dose influences cognitive and/or running performance in recreational athletes.

METHODS: Twenty-nine healthy individuals (23.7 ± 5 y (Mean ± SD), 16 males) completed two morning trials (repeated measures design, separated by 1 week), involving a choice reaction time (CRT) test followed by a 10km performance run. Prior to the first trial, participants indicated their beliefs of caffeine's effects on performance and any previous experience using caffeine as an ergogenic aid. On arrival to the testing facility, participants randomly received (and were told they were getting) "Low dose (100mg)" or "High dose (300mg)" of caffeine capsules (all contained placebo, (psyllium husk powder)) prior to commencing the CRT test (30min post capsule ingestion). Paired samples t tests were used to determine differences between trials and CRT latency (employing Ex-Gaussian analysis) and running performance using the entire participant sample and for the sub-groups exhibiting strong "beliefs" +/- prior experience.

RESULTS: Perceived caffeine dose did not influence CRT (μ -, σ - and τ -components respectively, Low: 400 ± 53ms vs High: 388 ± 4ms; Low: 35 ± 18ms vs High: 34 ± 17ms; Low: 50 ± 24ms vs High: 52 ± 19ms, all p 's > 0.05). Neither personal belief ($n = 9$), nor belief + experience ($n = 6$) influenced this effect. Furthermore, perceived caffeine dose did not influence run time (Low: 49.05 ± 3.75 min vs High: 49.06 ± 3.85 min, $p = 0.979$). Personal belief (Low: 48.93 ± 3.71 min vs High: 48.9 ± 3.52 min, $p = 0.976$), and belief + experience (Low: 48.68 ± 1.87 min vs High: 49.55 ± 1.75 min, $p = 0.386$) did not influence this effect.

CONCLUSIONS: Placebo effects of perceived caffeine-dose ingestion on cognitive and running performance were not observed in this study of recreationally active individuals, irrespective of individual's prior beliefs or caffeine use.

650 May 27 1:15 PM - 1:30 PM

The Perfect Timing For Sodium Bicarbonate Supplementation: Greater Possibilities With Probabilities

Luana F. Oliveira¹, Bryan Saunders¹, Guilherme Yamaguchi¹, Paul Swinton², Guilherme G. Artioli¹. ¹University of São Paulo, São Paulo, Brazil. ²Robert Gordon University, Aberdeen, United Kingdom. (Sponsor: Craig Sale, FACSM)
Email: oliveira.luana@usp.br
(No relevant relationships reported)

PURPOSE: To describe the reliability of blood bicarbonate pharmacokinetics to sodium bicarbonate (SB) supplementation and, based on those data, to estimate probabilities of SB ingestion timing before exercise using currently accepted thresholds. **METHODS:** Thirteen males (age 27±5 y; body mass (BM) 77.4±10.5 kg; height 1.75±0.06 m) ingested 0.3 g·kg⁻¹BM SB in capsules on 3 occasions (SB1, SB2 and SB3). Blood was obtained at baseline and every 10 min following SB ingestion for 3h, then every 20 min for a further hour to determine bicarbonate concentration. Time-to-peak (Tmax), absolute peak (Cmax), absolute peak change (ΔCmax) and area under the curve (AUC) were determined and analysed using mixed models, as was the intraclass correlation coefficient (ICC), coefficient of variation (CV) and typical error (TE). Individual variation in pharmacokinetic responses was assessed using a Bayesian simulation approach using multilevel models with random intercepts. **RESULTS:** No significant differences between sessions were shown for blood bicarbonate regarding Cmax, ΔCmax or AUC (all p>0.05), although Tmax occurred significantly earlier in SB2 (127±36 min) than in SB1 (169±54 min, p=0.0088) and SB3 (159±42 min, p=0.05). ICC, CV and TE showed moderate to poor reliability for these variables. Bayesian modelling estimated that over 80% of individuals from the population experience elevated blood bicarbonate levels greater than +5 mmol·L⁻¹ between 75-240 min after ingestion, and between 90-225 min for elevations greater than +6 mmol·L⁻¹ (Table 1). **CONCLUSIONS:** Assessing SB supplementation using discrete values showed only moderate reliability at the group level, and poor reliability at the individual level, while Tmax was not reproducible. However, when analysed as modelled curves, a 0.3 g·kg⁻¹BM dose was shown to create a long-lasting window of ergogenic potential, which has practical utility for athletes and suggests that individually tailored timings are not required.

Table 1. Probability estimates of elevating blood bicarbonate above 5 mmol·L⁻¹ and 6 mmol·L⁻¹ (from baseline) at different time points following sodium bicarbonate ingestion. Probability values were estimated using Bayesian simulation (n = 1 million)

Prob-ability of increases	Time after ingestion (min)																
	0	15	30	45	60	75	90	105	120	135	150	165	180	195	210	225	240
↑5 mmol·L ⁻¹ (%)	0	0	0	9	69	93	97	99	99	99	99	99	98	97	95	91	85
↑6 mmol·L ⁻¹ (%)	0	0	0	0	14	60	86	93	95	96	96	95	94	92	88	80	70

Muscle Glycogen Utilization During Exercise Following Ingestion Of Alcohol

Harry A. Smith. University of Bath, Bath, United Kingdom.
(Sponsor: Professor James Betts, FACSM)
Email: h.a.smith@bath.ac.uk
(No relevant relationships reported)

PURPOSE: Following alcohol ingestion, ethanol (EtOH) is metabolized gastrically and hepatically, which may influence metabolism at rest and/or during exercise. Previous experiments involving exercise have provided EtOH via intravenous infusion rather than oral ingestion, which alters the metabolic effects of EtOH. Furthermore, no previous studies have directly compared the effects of EtOH metabolism at rest followed by exercise.

METHODS: Eight recreationally active men (Mean ± SD, Age: 24 ± 5 y; Body Mass: 76.7 ± 5.6 kg; Height: 1.80 ± 0.04 m; $\dot{V}O_{2peak}$: 4.1 ± 0.2 L·min⁻¹) performed two bouts of fasted cycling exercise at 55 % $\dot{V}O_{2peak}$ for 2-h, with (EtOH) and without (CONTROL) prior ingestion of ethanol 1 h and immediately before exercise (total dose: 0.1 g·kg lean body mass⁻¹·h⁻¹ - 30.2 ± 1.1 g 40% ABV Vodka; fed in 2 equal boluses) in a randomized order, separated by 7-10 days. NHS REC: 17/SW/0219.

RESULTS: The rate of muscle glycogen degradation was not different between conditions (CONTROL:-214.5 [nCI: -287.6—-141.4] mmol·kg⁻¹ vs EtOH:-257.7 [nCI: -330.8—-184.6] mmol·kg⁻¹) and plasma glucose concentrations during exercise were similar (mean concentration: CONTROL: 5.26 [nCI: 5.17-5.34] mmol·L⁻¹ vs EtOH: 5.26 [nCI: 5.18-5.34] mmol·L⁻¹). Ingestion of EtOH suppressed plasma non-esterified fatty acids (NEFA) at rest (mean concentration: CONTROL: 0.40 [nCI: 0.31-0.50] mmol·L⁻¹ vs EtOH: 0.30 [nCI: 0.21-0.40] mmol·L⁻¹) but not during exercise. Plasma

lactate was higher across the rest period in the EtOH condition (mean concentration: CONTROL: 0.88 [nCI: 0.79-0.97] mmol·L⁻¹ vs EtOH 1.01 [nCI: 0.91-1.09] mmol·L⁻¹) but the response during exercise was similar.

CONCLUSIONS: Ingestion of a small dose of EtOH transiently altered the resting availability of systemic NEFA and lactate but this effect did not persist during exercise. Muscle glycogen utilization was similar during exercise in both trials, which reflects the similar concentrations of systemic metabolites observed during exercise.

Effects Of Vitamin C Enriched Hydrolyzed Collagen On Explosive Performance

Dana Marie Lis, Tayler Smith, Keith Baar, FACSM, Timothy Lipuma, Vera Weijer. University California Davis, Davis, CA.
Email: dmlis@ucdavis.edu
(No relevant relationships reported)

The stiffness of a tendon is determined by the amount and cross-linking of collagen within the tissue. Acute exercise and possibly vitamin C-enriched collagen supplementation have been shown to increase collagen synthesis as well as the expression of the primary enzyme involved in collagen cross-linking (lysyl oxidase). The result may be a denser and stiffer tissue. Stiffness is directly related to force transfer. Whether this nutritional supplementation can further augment response to training, in particular rate of force development (RFD), and translate to improved explosive performance compared to training alone is unknown. **Purpose:** To determine if nutritional supplementation with vitamin C-enriched collagen improves RFD compared to placebo (PLA) with an explosive power-based training regime. **Methods:** Healthy male collegiate football players (18-25 years) were enrolled in a 3-week double-blinded, parallel design study. Athletes were randomly assigned to the intervention group (COLL; 15g hydrolyzed collagen with 50mg vitamin C) or placebo group (PLA; 15g rice flour). Supplements were ingested 60min prior to training 5 days per week and with breakfast on rest days. Athletes completed the same training program and progression. RFD was measured from the best of three maximal isometric squats, countermovement jumps and squat jumps (Kistler, Novi, MI) performed at the same time on each testing day (baseline and after 1, 2 and 3 weeks of training). Two-way ANOVA (nutrition intervention and time) was used to compare RFD between groups. **Results:** At time of analysis there were no significant difference for maximal RFD in the maximal isometric squat between the interventions. RFD data from CMJ and SJ are yet to be determined. **Conclusion:** Supplementation with vitamin C-enriched collagen prior to training throughout a 3-week explosive power-based training program does not improve maximal RFD compared to exercise alone. More comprehensive analysis of all RFD parameters is required to fully interpret results from this study and will be completed prior to abstract presentation.

653 May 27 2:00 PM - 2:15 PM

Ketone Ester Supplementation Affects Neither Muscle Glycogen Utilization Nor Performance In A Simulated Cycling Race

Chiel Poffé, Stijn Bogaerts, Peter Hespel. KU Leuven, Leuven, Belgium.
Email: chiel.poffe@kuleuven.be
(No relevant relationships reported)

PURPOSE: Some recent literature data indicate that ketone bodies inhibit glycolysis in contracting muscles. Therefore, we investigated whether exogenous ketosis by oral ketone ester (KE) intake during prolonged cycling can induce a glycogen sparing action and thereby improve performance during the final phase of the event.

METHODS: In a randomized cross-over design, 12 highly-trained male cyclists and triathletes completed a simulated cycling race consisting of 3h submaximal exercise (EX₁₈₀) combined with 60g carbohydrates per h, immediately followed by a 15-min time-trial (TT₁₅) and a maximal sprint test (time to exhaustion at 175% of the anaerobic threshold). Subjects received 20-25g doses of either KE or a non-caloric placebo (CON) at 1h and 20 min before, and at 30 min during EX₁₈₀. Blood samples were collected at regular intervals. Biopsies from m. vastus lateralis were obtained before and after EX₁₈₀ and at the end of TT₁₅. **RESULTS:** KE intake transiently increased blood D-β-hydroxybutyrate to ~3 mM (range: 2.6-5.2 mM) during EX₁₈₀ (p<0.001 vs. CON). Blood pH concomitantly decreased from ~7.42 to 7.36 (range: 7.29-7.40), whilst bicarbonate dropped from 26.0 to 21.6 mM (range: 20.1-23.7) (p<0.001 vs. CON). EX₁₈₀ depleted muscle glycogen to the same degree in both groups (KE: -78 ± 9; CON: -60 ± 6 mmol/kg ww, p>0.05). Mean power output during TT₁₅ (KE: 273 ± 11; CON: 272 ± 11 W, p>0.05) and time-to-exhaustion in the sprint (KE: 59 ± 5; CON: 58 ± 5 s, p>0.05) also were similar between the groups. **CONCLUSION:** KE intake during a simulated cycling race does not cause glycogen sparing, neither does it affect performance in the final stage of the race.

654 May 27 2:15 PM - 2:30 PM
Effect Of Water-loading On Weight Cutting And Performance In Elite Judo Athletes
 Catherine Naulleau, Éric DB Goulet. *Université de Sherbrooke, Sherbrooke, QC, Canada.*
 Email: catherine.naulleau@usherbrooke.ca
 (No relevant relationships reported)

The use of water-loading to enhance weight cutting is getting increasingly popular in combat and weight category sports. Athletes are overdrinking water in order to increase urine production before engaging in a fluid restriction period in the belief that it will maximise fluid driven body mass loss. Research into this practice is lacking and further investigation is needed.

PURPOSE: Determine the impact of a water-loading protocol in combination with dietary adjustments on acute body mass loss, natremia, urinary markers of hydration and arm crank performance in elite judo athletes.

METHODS: Using a crossover design, 18 elite male judo athletes underwent 2, 6 days interventions interspersed by a washout period of 2 weeks. While following a controlled diet, athletes consumed either 40 mL/kg (control condition (CON)) or 80 mL/kg (water loading condition (WL)) on days 1-3, followed for both conditions by a fluid intake of 20 mL/kg on day 4. On day 5, fluid was restricted until 11h00, body mass was then measured and for the remaining of the day athletes consumed 60 mL/kg of fluid. On day 6, fluid was consumed *ad libitum* and arm crank performance measured between 9h00-12h00.

RESULTS: Water-loading ($2.4 \pm 0.5\%$) produced a significantly ($p = 0.03$, effect size = 0.7) greater decrease in body mass, compared with CON ($1.8 \pm 0.5\%$). Urine specific gravity and osmolality became progressively lower over time with WL ($p < 0.05$), compared with CON. However, whole blood sodium concentration remained within the physiological range of 135-145 mmol/L throughout the WL condition. There were no significant differences in arm crank performance for maximum power (CON: 663 ± 103 , WL: 677 ± 95 W) and mean power (CON: 330 ± 32 , WL: 335 ± 35 W).

CONCLUSION: Our results indicate that the water-loading protocol used in this study 1) improves acute body mass loss without affecting health or arm crank performance and; 2) should be considered by combat sports athletes looking to improve their weight cutting practices.

Consumption Of Multi-ingredient Supplement With Resistance Training Enhances Gains In Muscle Fibre And Muscle Area In Men And Women
 Mai Wageh. *McMaster University, Hamilton, ON, Canada.*
 (Sponsor: Stuart Phillips, FACSM)
 Email: wagehm@mcmaster.ca
 (No relevant relationships reported)

Resistance exercise training (RET) is a well-known stimulus for muscle protein synthesis. Protein supplementation in conjunction with RET has been shown to yield a superior combinatory effect, fostering greater accretion of lean body mass. Few studies have compared multi-ingredient with isonitrogenous supplements of differing protein quality. **PURPOSE:** We compared a whey protein-based supplement (containing leucine, creatine monohydrate, calcium citrate, and vitamin D), to an isonitrogenous collagen-containing protein supplement with regards to muscle fibre and whole muscle mass increases. We aimed to determine whether the multi-ingredient supplement would enhance lean body mass gains in young adults involved in a RET program. **METHODS:** Twenty-six healthy, recreationally active men and women (22 ± 2 years [mean \pm SD]) were randomly assigned to either the supplementation (SUPP, $n=13$) or control beverage (CON, $n=13$) group, ingesting their respective supplements twice daily. Participants underwent a 10-week linear RET program. Dual-energy X-ray absorptiometry (DXA), one-repetition maximum (1RM), and biopsies from the *vastus lateralis* muscle were performed. **RESULTS:** There were significantly greater increases in type II fibre cross-sectional area (CSA) in the SUPP group compared to the CON group (SUPP: $+47 \pm 24\%$, CON: $+34 \pm 25\%$; $p < 0.05$; $d = 0.53$), while changes in type I fibre CSA was not different between groups (SUPP: $+37 \pm 25\%$, CON: $+25 \pm 21\%$; $p = 0.08$; $d = 0.52$). Ultrasound *biceps brachii* CSA increase was significantly greater in the SUPP group (SUPP: $+42 \pm 39\%$, CON: $+14 \pm 10\%$, $p < 0.05$; $d = 0.98$), while increases in *vastus lateralis* CSA was not different between groups (SUPP: $+43 \pm 23\%$, CON: $+26 \pm 31\%$; $p = 0.06$; $d = 0.62$). **CONCLUSIONS:** The consumption of a multi-ingredient nutritional supplement increased type II fibre CSA and *biceps brachii* CSA, but not type I fibre CSA or *vastus lateralis* CSA in healthy young men and women.

656 May 27 2:45 PM - 3:00 PM
Comparable Exogenous Carbohydrate Oxidation With Lactose Or Sucrose Feeding During Endurance Exercise
 Oliver J. Odell, Tim Podlogar, Gareth A. Wallis. *University of Birmingham, Birmingham, United Kingdom.* (Sponsor: Janice L Thompson, FACSM)
 Email: oxo799@bham.ac.uk
 Reported Relationships: **O.J. Odell:** Industry contracted research; Volac International.

Purpose:

Endogenous carbohydrate (CHO) availability can limit endurance exercise performance. CHO ingested during exercise such as glucose, glucose polymers and sucrose are readily oxidized and can improve endurance performance. The extent to which lactose can be utilized as a fuel source during exercise is unknown. The purpose is to elucidate the metabolic response to lactose ingestion during endurance exercise, compared to sucrose or water.

Methods:

11 participants (mean \pm SD: 22 ± 4 years, 50.9 ± 4.7 mL \cdot min $^{-1}$ \cdot kg $^{-1}$) cycled for 150 min at 50% of W_{max} on 3 occasions. During exercise participants ingested, in a randomized order, water (WAT), lactose (LAC) or sucrose (SUC) containing beverages; a CHO dose of 0.8 g \cdot min $^{-1}$ (48 g \cdot h $^{-1}$) was used. Indirect calorimetry was used to calculate fat and total CHO oxidation and stable isotope tracer methodology (natural high ^{13}C abundance CHO ingestion, $^{13}C:^{12}C$ ratio determination in expired breath by isotope-ratio mass spectrometry) was used to quantify exogenous CHO oxidation. Venous blood samples were taken throughout exercise and analyzed for glucose, lactate and non-esterified fatty acids (NEFA).

Results:

Mean exogenous CHO oxidation rates in LAC (0.55 ± 0.19 g \cdot min $^{-1}$) and SUC (0.58 ± 0.10 g \cdot min $^{-1}$) were similar ($P = 0.68$). Endogenous CHO oxidation contributed less to energy expenditure (EE) in LAC ($39 \pm 14\%$) than in WAT ($50 \pm 11\%$, $P = 0.01$) and SUC ($50 \pm 8\%$, $P = 0.04$). Fat oxidation contributed most to EE in WAT ($50 \pm 11\%$), which was significantly greater than in LAC ($42 \pm 8\%$, $P = 0.04$) and SUC ($28 \pm 6\%$, $P < 0.01$), with fat oxidation higher in LAC than SUC ($P < 0.01$). Plasma glucose was significantly higher in LAC (5.2 ± 0.4 mmol \cdot L $^{-1}$) and SUC (5.3 ± 0.5 mmol \cdot L $^{-1}$) than WAT (4.6 ± 0.5 mmol \cdot L $^{-1}$, $P < 0.01$). Plasma lactate was significantly higher in SUC (1.7 ± 0.5 mmol \cdot L $^{-1}$) than WAT (1.5 ± 0.4 mmol \cdot L $^{-1}$, $P < 0.01$). Plasma NEFA were significantly higher in WAT (1.1 ± 0.4 mmol \cdot L $^{-1}$) than SUC (0.5 ± 0.3 mmol \cdot L $^{-1}$, $P < 0.01$), and tended to be higher in WAT than LAC (0.7 ± 0.4 mmol \cdot L $^{-1}$, $P = 0.08$).

Conclusions:

Exogenous CHO oxidation during exercise was comparable from ingested lactose and sucrose. However, lactose ingestion promoted higher fat and lower endogenous CHO oxidation during exercise than sucrose. This suggests that lactose may be at least as efficacious as commonly used CHO sources for improving exercise performance.

Oh Snap! I Got Hit In The Face.
Christina S. Gutta. *Prisma Health, Greenville, SC.* (Sponsor: Dr. Franklin Sease, FACSM)
(No relevant relationships reported)

HISTORY: 20 y.o. collegiate baseball player presents to physician in training room 1 hour after a resistance band snapped off a hook and hit him across the bridge of the nose and both eyes. He complains of immediate swelling around his eyes, difficulty opening eyelids and blurry vision for 20 minutes with tearing, difficulty opening his eyes and retro-orbital headache. He has a history of Hemophilia A with severe phenotype for which he administers Factor VIII every 2 days; with chest or head trauma, he administers an emergency dose of Factor VIII.

PHYSICAL EXAMINATION: He appears moderately distressed and uncomfortable; bilateral eyelids are swollen with tearing of clear fluid bilaterally, no periorbital ecchymosis, no proptosis, no hyphema. Bilateral subconjunctiva injection present. EOM intact but has pain in right eye when looking up. Left pupil is equal and reactive to light. Right pupil is oblong pointing towards 9 o'clock. Monocular diplopia present in both eyes. Vision 20/40 with corrective lens. No flashers or floaters. Cranial nerve exam is otherwise normal.

DIFFERENTIAL DIAGNOSIS: traumatic mydriasis, open globe injury, post-traumatic iritis, vitreous hemorrhage, retinal detachment, Retrobulbar hematoma, ocular contusion

TEST AND RESULTS: Intraocular pressure Right 15, Left 13. Fundus exam shows normal vitreous macula and intraorbital vessels. No evidence of retinal detachment. CT head WO contrast: No acute intracranial hemorrhage or infarct, no masses or midline shift. CBC 7.0>15.7/46.9<337 Factor VIII inhibitor negative. Factor VIII Clotting Activity: 61 (nl 50-180) PT 14. INR 1.1 PTT 33

FINAL WORKING DIAGNOSIS: ocular contusion

TREATMENT AND OUTCOME: He administered an emergency dose of Factor VIII immediately after the injury. Then he was admitted to the ICU for IOP monitoring and serial cranial nerve exams; was treated with Factor VIII 40 U/kg, or 3600 U q8h for 48 hours then resumed home Factor VIII dosing every 2 days. At discharge, he had normal IOP and reassuring neurologic exam. He used eye drops q2-4 hours for comfort. At ophthalmology follow up 1 week later, he had normal IOP and fundus exam. There is risk of developing angle recession glaucoma up to several months after injury and anticipatory guidance for sudden vision loss or eye pain discussed. He returned to full sport participation 2 weeks later.

Concussion: Bouncy House
Angela Rufo. *Maine Dartmouth, Augusta, ME.* (Sponsor: James Dunlap, FACSM)
(No relevant relationships reported)

HISTORY

10 y/o M football player was referred by PCP for a concussion. Patient was jumping on a bouncy house four days earlier when he fell off and hit his head on the hardwood floor. No LOC. Brought to the ED and diagnosed with a concussion and sent home.

Over the next couple of days, had multiple episodes of emesis. Brought back to the ED, CT head showed a right occipital comminuted calvarial fracture with displacement fragment of bone intracranially and with an extra axial hemorrhage that was concerning for a subdural or epidural hematoma. Transferred to Maine Medical Center for a neurosurgical evaluation. Seen by neurosurgery and pediatric rheumatology and discharged home given stable exam. Admits to headache, photophobia, phonophobia, feeling slower, fatigue, drowsiness, difficulty falling asleep, irritability. No history of learning disorders and no previous concussions. Symptom Score 36.

PHYSICAL EXAM

General: NAD

HEENT: TTP right occiput large hematoma. PEERLA,

Neck: No TTP Full ROM. Spurling (-)

Neuro: CN2-12 intact, Sensation/Motor in all extremities intact

Memory short term: word recall (5/5) x 3. long term: intact

Cognitive: Recite months backwards 12/12, Days 7/7, Numbers 3/3, 4/4, 5/5

VOMS: intact, convergence 6cm, finger to nose intact

BESS: two leg no errors, one leg 4 errors, Tandem 2 errors

Psych: mood normal

DIFFERENTIAL DIAGNOSIS

Concussion, TBI, Subdural hematoma, Epidural hematoma, Subarachnoid, Migraine, Basilar Fracture, Occipital Fracture, Seizure Disorder

TEST AND RESULTS

CT head: Right occipital comminuted calvarial fracture with displaced fragment of bone intracranially with extra-axial fluid collection which could be a subdural or epidural hemorrhage component.

FINAL DIAGNOSIS

Concussion, Occipital bone fracture, and Subdural hemorrhage

TREATMENT AND OUTCOME

Return to school with accommodations, avoid bright lights and loud noises, limit screen time, avoid. Per Neurosurgery: Avoid any physical activity for 2-3 months

Follow at 2 weeks: Symptom Score 3. Patient much improved. Exam remarkable for poor balance

Pending Neurosurgery follow up next month. Follow up in clinic office 1 month.

663 May 27 2:00 PM - 2:20 PM

Eye Injury- Baseball

Erika Leigh Cohen, Lisa Odendal, Danielle Hirsch. *Johns Hopkins All Children's Hospital, Saint Petersburg, FL.* (Sponsor: Dilipkumar R Patel, MBBS, MBA, MPH, FACSM)
Email: erika.shuster@jhmi.edu
(No relevant relationships reported)

HISTORY: A 12 year-old male sustained an injury to left eye during a baseball game. While playing first base, the outfielder threw a ball to him so patient could tag the runner out. When catching the ball, he missed, and instead the ball struck him in the face in the area of the left eye. There was no loss of consciousness, vomiting, hematoma or altered mental status. He initially had difficulty seeing out of the eye, but vision returned soon after and appeared blurry.

PHYSICAL EXAMINATION: Normocephalic. With the exception of limitation in upward gaze of left eye, the remaining extraocular movements were intact. Hyphema of left eye noted. Pupils equal, round and reactive to light bilaterally. Moderate left periorbital edema and ecchymosis. Vision intact to left eye. Sensation intact in V1-V3 distribution, facial nerve function intact bilaterally. Normal occlusion, midface stable. Hearing to spoken voice intact and TM's clear with no evidence of hemotympanum. Remainder of examination was normal.

DIFFERENTIAL DIAGNOSIS:

1. Orbital Ridge Fracture
2. Orbital Blowout Fracture
3. Hyphema
4. Retinal detachment
5. Commotio Retinae
6. Globe Rupture

TEST AND RESULTS:

CT facial bones:

- Blowout fracture of left inferior and medial wall of left orbit
- Left orbital emphysema with small contusion vs hematoma within the retrobulbar fat
- Minimal blood within the left ethmoid and maxillary sinus

Ophthalmology Consult:

- Visual Acuity 20/30 Right, 20/200 Left
- 3 mm Hyphema of left eye
- Commotio Retinae of left macula
- Normal intraocular pressure

FINAL/WORKING DIAGNOSIS: Left orbital floor fracture, Traumatic Hyphema,

Commotio Retinae involving the macula

TREATMENT AND OUTCOMES:

1. CT scan without significant displacement and no ocular muscle entrapment on repeat exam, no operative repair needed; follow-up with plastic surgery 1-2 weeks
2. Per ophthalmology recommendations:

- a. Ongoing observation for cataract, retinal detachment, and glaucoma due to increased risk from blunt ocular trauma
- b. Bed rest with bathroom privileges 3-4 days
- c. Ophthalmic prednisolone and ophthalmic atropine for hyphema with monitoring for absorption and rebleed
- d. Monitor for macular hole as increased risk secondary to commotio retinae
- e. Follow-up in 1-2 days

664 May 27 2:20 PM - 2:40 PM

Head Injury - Soccer

Mark Sederberg, Melinda Loveless. *University of Washington, Seattle, WA.* (Sponsor: Stanley Herring, MD, FACSM)

Email: mseder@uw.edu

(No relevant relationships reported)

HISTORY:

A 16 year-old male presented to an outpatient sports medicine clinic one month after a head-to-head collision during a soccer match with concern for concussion. There was no loss of consciousness, and he continued to play the rest of the game with a mild headache. He felt normal and asymptomatic that evening and was able to complete homework. The following morning he felt tired, but was able to perform adequately at school. Over the coming weeks, he noticed progressive worsening of his cognitive symptoms and tiredness. His athletic trainer became concerned for a concussion and held him from practice. One week prior to presentation he noted midline lower lip numbness, teeth pain while chewing, hearing his pulse in his left ear, and poor sleep due to sweatiness. He also felt progressive lethargy and difficulty concentrating and missed the last three days of school due to these symptoms. His medical history was significant only for a recently diagnosed inguinal hernia.

PHYSICAL EXAMINATION:

Mild cognitive deficits in attention and memory, impaired balance on BESS, normal motor strength. Cranial nerve exam showed ptosis of the left eye, mild left facial nerve palsy, decreased hearing in the left ear, and altered sensation to light touch over the middle lower lip. There was no focal tenderness or deformity of the skull or scalp.

DIFFERENTIAL DIAGNOSIS:

Mild traumatic brain injury

Intracranial hemorrhage

Cerebral mass

Bell's palsy

TESTS AND RESULTS:

MRI Brain with and without contrast: Asymmetric enhancement of the left 7th cranial nerve, asymmetric nodular enhancement along the left 5th nerve with enhancement of muscles of mastication, diffuse bilateral pachymeningeal enhancement.

Complete Blood Count: WBC 19k, platelets 80, hematocrit 30.4

CT Chest, Abdomen, Pelvis: Large abdominal soft-tissue mass herniating through the inguinal canal, most consistent with a lymphoma

CSF Cytology: Enlarged B-cells most consistent with Burkitt lymphoma.

FINAL DIAGNOSIS:

Stage IV Burkitt lymphoma, with primary lesion in abdomen, and perimeningeal spread, causing cranial nerve V and VII palsies.

TREATMENT AND OUTCOMES:

- 1. Admitted for prompt initiation of chemotherapy.
- 2. Cranial nerve symptoms resolved with chemotherapy and steroids.
- 3. After multiple rounds of chemotherapy, there is no evidence of residual lymphoma.

665 May 27 2:40 PM - 3:00 PM

A Head-Scratching Head-to-Head Case

Priya Veda Nagarajan, Carrie A. Jaworski, FACSM. *University of Chicago NorthShore, Chicago, IL.*

(No relevant relationships reported)

HISTORY: A 16-year-old high school defensive linebacker with a history of two prior concussions sustained a head injury with impact on the left side of his head. He immediately fell to the ground and with loss of consciousness for 1-2 seconds. Once he awoke, he was able to stand and be assisted off the field. He noted bilateral upper extremity numbness and weakness along with right-sided facial "heaviness." He was assessed on the sideline and did not show signs of focal deficits but was symptomatic after vestibular testing and was held from playing the rest of the game. Approximately one hour after the injury, he became increasingly fatigued with return of his bilateral upper extremity numbness and right facial heaviness. He was transported to the emergency department at this point. **PHYSICAL EXAMINATION:** Sideline exam at time of injury revealed symmetric and normal cranial nerve exam, no C-spine tenderness, and symmetric upper and lower extremity strength and sensation. He exhibited dizziness with VOMS testing but no irregular eye movements. In the ED, he had right-sided facial droop, decreased sensation in the right cheek and jaw, and an otherwise normal exam. **DIFFERENTIAL DIAGNOSIS:** 1. Intracranial hemorrhage 2. Cranial nerve palsy 3. Cervical neuropraxia 4. Concussion **TEST AND RESULTS:** CBC, CMP, and coagulation tests all normal. CT head and neck: normal MRI brain and neck: normal. MRA brain and neck: irregular petrous segment of right

internal carotid artery lumen with concern for stenosis, possibly due to artifact versus nonocclusive arterial dissection, CTA recommended. CTA head and neck: normal. **FINAL WORKING DIAGNOSIS:** 1. Concussion 2. Neuropraxia of cervical spine 3. Neuropraxia of right marginal mandibular nerve (CN V) and zygomatic and buccal branches of right facial nerve (CN VII) versus entrapment of CN VII **TREATMENT AND OUTCOMES:**

- 1. Hospitalized for two days with evaluation by neurosurgery, trauma surgery, plastic surgery, and neurology 2. 5-day course of oral steroids 3. School accommodations given related to concussion symptoms 4. Right-sided facial droop fluctuated and persisted for 2 weeks with subsequent resolution 5. Cleared to start return to play protocol by neurosurgery at 3 weeks once exam returned to baseline 6. Finished seasons with no additional issues related to injury

Buttock Pain - Marathoner

Allison N. Schroeder, Allison Bean, Kentaro Onishi. *University of Pittsburgh Medical Center, Pittsburgh, PA.* (Sponsor: Tom Best, MD, PhD, FACSM)

Email: aschroel@alumni.nd.edu

(No relevant relationships reported)

HISTORY: History and Physical Examination: A 50-year-old competitive marathoner presented with sudden onset right buttock pain that started while sprinting during a pub run 3 days prior to presentation. He described the pain as a deep ache that localized just medial to the right ischial tuberosity. Pain was worse with truncal flexion and knee flexion. It was most apparent when walking, but improved when he applied pressure over his ischial tuberosity while walking. He denied weakness and numbness/tingling that radiated down the leg.

PHYSICAL EXAMINATION: On examination, gait was not antalgic. There was no bruising, swelling, or change in muscle bulk of the right buttock and posterior thigh. Right hip range of motion was full but end range hip flexion induced pain. He was tender to palpation in the medial and cephalad aspect of the ischial tuberosity with no tenderness over the conjoint tendon or hamstring head of the adductor magnus at the ischial tuberosity. Strength was 5/5 in the bilateral lower extremities, but he had pain with resisted right knee flexion. Sensation was intact in the bilateral lower extremities.

DIFFERENTIAL DIAGNOSIS: 1. Hamstring tear or tendinopathy 2. Piriformis syndrome 3. Tear or tendinopathy of the deep hip internal rotators (obturator internus, super gemellus, inferior gemellus) 4. Gluteus maximus muscle injury 5. Sacrotuberous ligament sprain or tear 6. Ischial femoral impingement 7. Sciatic neuropathy 8. Atypical L5 radiculopathy

TEST AND RESULTS: Limited diagnostic ultrasound of the right ischial tuberosity region was performed with a 15-6 MHz linear array transducer and showed a normal hamstring without sonopalpation tenderness. The area just proximal and medial to the conjoint tendon origin was exquisitely tender on sonopalpation at the expected site of the sacrotuberous ligament. Cortical irregularity was present on the superior medial ischial tuberosity.

FINAL WORKING DIAGNOSIS: Right sacrotuberous ligament sprain

TREATMENT AND OUTCOMES: He was referred to physical therapy for right sacrotuberous ligament sprain focused on core strengthening and frequent gentle hamstring stretching. He was pain free after one month and was able to return to running.

670 May 27 1:20 PM - 1:40 PM

Abstract Withdrawn

671 May 27 1:40 PM - 2:00 PM

Bilateral Foot Pain--Cross CountryBrian F. Allen. *University of Minnesota, Minneapolis, MN.*

(Sponsor: David E. Olson, FACSM)

Email: allen793@umn.edu

(No relevant relationships reported)

HISTORY: A 15-year-old cross-country runner presented with 6 months of bilateral foot pain. Patient described "burning" pain over lateral aspect of both feet that would occur predictably after running 1-2 miles, then gradually resolve with rest within 2 hours. No symptoms reported at rest. She denies any associated back pain, lower extremity numbness or weakness. Prior treatments included changing shoes, orthotics, therapy for plantar fasciitis, and extended rest without any improvement.

PHYSICAL EXAM:

Bilateral pes planus. No deformity, swelling, or erythema. Full ankle range of motion. 5/5 strength. Nontender palpation over the first through fifth metatarsals, tarsals, phalanges, metatarsal pads, intermetatarsal spaces, base of 5th metatarsal, or navicular. She is nontender over the medial or lateral plantar fascia. Manipulation of the foot cannot reproduce the patient's pain. She has intact sensation and strong pedal pulses.

DIFFERENTIAL DIAGNOSIS:

1. Bilateral S1 radiculopathy
2. Lateral plantar nerve compression
3. Chronic exertional compartment syndrome
4. Bilateral bone stress injury
5. Intermetatarsal neuroma

TESTS AND RESULTS:

XR Foot bilateral: Normal

MRI Left Foot: Bone marrow edema around lateral cuneiform, cuboid, and base of 3rd and 4th metatarsal.

MRI Right Foot: Bone marrow edema of the cuboid, base of 3rd and 4th metatarsals.

EMG: Normal study. Exam limited to right side due to patient tolerance.

Running Analysis: Significant hindfoot hypomobility, lack of pronation moment, decreased proximal hip strength and core control

FINAL/WORKING DIAGNOSIS:

1. Lateral plantar nerve compression secondary to impaired running mechanics
2. Bilateral bone stress injuries

TREATMENT AND OUTCOMES:

1. Activity modification and relative rest
2. Continued to recommend manual therapy and subtalar joint mobilization
3. Neuro re-education and therapeutic exercise program
4. Return to run protocol

672 May 27 2:00 PM - 2:20 PM

Achilles Tendon - RunningJulie B. Barnett¹, Annette M. Zaharoff². ¹UT Health San Antonio Texas, San Antonio, TX. ²The Non-Surgical Center of Texas, San Antonio, TX. (Sponsor: Alexis Ortiz PT, PhD, SCS, FACSM, FACSM)

Email: barnettj3@uthscsa.edu

(No relevant relationships reported)

BACKGROUND

The Achilles tendon is a common site for chronic tendinosis, a condition characterized by overuse and degeneration of a tendon due to repeated micro-trauma and eccentric demands commonly used in athletic demands such as running. This can lead to pain and functional limitations for an athlete. There is a growing interest in non-surgical forms of treatment for this condition including provision of regenerative injection therapy (autologous blood and platelet rich plasma injections, PRP). In this case study, a runner with an Achilles tendon injury treated with PRP later underwent an MRI after her re-injury. The MRI finding corroborate healing and in this case read as a "surgical repair" when surgery had not been performed.

PURPOSE

The study objective was to discuss an MRI finding on a prior Achilles tear treated with PRP. The Achilles was reinjured and on the subsequent MRI, the findings said that the Achilles tendon had been previously surgically repaired when the treatment had been PRP injections only and not surgery.

METHODS

A review of literature for Achilles tear reveals data in support of eccentric strengthening and platelet rich plasma injections vs surgical repair if not a complete tear. Re-injury rates and rehabilitation protocol timelines for ankle tendon injuries in sports medicine are critical for successful outcomes.

RESULTS

The Achilles tendon initial injury was treated non-surgically with regenerative injections and physical therapy. The athlete returned to sport and reinjured the same tendon. The subsequent MRI read that the tendon had been surgically repaired.

CONCLUSION

Regenerative injection therapy results in MRI changes that appear to be of surgical repair imaging. Re-injury rates need to be evaluated in regards to return to play and rehabilitation protocols post regenerative injections with the inclusion of eccentric rehabilitation. True tissue healing, without scar tissue repair, has been discussed at the cellular level of healing for soft tissue injuries with the use of regenerative injections.

673 May 27 2:20 PM - 2:40 PM

Bilateral Foot Pain-Middle Distance RunnerDimitri Constantinou, FACSM¹, Paulo Ferrao², Nickiforos Saragas². ¹University of the Witwatersrand, Johannesburg, South Africa. ²Netcare Linksfield Medical Centre, Johannesburg, South Africa.

Email: dimitri.constantinou@wits.ac.za

(No relevant relationships reported)

HISTORY: A 14-year-old female middle-distance athlete presented with a history of unilateral (right) foot pain, diagnosed as a navicular stress fracture which was managed non-surgically and made a full clinical recovery. Nine months later she sustained a suspected traumatic spring ligament injury on the opposite side, with subsequent recurrence of pain in the right foot due to overload from the non-weight bearing management of the left foot injury. She therefore presented with bilateral athletics-related foot pain, one-sided apparently traumatic in nature and the other an overload injury.

PHYSICAL EXAMINATION: On clinical examination she was noted to have bilateral mild cavus feet with an antalgic gait pattern. Right foot: Calf and Achilles tendon did not reveal any abnormalities (Silfverskiold negative). Ankle was asymptomatic. The hindfoot joints were mobile and non-tender. There was significant tenderness over the talar navicular bone ("N" spot). The mid and forefoot examination did not reveal any abnormalities. The foot was neurovascularly intact. Left foot: Calf and Achilles tendon did not reveal any abnormalities (Silfverskiold negative). The ankle was asymptomatic. The hindfoot joints were mobile and non-tender. There was once again significant tenderness over the talar navicular bone with mild swelling. The spring ligament was not tender. The mid and forefoot examination did not reveal any abnormalities. The foot was neurovascularly intact. **DIFFERENTIAL DIAGNOSIS:** Navicular stress fractures, tendinopathy of the posterior tibialis tendons, tear of the spring ligament, separation of an accessory navicular

TEST AND RESULTS: Imaging with MRI revealed bilateral navicular stress fractures (figure 1), as indicated by bony edema and a fracture line. On close inspection, the navicular fracture lines were visible on x-ray (Figure 2). Further imaging with CT scans confirmed the navicular fractures and demonstrated sclerosis along the fracture borders with no cross trabeculation, suggestive of a non-union (figure 3). **FINAL WORKING DIAGNOSIS:** Bilateral navicular stress fractures

TREATMENT AND OUTCOMES: Open reduction and internal fixation (ORIF) and bone grafting. Postop rehabilitation and graded return to activity. Back to sports with no pain or swelling in her feet 1 year post surgery.

674 May 27 2:40 PM - 3:00 PM

Return To Activity After Exertional Heat Stroke - 14 YO RunnerWilliam O. Roberts, FACSM. *University of Minnesota, Minneapolis, MN.*

Email: rober037@umn.edu

(No relevant relationships reported)

HISTORY: 14 yo CC runner in for RTP recommendation 3 wks following collapse during his 1st race. 15 min into the race his legs felt tingly & he collapsed to the ground; he could feel the grass on his face & had a hard time opening his eyes; his breathing was labored & shallow; skin was blotchy & pale. His parents transported him car to the local hospital. The ED team started cooling immediately. He was confused, combative, swearing profusely, and throwing punches at staff. As his rectal temp decreased from 41.2°C to <39°C; his behavior improved, his skin color returned to NRL, & his HR dropped from 170 bpm to NRL. ED labs were Na 140, K 4.2, & glc 89. When he arrived at Children's Hospital by helicopter, his rectal temp was 37°C. He felt a little groggy his first day back to school, but quickly returned to baseline. He participated in a low level flag football game during gym class & was told that his cheeks became flushed & blotchy. He returned to cross country practice doing the warm up, which caused him no trouble. He was eating & sleeping normally & doing his school work.

PAST MEDICAL HISTORY: No prior heat injury or heat stroke. Normal cardiac workup (2015) for palpitations; his EKG no pre-excitation.

FAMILY HISTORY: No EHS, malignant hyperthermia, or genetic issues.

PHYSICAL EXAMINATION: BP 112/75; Pulse 68; Temp 37.1°C (O); Ht 157.5 cm; Wt 54.1 kg; SpO2 99%; BMI 21.8 kg/m²; APPEARANCE: Healthy NAD. SKIN: Color NRL. CV: RR no S3, S4, or murmur. LUNGS: Clear
DIFFERENTIAL DIAGNOSIS: EHS; EHI; He with dehydration
TESTS & RESULTS: Slight SGOT elevation, transient bump in CK level, no myoglobinuria; sickle cell trait negative; EKG & echocardiogram normal
FINAL WORKING DIAGNOSIS: EHS
TREATMENT & OUTCOMES: Risk factors for EHS include a previous history & lack of acclimatization. He had 7 practices prior to the meet & he may not have been fully acclimatized. He tends to go all in during competition & that may be part of his EHS collapse. Plan to return to practice at low level exercise & gradually progress his effort over the next 3 weeks; he was already doing warm-ups; add a quarter of a workout for week 1, half the workout for week 2, & full workout for week 3. If he tolerates progressive training, he can go back into competition in about 3 weeks. The weather conditions will cool as the CC season progresses. If he has another EHS episode, will get genetic & heat lab testing.

B-19 Rapid Fire Platform - Posture and Balance in Older Adults

Wednesday, May 27, 2020, 1:00 PM - 2:20 PM
Room: CC-Exhibit Hall

675 **Chair:** Jean L. McCrory, FACSM. *West Virginia University, Morgantown, WV.*
(No relevant relationships reported)

676 May 27 1:00 PM - 1:10 PM Hip Abductors And Adductors Explosive Capacity Correlate With Step Reaction Time In Older Adults

Marcel B. Lanza, Odessa Addison, Alice Ryan, Vicki Gray.
University of Maryland Baltimore, BALTIMORE, MD.
Email: marcel.lanza@gmail.com
(No relevant relationships reported)

A loss of strength and explosive capacity (the ability to produce force as quickly as possible) may be risk factors for falls in older individuals. However, it is poorly understood if the explosive capacity of an older individual correlates with the reaction time (RT) of a predictable or unpredictable response. **PURPOSE:** Our primary aim was to investigate the relationship between rate of torque development (RTD) of the hip abductors and adductors with anticipatory postural adjustments (APA) and RT to a simple (SRST) and choice reaction step (CRST). **METHOD:** Nine older adults (5 females; 73 ± 4 y; 1.66 ± 0.07 m; 74 ± 12 kg; X ± SD) performed maximal voluntary isometric contractions (MVIC) in a standing position at 30° hip abduction. Participants performed the test as hard and fast as possible and held for ~5s. RTD was measured at 50, 100, 200 and 300 ms from torque onset (RTD₅₀, RTD₁₀₀, RTD₂₀₀ and RTD₃₀₀) and normalized to body weight and height. For the SRST and CRST a visual stimulus displayed at eye level in front of the participants indicated when to step laterally as fast as possible. APA was calculated as the first time when the difference in vertical force under the two feet increased by 5% of body weight while RT was the time between the visual stimulus and removal of the foot from the force plate. **RESULTS:** No significant correlations were found between RTD₅₀ and APA or RT. Hip abductors APA did not correlate with RTD while adductors APA correlated with RTD₂₀₀ and RTD₃₀₀ for both SRST and CRST (r = -0.71, P ≤ 0.032). Hip abductors RT correlated with RTD₁₀₀, RTD₂₀₀ and RTD₃₀₀ during CRST (r = -0.73, P = 0.025; r = -0.783, P = 0.013 and r = -0.74, P = 0.025; respectively) which was similar between hip adductors RTD₂₀₀ and RTD₃₀₀ during CRST (r = -0.85, P = 0.004; r = -0.93, P < 0.001; respectively). Hip adductors RT at RTD₃₀₀ correlated with SRST (r = -0.70, P = 0.036). **CONCLUSION:** Older adults hip abductors and adductors explosive capacity may be important when responding rapidly to an unpredictable stimulus while hip adductors also appear important in reacting to an expected stimulus. Therefore, older individuals that are not able to produce torque as fast as possible, especially during the late phase of contraction, in order to initiate the step possibly present larger risk of falls.

677 May 27 1:10 PM - 1:20 PM

Do Muscle Strength And Functional Mobility Underpin Balance Confidence In Older Adults?

Ying Liu¹, Yujie Tong¹, Xinyi Xu¹, Gordon Waddington², Roger Adams², Jeremy Witchalls², Jia Han¹. ¹*Shanghai University of Sports, Shanghai, China.* ²*University of Canberra, ACT, Australia.*

(No relevant relationships reported)

PURPOSE: Physiological, psychological and social factors are the three major determinants of falls in older adults. Psychological factors, especially balance confidence, have been suggested to be strongly associated with falls. However, it is unclear whether strength and mobility are associated with balance confidence. The purpose of the current study was to explore whether muscle strength and functional mobility reflect balance confidence in the elderly. **METHODS:** A group of 27 healthy community-dwelling adults (8M, 19F, 70.22±4.9yrs old) were recruited. Balance confidence was evaluated by using the Falls Efficacy Scale International (FES-I); functional mobility was measured by single-task Timed Up and Go test (TUG), motor dual-task TUG and cognitive dual-task TUG tests; upper limb muscle strength was measured by grip strength with a hand dynamometer; lower limb muscle strength was measured by the 30-second Sit to Stand test (30STS). SPSS was used to analyze data, with Pearson's correlation and independent samples t-test employed to examine the relationships among the measures. **RESULTS:** Pearson's correlation showed that FES-I scores for the group were moderately correlated with single TUG (r=0.569, p=0.002), cognitive TUG (r=0.463, p=0.015) and motor TUG scores (r=0.562, p=0.002). However there was no significant correlation between FES-I scores and upper or lower limbs strength (both p>0.05). According to the FES-I cut-point score of 23 for low balance confidence, participants were divided into "high balance confidence" subgroup (n=12) and "low balance confidence" subgroup (n=15). Independent samples t-tests showed significantly worse scores for the low balance confidence subgroup in single task TUG (p=0.035) and motor dual task TUG (p=0.025). **CONCLUSIONS:** The findings from this preliminary study suggest that balance confidence is associated with functional mobility, but not with muscle strength. Thus, in order to improve balance confidence, interventions based on improving functional mobility, rather than strength, should be particularly targeted involved in physiotherapy programs.

678 May 27 1:20 PM - 1:30 PM

The Relationship Between Power Production And Fall Risk

Michele Aquino. *Adelphi University, Garden City, NY.* (Sponsor: Robert M. Otto, FACSM)
Email: maquino@adelphi.edu

(No relevant relationships reported)

Falls can lead to prolonged periods of hospitalization and increased medical costs. Balance has commonly been defined as a three-system model (visual, vestibular, proprioception). However, there is a normal degeneration of these systems as we age which can increase fall risk (FR). Power production is required to catch oneself from a fall, therefore it may be an important aspect to consider in the treatment of those at risk of falling. **Purpose:** The purpose of this study is to explore the relationship between isokinetic average power production (IPP), of the knee extensors (KE) and ankle plantar flexors (APF), and FR utilizing the Fall Risk Questionnaire (FRQ), Five Times Sit to Stand (5xSTS), and the Dynamic Gait Index (DGI). **Methods:** 14 Older Adults (age: 74.8±9.1 yrs., height: 172.1±10.5 cm, body mass: 77.7±14.4 kg, 11 ♀) volunteered to participate in the study. Subjects began by completing the FRQ, thereafter, in a randomized manner, subjects were assigned to one of four tests: KE IPP, APF IPP, the 5xSTS, and the DGI. IPP was performed at 4 speeds (60, 120, 180 and 240°/s) for 5 repetitions, respectively with 5 min rest between trials. The highest average power (AP) for KE and APF was recorded. The 5xSTS was timed using an Apple iPhone stopwatch and the DGI was scored by a licensed Physical Therapist. **Results:** Statistical analysis by Pearson's r correlation with 95% confidence level revealed significant r values (p<.05) between variables. Mean FRQ scores, 5xSTS times, and DGI scores were 2.4±2.8, 9.2±5.1 sec, and 19.9±2.8, respectively. Mean KE-AP and APF-AP were 114.6±54.6 W and 55.2±25.1 W, respectively. Mean AP normalized per kg body weight were 1.45±.64 W/kg for KE-AP and .71±.3 W/kg for APF-AP. The FRQ demonstrated a significant r = .768 and r = -.896 with the 5xSTS and DGI, respectively. APF-AP was significantly correlated with FRQ and DGI (r = -.557; r = .610). Significant correlations were noted between APF-AP/kg and the FRQ and DGI (r = -.618; r = .691) along with KE-AP/kg and the 5xSTS (r = -.559). **Conclusion:** For one to complete these FR assessments, significant lower extremity power must be generated to maintain upright positions and promote a dynamic balance strategy. KE-AP and APF-AP demonstrate critical importance in successfully maintaining an adequate balance strategy, which is associated with decreased fall risk.

Mental Workload During Balance Training In Older Adults With Fall RiskLauren Q. Higgins. *University of North Carolina at Greensboro, Greensboro, NC.*

Email: lqhiggin@uncg.edu

(No relevant relationships reported)

The attentional demand of postural control is greater for older adults and increases further for older adults with balance impairments or who experienced a recent fall. Training interventions have examined balance and fall risk in older adults; focusing on improving physical factors related to balance. Further benefit to these interventions may be observed by incorporating cognitive factors such as attentional focus. It has been proposed that an external focus (EF) of attention uses automatic processing, reducing the attentional demand of postural control. This may be reflected in the mental workload (MWL) required for task execution. **PURPOSE:** This study investigated if EF of attention reduces MWL during balance training in older adults with fall risk.

METHODS: Older adults (N = 15, 4 males; 78.5 ± 7.0 yrs) who reported a fall in the past year were randomly assigned to either an EF group (N=9) or internal focus (IF) group (N=6). Participants completed 12 weeks of balance training on balance boards, twice per week for 20 minutes (20 trials; 30s balance, 30s rest). Prior to each trial, groups received respective attentional focus cues. At weeks 1, 3, and 6, heart rate variability (HRV) during balance training, and the NASA Task Load Index (NASA-TLX) were used as an assessment of MWL. HRV, R-R interval data was collected using a heart rate monitor chest strap.

RESULTS: Two-way repeated measures ANOVA's revealed a significant effect of time on four HRV outcomes: SDNN (F(2, 10) = 6.66, p = .015, partial η^2 = .571), RMSSD (F(2, 10) = 9.18, p = .015, partial η^2 = .647), (F(2, 10) = 4.18, p = .048, partial η^2 = .455), and DFA short term fluctuation slope (F(2, 10) = 6.84, p = .013, partial η^2 = .578). A significant interaction effect was observed for the NASA-TLX (F(2, 10) = 4.22, p = .047, partial η^2 = .458). Follow-up analysis revealed no significant main effects due to a cross over interaction with EF means decreasing and IF increasing from week 1 to 6. **CONCLUSIONS:** Preliminary findings suggest objective measures of MWL represent a practice effect of balance training with attentional cues. Additionally, the observed cross over interaction for MWL proposes that an external focus of attention may be an advantageous training strategy for reducing perceived MWL.

Effects Of Resting Posture On Gait Features During Timed Up And Go In Older AdultsEryn N. Murphy. *New Mexico State University, Las Cruces, NM.*

(Sponsor: Joseph Berning, FACSM)

Email: emurphy2@nmsu.edu

(No relevant relationships reported)

Altered gait mechanics and longer time to complete a 3-meter timed up and go (TUG) task are risk factors for falls in older adults. While acute change in posture influences static balance, it remains unclear if a supine resting position alters gait patterns, compared to seated rest in older adults. **PURPOSE:** The purpose of the present study is to explore the effects of resting postures on TUG performance and gait features during the TUG task. **METHODS:** In this within-subject design study, thirty-eight older adults (73.55 ± 1.04 yrs, 71.89 ± 2.31 kg, 1.64 ± 0.01 m) completed the TUG under two randomly ordered resting conditions; following 10 minutes of seated rest (SEAT) and following 10 minutes of supine rest (SUP). Participants were instructed to begin on "go" and "begin when they were ready", with time starting when they reached a seated position in SEAT and SUP conditions respectively. Total time (TUG_{TOT}, s), averaged gait velocity (TUG_{VEL}, cm/s), cadence (TUG_{CAD}, spm), and active propulsion (TUG_{APT}, %) of the percentage of gait time when the center of gravity extends beyond the base of support until contralateral heel contact) over the single trial were calculated. TUG trials were calculated using Tekscan Walkway system. Paired sample t-tests were used to determine gait differences between two resting conditions. **RESULTS:** TUG_{TOT} was significantly longer after the SUP compared to the SEAT (12.14 ± 4.35 s vs. 10.52 ± 2.65 s, p=0.001). TUG_{VEL} was significantly slower after the SUP compared to the SEAT (85.28 ± 28.73 cm/s vs. 102.03 ± 21.43 cm/s, p<0.001). TUG_{CAD} was significantly lower after the SUP compared to the SEAT (108.94 ± 21.57spm vs. 119.44 ± 13.50 spm, p=0.001). TUG_{APT} was significantly less after the SUP compared to the SEAT (58.00 ± 25.53% vs. 71.72 ± 22.14%, p=0.012). **CONCLUSIONS:** Clinical standards identify older adults that take longer than 12 seconds to complete the TUG at increased risk of falling. Our results indicate that a sudden postural change from supine resting position results in increased falls risk. These findings have potential to inform patient, provider, and caregiver efforts to lower risk of falls in older adults.

681 May 27 1:50 PM - 2:00 PM

Rate Of Force Development Parameters In Young And Older Males During A Chair RiseTyler M. Smith, Phuong L. Ha, Alex A. Olmos, Matthew T. Stratton, Trisha A. VanDusseldorp, Alyssa R. Bailly, Yuri Feito, FACSM, Micah J. Poisal, Joshua A. Jones, Benjamin E. Dalton, Garrett M. Hester. *Kennesaw State University, Kennesaw, GA.*

(Sponsor: Yuri Feito, FACSM)

(No relevant relationships reported)

Assessing vertical ground reaction forces (VGRF) during a chair rise may yield insight regarding age-related differences in physical function, but a comprehensive assessment of rate of force development (RFD) during this task is lacking. **PURPOSE:** To compare RFD parameters during a chair rise in young (YM) and older (OM) males, and examine correlates of chair rise time. **METHODS:** Healthy, YM (n=15, age=20.7±2.2 yrs) and OM (n=15, age=71.6±3.9 yrs) performed a single chair rise as quickly as possible on a force plate without upper-body assistance. Peak VGRF (PF), as well as peak (highest 100 ms rolling average), early (minimum VGRF to 50% PF), late (50% PF to PF), and overall (minimum VGRF to PF) RFD were recorded. RFD was calculated as the linear slope of the force-time curve (Δ force/ Δ time) during the corresponding time spans. All force measures were derived from the normalized (body mass) force signal. Chair rise time was also obtained and the trial with the shortest time was used for subsequent analysis. Independent samples t-tests were used for group comparisons, and Pearson correlation coefficients were calculated for each group to examine select relationships. **RESULTS:** Chair rise time was similar between groups (p=0.256). Early RFD was similar (p=0.051), while PF (YM=1.57±0.13 vs. OM=1.33±0.10 N/kg; p<0.001), peak (YM=12.60±1.56 vs. OM=9.05±1.46 N/s/kg¹; p<0.001), late (YM=8.12±1.63 vs. OM=4.97±1.10 N/s/kg¹; p<0.001), and overall RFD (YM=7.57±1.24 vs. OM= 5.49±1.16 N/s/kg¹; p<0.001) were lower in the OM. For OM, only PF (r=-0.875; p<0.001) and peak RFD (r=-0.783; p=0.001) were correlated with chair rise time, while no correlations were present in YM. **CONCLUSION:** PF and RFD, especially peak and late RFD, were dramatically diminished during a chair rise in OM. PF and peak RFD demonstrated a strong inverse relationship with chair rise time in OM.

Comparison Of Age, Gender, And Sport On Performance Of Stability Test In Senior ParticipantsRomina Villamonte¹, Dennis Eggert², Brent J. Feland². ¹*New Zealand Institute of Sport, Epsom, Auckland, New Zealand.* ²*Brigham Young University, Provo, UT.* (Sponsor: Ty Hopkins, FACSM)

Email: romina.villamonte@nzis.ac.nz

(No relevant relationships reported)

PURPOSE: The purpose of this study was threefold: to observe the differences in performance variables of the Modified Clinical Test of Sensory Interaction in Balance in active elderly participants and to compare results by age (50-59, 60-69, 70-79, 80+), sports (aerobic, basketball, golf, tennis, volleyball, and none), and gender. **METHODS:** Analyses were based on a sample of 525 World Senior Games attendees who were age 50 and over. Data were obtained from voluntary participation in balance and mobility screening as part of the health fair offered to all participants at the annual Hunstman World Senior Games. Of the 525 participants tested, 383 were participants in at least one sporting event at the games and 142 were non-participants. All modified CTSIB were performed on the NeuroCom Balance Master. The measured variables (center of gravity sway (degrees/sec)) were; firm surface with eyes open, firm surface with eyes closed, foam surface with eyes open, and foam surface with eyes closed. **RESULTS:** All data were analysed using SAS, version 9.4. An initial analysis of gender and age category was performed. A final model was run with the significant variables from the initial analysis plus sports category. Post hoc Tukey pairwise comparisons were also performed. A significant difference ($p < 0.0001$) was found between stratified age groups in all balance test variables. No significant differences were found between gender nor sports categories for the 4 balance variables.

Age (years)*	Participants (n)	*Firm Eyes Open	*Firm Eyes Closed	*Foam Eyes Open	*Foam Eyes Closed
50 - 59	140	0.2004	0.2494	0.6561	1.5904
60 - 69	237	0.2306	0.2816	0.7635	1.8823
70 - 79	128	0.2804	0.3448	0.8736	2.0625
80 +	20	0.3426	0.4966	1.1106	2.4164

CONCLUSION: While balance sway significantly increases with age in all 4 variables, they remain similar when comparing between gender and sports. This test may not be sensitive enough to detect differences between sports in our participants. Also,

our participants are probably too active to detect differences in the variables tested regardless of sports category. Further research is needed to better differentiate between active and non-active individuals and performance on the modified CTSIB.

683 May 27 2:10 PM - 2:20 PM
Balance Assessments In Older Adults After A Six-week Walking Intervention With Different Gait Devices

Abbie Payne, Megan Ruppert, Lana Prokop, Joshua Guggenheimer. *St. Catherine University, St. Paul, MN.* (Sponsor: Mark Blegen, FACSM)
(No relevant relationships reported)

Older adults have a relatively high incidence of falls, which are costly for both the individual and the medical system. Falls result not only in physical injury or death, but also can lead to a decreased quality of life - both mentally and socially. Measuring different aspects of balance can help predict the risk for falling. **PURPOSE:** This study investigated how walking with no device, walking poles, or a gait trainer impacted balance measures in older adults. **METHODS:** Fourteen participants (3 men, 11 women, aged 77.53 +/- 7.28 years) were randomized to one of three walking groups: Control (C) (n=4), Walking Poles (WP) (n=5), or Gait Trainer (GT) (n=5). The gait trainer is a new device aimed at preventing age-related gait decline. Assessments were performed at three separate times: prior to the intervention (Pre-test), immediately after the intervention (Post1), and six weeks after Post1 (Post2). Assessments included subjective measures of balance confidence during activities of daily living (Falls Efficacy Scale International and Activities-Specific Balance Confidence), and physical measures of balance (Berg Balance Scale (BBS) and the Timed Up and Go (TUG)). For the six-week intervention, all participants walked three times per week for 30 minutes in their assigned walking group. **RESULTS:** An ANOVA showed there were no statistically significant differences between the groups at Pre-test for all metrics ($p > 0.05$). All groups were below the cut off score of a high fall risk (≥ 14 s) for the TUG at Pre-test: C 9.00 ± 2.18 s, WP 9.41 ± 2.41 s, and GT 11.29 ± 4.99 s. All groups were above the cut off score (<45 out of 56) for greater risk of falls on the BBS at Pre-test: C 51.5 ± 1.29, WP 52 ± 5.00, and GT 48.4 ± 5.03. Between group measurements across time were analyzed using linear regression models for all metrics, with an alpha set at $p < 0.05$. There were no statistically significant differences between groups across time. **CONCLUSION:** This study found that the walking group did not impact balance measurements over time with the six-week walking intervention. All three groups were relatively high-functioning compared to age norms, which may have impacted scoring sensitivity on the TUG and BBS. Future studies may consider using more challenging interventions and balance assessments for higher-functioning older adult populations.

B-44 Thematic Poster - Biomechanics During Military Tasks

Military Parachuting Effects In Kinetic Variables From Countermovement Jump In Kinetics From Colombia

Jenner Cubides¹, Rodrigo E. Argothy², Maria Alejandra Dias³, Daniel Cohen⁴. ¹Militar school of cadets "General José María Córdova, Bogota, Colombia. ²Ministry of Sports, Bogota D.C., Colombia. ³Militar school of cadets "General José María Córdova, Bogota D.C., Colombia. ⁴University of Santander (UNDES), Bogota D.C., Colombia.
 Email: reargothyb@gmail.com
(No relevant relationships reported)

The military parachuting course (MPC) is one of the combat courses offer during the Colombian military career. A literature research shows that this type of courses presents a high incidence and prevalence of injuries in the lower limbs in the landing phase. Additionally, different studies show that the injury rate in the lower limbs is 2-20 every 1000 jumps performed. The most compromised areas are the ankle and knee (ligament and sprains), where 80% of the injuries occur. Moreover, the militaries present a higher injury risk because of variable conditions: high wind speeds, external load and ground conditions. Then, a good landing is very important and it requires a good stability at the knee and a good distribution of the energy at the time of contact with the ground. **PURPOSE:** Identify the effects of the military parachuting course on the muscular performance of the lower limbs **METHODS:** Descriptive observational

study with an analytical component, in 43 male cadets of the Military School from Colombia, who participated in the MPC for 4 weeks. The performance of the lower limbs was evaluated by using uniaxial force platforms before and after the course. A statistical analysis was performed using the student T test and the Wilcoxon test statistic was used to evaluate changes after the MPC **RESULTS:** Significant differences were found in the jump height (29.32 ± 3.8 vs. 26.03 ± 3.6 cm, $p = 0.0001$), peak power (43.29 ± 3.4 vs. 40.62 ± 4.3 W/kg, $p = 0.0002$), peak landing force (57.65 ± 9.8 vs. 65.15 ± 12.4 N, $p = 0.002$), eccentric peak velocity (-1.09 ± 0.1 vs. -1.01 ± 0.2 m/s, $p = 0.005$), concentric mean power (23.72 ± 2.5 vs. 22.78 ± 2.8 N/kg, $p = 0.022$) and eccentric mean power/BM (5.88 ± 1.03 vs. 5.36 ± 1.09 N, $p = 0.001$). **CONCLUSIONS:** There is an impact on neuromuscular performance that affects the strength and power of the lower limbs, and increases the ground reaction forces in the landing phase. It could become a risk factor for injuries due to a change in the mechanism of acceptance of load at the landing stage.

Kinetic Changes of Countermovement Jump Test

Medial Compartment Gap Is Decreased During Forced Marching And Running Load Carriage Tasks

Camille C. Johnson, Kellen T. Krajewski, Dennis E. Dever, Ajinkya Rai, Katelyn F. Allison, Mita Lovalekar, William J. Anderst, Christopher Connaboy. *University of Pittsburgh, Pittsburgh, PA.*
 Email: ccj17@pitt.edu
(No relevant relationships reported)

Medial compartment cartilage thickness can provide an indication of early stage osteoarthritis (OA), so determining tibiofemoral joint space during dynamic loading tasks is an important step in investigating potential long-term joint degeneration. Women experience higher rates of knee OA than men and military personnel are at an even greater risk, so understanding how military-relevant load carriage tasks will affect tibiofemoral arthrokinematics in a female population is of great importance in order to inform training strategies and prevent injury. **PURPOSE:** The purpose of the study was to determine the effects of load carriage and locomotion pattern on tibiofemoral dynamic joint space. **METHODS:** Twelve physically active females (age: 24.5±2.4 years) walked (WK), ran (RN), and force marched (FM, or walking at a high velocity) on a treadmill while unloaded (bodyweight, or BW) and while loaded with an additional +25%BW or +45%BW (14.3±2.0 kg, 25.6±3.5 kg). Synchronized biplane radiographs of the right knee were collected at 150 images/second for 1 second during each movement trial. A validated model-based tracking system determined femur and tibia motion (accuracy: 0.9°, 0.7 mm). Subchondral bone distances were calculated. Two-way RMANOVA with post-hoc Bonferroni correction were used to analyze the interactions and within-subjects effect of load (BW, +25BW, +45%BW) and percent of right leg support (0%, 10%, 20%, 30%) on minimum medial and lateral compartment gap during WK, RN, and FM, independently ($\alpha=0.05$). **RESULTS:** No significant interactions were observed between load and percent support. Medial and lateral gap was lower at initial contact vs. 10% and 20% support for FM (Medial: 38%, 33% decrease, Lateral: 26%, 23% decrease). Medial gap was 23% lower at 30% vs. 20% support for FM. For RN, medial gap was lower at 30% support vs. 10% and 20% (35%, 19% decrease). No significant changes in joint space were observed for lateral RN or medial/lateral WK. No significant differences due to load were observed. **CONCLUSION:** Changes in knee dynamic joint space appear to be more sensitive

to differences in knee kinematics rather than additional load magnitude and suggest kinematics plays a vital role in knee cartilage loading and potentially the development of OA. Supported by the Freddie Fu Student Research Grant.

The Effects Of External Loading On Lower Extremity Landing Biomechanics In College Rotc Cadets

Jae P. Yom¹, Allen Redinger², Dustin Grooms², Janet Simon².

¹University of Illinois Springfield, Springfield, IL. ²Ohio University, Athens, OH.

(No relevant relationships reported)

Military personnel performs in combat and physical training with extensive external loading from combat gear that may increase risk for lower extremity musculoskeletal injury. Lower extremity musculoskeletal injury risk is high in this population and can threaten deployment, completion of duty, and quality of life. However, there is limited research determining the effects of external loading on landing biomechanics in military situations. **PURPOSE:** To determine if external loading affects lower extremity landing biomechanics during a jump landing task in ROTC cadets.

METHODS: Twenty five ROTC cadets (age: 20.2±1.3yr; height: 174.4±11.3cm; mass: 77.0±5.1kg) were recruited and performed two conditions of three jump landings (baseline vs loaded landing with an additional 35% body weight (BW) vest) from a 30cm high box. The box was placed a distance of 50% of their height from the landing zone of two force plates. Lower extremity angular joint kinematics and ground reaction forces (GRFs) were compared between the two conditions using paired t-tests ($\alpha < .05$).

RESULTS: The loaded landing compared to baseline landing, resulted in decreased knee (16.8±3.7 and 19.4±4.7°) and hip (30.4±6.3° and 32.7±5.4°) flexion at initial contact (IC), and increased maximal joint flexion displacements for ankle (36.0±11.5° and 31.4±9.9°), knee (56.2±7.2° and 49.0±6.5°), and hip (23.8±5.6° and 18.5±4.9°). Furthermore, loaded landings, compared with baseline landings, exhibited significantly lower vertical GRF (2.3±0.5 N·kg⁻¹ and 2.7±0.5 N·kg⁻¹) and posterior GRF (0.6±0.1 N·kg⁻¹ and 0.7±0.1 N·kg⁻¹). **CONCLUSION:** Loaded landings increased key injury risk landing biomechanics. Less knee and hip flexion at IC have been associated with potential anterior cruciate ligament (ACL) injury risk and may increase ACL loading during landing. However, the less peak vertical and posterior GRFs with greater displacement of all three lower extremity joints on during loaded landing suggests cadets employed a compensation strategy that may reduce ACL loading after IC.

Sex-related Differences In Patellofemoral Joint Stress With Fighting And Approach Load Carriage

Marin Plemmons, Brent Ruby, FACSM, Brittany Hanser, Kelly Christensen, Alexis Doust, Richard W. Willy. University of Montana, Missoula, MT.

Email: marin.plemmons@umconnect.umt.edu

(No relevant relationships reported)

PURPOSE: Female Soldiers have 2.2x greater risk for patellofemoral pain (PFP) compared with male Soldiers. Females may experience larger increases in knee loads, versus males, with added load carriage, which is standardized in the military across sexes. Thus, we assessed sex-related differences in patellofemoral joint stress (PFJS) metrics with the addition of fighting (20 kg) and approach (35 kg) load carriage.

METHODS: Via motion capture procedures, 34 healthy, well-trained individuals with load carriage experience (17 male(M):26.8 yrs±4.3, 78.9kg±6.8; 17 female(F): 23.8yrs±4.6, 64.3kg±8.1) completed instrumented treadmill trials (1.35 m/s) with and without 20-kg and 35-kg load carriage. Peak PFJS and PFJS loading rate were estimated with a musculoskeletal model and analyzed via repeated measure ANOVAs [Sex(2) x Load(3)]. Standard mean differences (SMD) were calculated on the relative change rate of PFJS metrics in males versus females with added load carriage.

RESULTS: Significant Sex X Load interactions ($p < .01$) were found for both peak PFJS and PFJS loading rate. While moderate SMDs were found between 0kg and 20kg carriage, large SMDs were found between 0kg and 35kg carriage indicating larger relative increases in PFJS metrics in females versus males. TABLE: Mean and standard deviations for variables. *corresponds to $p < .05$ between 0kg and 20kg; †Corresponds to $p < .05$ between 0kg and 35kg.

Variable	0 kg	20 kg	SMD 0 kg =>20kg	35 kg	SMD 0 kg =>35kg
Peak PFJS	M: 2.2 mPa± 0.6 F: 2.0 mPa± 0.6	M: 2.6 mPa± 0.9* F: 2.7 mPa± 0.6*	d=0.39	M: 2.9 mPa± 0.9*† F: 3.4 mPa± 1.0*†	d=1.03
PFJS Loading Rate	M: 22.8 mPa/s ±9.7 F: 18.7 mPa/s ±10.0	M: 25.8 mPa/s ±11.8 F: 25.9 mPa/s ±13.0*	d=0.42	M: 29.2 mPa/s ±12.1*† F: 34.5 mPa/s ±12.8*†	d=0.96

CONCLUSIONS: Females experienced greater relative increases in PFJS metrics with added load carriage compared with males, but only the approach load (35 kg) resulted in large SMDs. Thus, training volume, e.g., march distances, with approach loads should be increased more cautiously in females compared with males whereas fighting loads (20kg) appear less risky and may require minimal adjustments in training volume between sexes. These findings provide insight into why females have a disproportionately higher rate of PFP in the military than the general population.

Compromised Perception-action Coupling Performance In Military Personnel May Be Related To Increased Deep Sleep

Alice D. LaGoy¹, Shawn R. Eagle¹, Aaron M. Sinnott¹, Meaghan E. Beckner¹, William R. Conkright¹, Shawn D. Flanagan¹, Brian J. Martin¹, Bradley C. Nindl, FACSM¹, Fabio Ferrarelli², Anne Germain², Christopher Connaboy¹. ¹University of Pittsburgh, Pittsburgh, PA. ²University of Pittsburgh School of Medicine, Pittsburgh, PA.

Email: adl59@pitt.edu

(No relevant relationships reported)

Operational stressors, such as caloric and sleep restriction and physical fatigue, may compromise perception-action coupling, the cooperative function of the sensory and motor systems, in military personnel. Prior sleep may protect against performance decrements and different sleep stages may conserve different aspects of performance.

PURPOSE: To investigate changes in perception-action coupling during simulated military operational stress and understand the role of sleep stages on performance. **METHODS:** As part of a 5-day study assessing resilience to simulated military operational stress, thirty-three (6 female) active duty and reserve status service members (25.8 ± 4.7 years) completed three trials of a novel perception-action coupling task (PACT) at 1700 after a night of baseline sleep (BASE), two nights of sleep restriction (T1) and a night of recovery sleep (T2). Participants had 8-hr for baseline and recovery sleep (2300-0700) and 4-hr disturbed sleep on intervention nights (0100-0300 and 0500-0700). Polysomnography was used to identify sleep stages. The tablet-based PACT requires participants make quick, accurate perceptual judgments and responses about whether varying sized virtual balls fit through virtual apertures. Outcomes of interest included response time (RT) and accuracy (ACC). Percent time in stage 2 (N2), slow wave (SWS) and rapid-eye movement (REM) sleep were median split to form high (more sleep in a stage) and low sleep groups. Differences in PACT performance between sleep groups across time were assessed using multiple mixed model (2 x 3) ANOVA. **RESULTS:** No significant sleep group x time interaction or main effect of time were found for RT or ACC. A significant main effect of SWS sleep group was found for RT ($F_{1,31} = 4.898, p = .034, \eta^2_p = .136$). The high SWS group had slower (worse) RT than the low SWS group (.886 ± .023 vs .814 ± .024 s). No other significant main effects of sleep group were found. **CONCLUSION:** Perception-action coupling was maintained during simulated military operational stress. Participants with more baseline SWS had worse PACT performance but other sleep stages, N2 and REM, did not relate to perception-action coupling. This suggests a specific effect of SWS, which is deep sleep, on perception-action coupling abilities and behaviors.

Stroboscopic Effect On Functional Balance Performance In Special Operations Forces Combat Soldiers

Jason P. Mihalik, FACSM¹, Cassie B. Ford¹, Stephen M. DeLellis², Marshall L. Healy³, Shawn F. Kane, FACSM¹, Gary E. Means³, James H. Lynch, FACSM³. ¹The University of North Carolina at Chapel Hill, Chapel Hill, NC. ²Defense Medical Strategies LLC, Fayetteville, NC. ³United States Army Special Operations Command, Fort Bragg, NC.
Email: jmihalik@email.unc.edu

Reported Relationships: J.P. Mihalik: Ownership/interest/stock; Dr. Mihalik has an equity interest in Senaptec Inc., the company that manufactures and sells the stroboscopic eyewear used in this study.

Previous work has identified that standard concussion balance measures (e.g., BESS) do not differentiate Special Operations Forces (SOF) combat soldiers with and without concussion history. Recent evidence also associates incident concussion with a subsequent increased musculoskeletal injury risk. There is a need to study functional balance performance tasks designed to challenge this military population.

PURPOSE: To study the interaction between concussion history and increasing visual occlusion on functional balance performance in SOF combat soldiers. **METHODS:** 74 SOF combat soldiers (age=34.0±4.7 yrs) participated in our study and self-reported concussion history (33 no, 41 yes). All participants completed the Y-Balance Test (YBT) under 3 different counterbalanced visual conditions: 1) eyes-open, 2) low occlusion, and 3) high occlusion. Low (level 2) and high (level 6) occlusion conditions were produced using stroboscopic eyewear. Dependent variables included the right and left composite reach distance (percentage) for each vision level. Mixed model ANOVAs evaluated differences in composite reach distance between visual conditions and concussion history. **RESULTS:** Increasing vision occlusion affects right ($F_{2,144}=11.93$; $p<0.001$) and left ($F_{2,140}=14.41$; $p<0.001$) limb YBT performance regardless of concussion history, with both low (103.5%, 95%CI: 101.2,105.8) and high (102.3%, 95%CI: 100.1,104.4) occlusion resulting in diminished YBT performance compared to eyes open (105.3%, 95%CI: 103.1,107.5). SOF combat soldiers with no concussion history demonstrated better right ($F_{1,72}=5.28$; $p=0.025$) and left ($F_{1,70}=8.49$; $p=0.005$) limb YBT performance compared to those self-reporting concussion history regardless of vision occlusion. There was no interaction effect between visual occlusion and concussion history on right ($F_{2,144}=0.71$; $p=0.492$) or left ($F_{2,140}=0.01$; $p=0.993$) limb YBT performance in our sample. **CONCLUSION:** Increasing visual occlusion or self-reporting concussion history negatively affect SOF combat soldiers' YBT performance. These data suggest introducing stroboscopic eyewear and presenting SOF combat soldiers with a challenging balance task (e.g., YBT) may be an effective post-concussion assessment consideration. (No relevant relationships reported)

Military personnel are at risk of stress fracture injuries, especially those in load carriage-based military occupational specialty, such as infantry. Recently, wearable inertial measurement unit (IMU)-based accelerometry has become a useful tool for identifying markers of lower extremity musculoskeletal injury risk in soldiers in field settings. **Purpose:** To compare differences in accelerometry between non-dominant and dominant foot using foot-worn IMU sensors during a 2km best effort run with heavy (20kg) load carriage. **Methods:** Acceleration data from six healthy participants (3 male: 30.33±6.7 y, 1.82±0.01 m, 77.80±11.0 kg and 3 female: 21.0±2.6 y, 1.66±0.1 m, 64.62±13.5 kg) were recorded using tri-axial IMU affixed to the dorsum of each foot. Participant performed a 2km best effort march (run and walk) across grass carrying 20 kg on their back. Data were divided into 200m +/- blocks from the beginning, middle and end of the exercise for analysis. The acceleration amplitudes from each trial were expressed as the root mean square (G_{RMS}), calculated as the average of the square of the acceleration over time, and were used to quantify the accelerations attenuation. The magnitude of the resultant acceleration signal Acc_x referred to as the "composite acceleration signal", was computed as: $\sqrt{acc_x^2 + acc_y^2 + acc_z^2}$, where acc_x , acc_y , and acc_z are obtained from each individual axis of the

tri-axial accelerometer. **Results:** The mean G_{RMS} values at the three phases obtained for the dominant and non-dominant feet of the men were 4.72, 5.15, and 5.23, and 4.93, 4.75, and 4.41 m/s^2 , respectively whereas those obtained for the dominant and non-dominant feet of the women were 3.91, 4.32, and 3.87, 4.42, and 4.71 m/s^2 , respectively. These findings revealed that the G_{RMS} values of the feet obtained for both sexes gradually increased during the load carriage task, except for the non-dominant foot of the men, which decreased. **Conclusion:** Increases in G_{RMS} during loaded marching suggest non-linear increases in culminative mechanical stress exposure as distance increases. Foot worn IMU-based measurement systems may provide means to accurately assess injury risk in real time. Supported by UK Ministry of Defence (WGCC 5.5.6-Task 0107) and US Dept. of Defense (W81XWH-17-2-0070).

Practical And Applied Knowledge Of Athletic Trainers On The Female Athlete Triad

Jennifer L. Scheid, Erin M. DeHeer. Daemen College, Amherst, NY.
Email: jscheid@daemen.edu
(No relevant relationships reported)

BACKGROUND: The female athlete triad is the interrelation of low energy availability, menstrual dysfunction, and low bone mineral density. Athletic trainers are in a position to be able to identify the female athlete triad in athletes. However, limited research exists regarding practical and applied knowledge of the female athlete triad. **PURPOSE:** The purpose of this study was to determine the level of practical knowledge of athletic trainers on the female athlete triad and also determine if athletic trainers are applying this knowledge by properly screening athletes for the female athlete triad. **METHODS:** Certified athletic trainers (n=116) completed an online survey via Qualtrics that assessed both knowledge of the female athlete triad and current practical application of the female athlete. Linear-by-linear tests were used to find associations between practical knowledge and applied knowledge for related components of the triad. **RESULTS:** The athletic trainers mostly work with high school athletes (39%) and college athletes (32%). Fifty percent of the athletic trainers had at least 7 years of experience. Sixty-nine percent of the athletic trainers were female. While most of the general knowledge of the athletic trainers was high (for example 70% believe that increasing energy availability is key when returning an athlete back to sport and 73% believe that repeated stress fractures is a red flag for the female athlete triad) most of the applied knowledge was low (for example only 14% screen their athletes for eating disorders and only 36% ask about history of stress fractures). Linear-by-linear association ($p=0.050$) demonstrated an association between agreeing about importance of energy availability and always screening for eating disorders. However, we did not demonstrate linear-by-linear association ($p=0.354$) between agreeing that stress fractures are a red flag for the female athlete triad and asking about history of stress fractures. **CONCLUSION:** While general knowledge of the female athlete triad is high, a low percentage of athletic trainers appear to be applying their knowledge in prevention and detection of the female athlete triad. More education is need to help athletic trainers to implement screening, prevention, and return to play techniques to keep our athletes safe.

Prevalence And Impact Of Dysmenorrhea In Japanese Female Athletes

Reiko Momma¹, Akemi Sawai², Maho Takeda¹, Hiroaki Natsui³, Naoki Mukai¹, Koichi Watanabe¹. ¹University of Tsukuba, Tsukuba, Japan. ²International Pacific University, Okayama, Japan. ³Japan Women's College of Physical Education, Setagaya, Japan.
(No relevant relationships reported)

Dysmenorrhea (menstrual cramps) is one of the big problems that many women suffers. It has been previously reported that dysmenorrhea is associated with lifestyle habit including sleep, exercise, smoking, and alcohol. Many female athletes have been reported to suffer with dysmenorrhea, however, the prevalence and impact of

dysmenorrhea and in relation to lifestyle in Japanese female athletes are not clarified yet. **Purpose** To investigate the prevalence and impact of dysmenorrhea in Japanese female athletes. **Methods** 98 collegiate female athletes participated in this study (mean age 21±1.6). Sports type in participants were soccer (n=23), track and field (n=31), kendo (n=13), wheel gymnastics (n=10), lacrosse (n=21). Demographic information questions addressed age, height, weight, length of sporting career, and training volume (training hour, training frequency per week, training hour per time). Lifestyle habits questions included daily wake-up time and bedtime, sleeping hours, dietary habit, coffee-drinking, alcohol-drinking and smoking habits. Age of menarche, day counts of menstrual cycle, day counts of menstruation, dysmenorrhea symptoms (e.g.; breast tenderness, abdominal pain, low back pain, headache), dysmenorrhea severity (from 0 to 10; none to very severe), and medication during menstruation were asked in the menstrual questionnaire. **Results** The dysmenorrhea symptom that many subjects complained were lower abdominal pain and fatigue. Length of sporting career, menarche age, training habits and lifestyle habits did not show significant correlation with severity of dysmenorrhea. However, the prevalence of severe dysmenorrhea positively correlated significantly with age ($p = 0.004$, $r = 0.29$). **Conclusions** In this study, we showed that severity of dysmenorrhea was associated with older age in Japanese female athletes. Therefore, in female athletes it is necessary to deal with dysmenorrhea considering age.

Female Athletes And Osteoporosis Risk

Sonya L. Sanderson¹, Pamela Anderson². ¹Middle Tennessee State University, Murfreesboro, TN. ²Georgia Gwinette College, Lawrenceville, GA. (Sponsor: Melissa J. Benton, FACSM)
Email: sonya.sanderson@mtnsu.edu

(No relevant relationships reported)

Female athletes are participating in greater numbers than ever before. Across the last year, nearly 3.4 million female high school (NFSH, 2019) and 216,400 NCAA college-aged females (NCAA, 2018) competed in a variety of sports. Unfortunately, this phenomena has elevated concerns regarding the impact of relative energy deficiency in sport (RED-S) among such populations. The elevated energy expenditure required to drive such participation may lead to decreased energy availability, this coupled with hypothalamic disruption may place female athletes at greater risk of bone mineral density (BMD) loss than previously anticipated. **Purpose:** To evaluate BMD in female athletes. **METHODS:** Participants included 60 NCAA Division II college-aged female athletes from two southern universities and 13 participants aged 15 to 18 on a club team. The females identified themselves as Caucasian ($n = 59$), African American ($n = 8$), Latina ($n = 2$), or other ($n = 4$). BMD of the phalanges on the non-dominant hand was collected. Self-reported information about calcium intake, diet, and physical activity level were collected along with administration of the EAT-26. **Results:** The athletes ranged in age from 15-33 ($M = 19$, $SD = 2.2$) with a mean weight of 66.4 kg ($SD = 9.5$) and height of 1.7 m ($SD = .07$). The population was classified as asymptomatic and free of any self-reported disordered eating, and yet, not consuming the recommended amount of calcium daily (1200-1500 mg). Moreover, 31 (43.6%) participants currently had secondary amenorrhea, 15 participants (20.5%) reported a history of osteoporosis in their immediate family, and 12 participants (16.7%) had experienced a stress fracture. Of the 73 participants, 16 females (21.9%) were determined to have osteopenia. All 16 females were Caucasian. Consequently, there was a relationship between BMD and race ($r = .26$, $p < .05$) in addition to BMD and alcohol consumption ($r = .22$, $p < .05$). **Conclusion:** No relationship was found between the components of RED-S (amenorrhea and low energy availability) and BMD. However, Caucasian female athletes were at a greater risk for osteopenia than other races. This study was limited by the instrument utilized and site scanned. Further research should be conducted regarding site and sport specific adaptations on BMD employing scans from both the upper and lower body.

Comparing Bioelectrical Impedance Analysis To Air Displacement Plethysmography For Body Composition Assessment In Female Athletes

Austin Katona, Caroline Riewe, Samantha Zalewski, Kelly Powers, Robert Mangine, Abigail Peairs. *University of Cincinnati, Cincinnati, OH.* (Sponsor: J. Derek Kingsley, FACSM)
Email: katonaaaj@mail.uc.edu

(No relevant relationships reported)

PURPOSE: To compare bioelectrical impedance analysis (BIA) and air displacement plethysmography (ADP) for body composition assessment in female collegiate athletes.

METHODS: Retrospective review of body composition data for 61 NCAA female collegiate athletes (basketball $n = 14$, soccer $n = 31$, volleyball $n = 16$), measured by BIA and ADP on the same day. Paired t-tests, effect size using Cohen's d , Pearson's

correlation, and Bland-Altman plots were used to compare percent body fat (%BF) and fat-free mass (FFM) measurements from BIA and ADP for the whole sample, and within sports.

RESULTS: The sample included 61 female athletes ages 18-25 years ($\bar{x} = 19.5 \pm 1.4$ years), with heights ranging from 160-190.5 cm ($\bar{x} = 172.3 \pm 8.9$ cm), %BF measures ranging from 6.0-38.5% ($\bar{x} = 21.3 \pm 6.3\%$) for ADP and 13.4-36.0% for BIA ($\bar{x} = 22.5 \pm 4.7\%$) and FFM measures ranging from 36.2-69.3 kg ($\bar{x} = 53.4 \pm 6.8$ kg) for ADP, and 38.8-63.8 kg for BIA ($\bar{x} = 52.4 \pm 5.8$ kg). Overall, BIA and ADP had strong positive correlations for %BF ($r = 0.67$) and FFM ($r = 0.891$). BIA significantly underestimated FFM when compared to ADP (mean difference [MD] = -0.99 kg, $p = 0.016$, $d = -0.32$), while no significant difference was observed in %BF (MD = 1.17%, $p = 0.056$, $d = 0.25$). Linear regression on the Bland-Altman plots revealed small but significant negative trends for both %BF ($\beta = -0.34$, $p = 0.004$) and FFM ($\beta = -0.166$, $p = 0.01$) estimation by BIA in the total sample. This indicates possible proportional bias, in which BIA is more likely to overestimate %BF and FFM at low values, and underestimate %BF and FFM at high values. When comparing sports, BIA significantly overestimated %BF (MD = 5.42%, $p = 0.001$, $d = 1.14$) and underestimated FFM (MD = -3.71 kg, $p = 0.001$, $d = -1.07$) for basketball players and significantly underestimated %BF (MD = -2.06%, $p = 0.04$, $d = -0.56$) in volleyball players, when compared to ADP. No significant measurement differences were found in soccer players.

CONCLUSIONS: BIA gives comparable body composition results to ADP for soccer players, but gives conflicting results regarding over and underestimation of %BF and FFM in basketball and volleyball players. Conflicting conclusions based on sport may indicate the need for specialized equations when extrapolating body composition measures using BIA for athletes at the higher and lower ends of the spectrum of %BF and FFM.

Urogenital Dysfunction Among Female And Male High School Cross-country Runners

Mitchell J. Rauh, FACSM, Lori J. Tuttle. *San Diego State University, San Diego, CA.*
Email: mrauh@mail.sdsu.edu

(No relevant relationships reported)

While urinary stress incontinence or dysfunctions associated with this condition has been reported in various adult and female sport populations, less is known on their prevalence among distance runners, particularly adolescent female and male distance runners. **PURPOSE:** To determine the prevalence of urogenital dysfunction (UD) among female and male high school cross-country runners. **METHODS:** Participants consisted of 104 runners (48 females, 56 males; age: 15.7 ± 1.2), who competed in interscholastic cross-country in southern California. Each runner completed the Urinary Distress Inventory 6 (UDI-6) to assess urinary dysfunction. The UDI-6 is a six-symptom inventory that allows participants to categorize their symptoms during activities. Runners were identified as having had UD if they reported experiencing any of the six symptoms during the past 3 months. The runners completed the UDI-6 separately for symptoms during running and non-running activities. If a runner reported any of the six symptoms with "somewhat", "moderately", or "quite often", they were considered to have demonstrated UD. Relative risks (RR) and 95% confidence intervals (CIs) were calculated to examine associations between sex and UD. **RESULTS:** Overall, the number of runners reporting at least one UD symptom was twice as high during non-running activities (56.5%) than running activities (28.3%). Females were more likely than males to report two or more different UD symptoms during non-running activities (39.2% vs. 19.4%; $p=0.06$) and running activities (13.7% vs. 8.1%; $p=0.04$). Two female runners reported all 6 UD symptoms during running. Overall, frequent urination and leakage related to feeling of urgency were the most common urogenital dysfunction symptoms reported by the runners; and were reported more commonly during non-running activities compared to running activities (i.e., 45.2% vs. 13.5%, 21.2% vs 7.7%; respectively). Females were twice as likely (RR=2.06, 95% CI: 1.4-3.0; $p=0.001$) than males to report leakage related to feeling of urgency during non-running activities. **CONCLUSIONS:** Our findings indicated that urinary dysfunction symptoms are prevalent during non-running and running activities in high school cross-country runners; more so for females.

Physiological Parameters Of Bone Health In Elite Ballet Dancers

Bradley Lambert, Michael Cain, Tyler Heimdal, Joshua Harris, Vijay Jotwani, Steven Petak, Patrick McCulloch. *Houston Methodist Hospital, Houston, TX.*
Email: bslambert@houstonmethodist.org

(No relevant relationships reported)

Stress fractures are common among elite ballet dancers whereby musculoskeletal health may be affected by energy balance and overtraining. **PURPOSE:** To characterize bone health in relation to stress fracture history, body composition, and

eating disorder risk in professional male and female ballet dancers. **METHODS:** A single cohort of 59 professional ballet dancers (M=30, 24±6yr; F=29, 23±5yr) was recruited. All participants underwent bone and body composition measures using dual-energy-xray-absorptiometry (DXA). A nutritional screen and stress fracture history was also collected. Aged-matched Z-scores were calculated for bone mineral density (BMD) and body composition. A 1x3 ANOVA and Chi-Square test was used to compare BMD and frequency for history of stress fractures for those scoring 0-1, 2-6, and 7+ using the EAT26 questionnaire for eating disorder risk. Regression was used to predict BMD from body composition and demographic information. **RESULTS (Table):** Female dancers demonstrated reduced spinal (42nd percentile, 10%Z<-1) and pelvic (16th percentile, 72%Z<-1) BMD. Several anthropometric and demographic measures were predictive of BMD (p<0.05, r²=0.66-0.90, SEE=0.08-0.10g/cm²). Those with a 7+ EAT26 score were observed to have a higher frequency for history of stress fracture (p<0.05). Higher EAT26 scores were also associated with lower total and spine BMD. **CONCLUSIONS:** Professional female ballet dancers exhibit reduced BMD (particularly in the pelvis) and body mass compared to the general population whereby low BMD and stress fractures tend to be more prevalent in those with a higher risk of disordered eating. When considering only total BMD, regions of high BMD (legs) were found, in some cases, to mask areas of low BMD (spine, arms, pelvis). Lastly, anthropometric and demographic variables are predictive of BMD in this population and may be used as a field proxy in the absence of DXA.

A - BONE MINERAL DENSITY (All Dancers)

Parameters Of The Athlete Triad In Male Ncaa Division I Athletes
 Brianne L. Guilford, Jose M. Moris, Chelsie M. Zajac, Andrea M. Frerker, Bharath S. Selvaraj, Aubrey R. Kamp, Jennifer L. Zuercher, Maria Fernandez-Del-Valle, Bryan K. Smith.
Southern Illinois University Edwardsville, Edwardsville, IL.
 (No relevant relationships reported)

Male athletes are at risk of developing a condition similar to the female athlete triad that is characterized by low bone mineral density (BMD), low energy availability (EA), and reduced reproductive hormones. However, the triad has not been well studied in males.

PURPOSE: The purpose of this study was to assess BMD and EA in male NCAA division I athletes participating in leanness emphasized sports (cross country and wrestling) and non-leanness sports (soccer and basketball). We hypothesized that EA and BMD would be lower in XC and wrestling compared to soccer and basketball and EA would be positively correlated with BMD.

METHODS: Participants included 27 NCAA division I male athletes (20.3 ± 0.3 yr) participating in soccer (n = 5) or cross country (XC, n = 7), wrestling (n = 10), or basketball (n = 5). Following a 12 hr fast and abstinence from physical activity, a resting metabolic rate test, dual energy X-ray absorptiometry scan, and 24-hour food intake recall was performed during an early morning testing session. Two unannounced follow-up food intake recalls were performed over the phone and used to determine mean daily energy intake. Activity energy expenditure was assessed using an Actigraph accelerometer for 7d. Low EA was defined: [(energy intake - activity energy expenditure) / fat free mass (kg)] ≤ 20 kcal/kg.

RESULTS: XC had lower BMI, fat free mass, total, lumbar spine, and dual femur BMD (g/cm²) compared to soccer, wrestling, and basketball. XC athletes also had lower total BMD, lumbar spine, and dual femur Z-scores compared to wrestling and basketball, but not soccer. XC had significantly greater EA than basketball.

CONCLUSIONS: In support of our hypothesis, BMD was lower in athletes participating in XC, a leanness sport, compared to all other sports. Surprisingly,

EA was highest in XC and negatively correlated with BMD. These data suggest the interrelationship between components of the athlete triad is complex and low EA may not be the primary cause of low BMD in male athletes.

	XC	Wrestling	Soccer	Basketball	Overall Sports
BMI (kg/m ²)	20.6 ± 1.1 ^b	25.7 ± 1.1 ^a	25.1 ± 1.0 ^a	26.9 ± 1.0 ^a	24.9 ± 0.7

784 Board #8 May 27 3:15 PM - 5:15 PM
Weekly Training Volume Impacts On The Prevalence Of Iron Depletion In Female Athletes
 Nenad D. Ponorac¹, Aleksandar M. Ignjatovic², Dragan S. Radovanovic³. ¹Faculty of Medicine, University of Banja Luka, Banja Luka, Bosnia and Herzegovina. ²Faculty of Education in Jagodina, University of Kragujevac, Jagodina, Serbia. ³Faculty of Sport and Physical Education, University of Nis, Nis, Serbia.
 (No relevant relationships reported)

Female athletes undergo rigorous training, travel, and competition schedules, and therefore may be susceptible to iron deficiency (ID), with further progression to stages 2 [iron-deficient erythropoiesis (IDE)] and 3 [ID anemia (IDA)]. **PURPOSE:** To investigate whether sporting discipline and training volume (≥ 10 h/week) impacted the prevalence of ID, IDE, and IDA in female athletes.

METHODS: A total of 85 athletes involved at higher levels of competition were assigned into groups according to sporting discipline (volleyball, n=36; handball, n=24; soccer, n=19; judo, n=6) and training volume (≥ 10 h/week, n= 47; <10h/week, n=38). The following iron depletion categorization was used: first stage-ID defined as serum ferritin <35 µg/L, transferrin saturation >16%, and hemoglobin >115 g/L; second stage-IDE defined as serum ferritin <20 µg/L, transferrin saturation <16%, and hemoglobin >115 g/L; and third stage-IDA defined as serum ferritin <12 µg/L, transferrin saturation <16%, and hemoglobin <115 g/L.

RESULTS: The prevalence of ID, IDE, and IDA were not significantly different between sporting disciplines (p>0.05). According to training volume, there was no difference (p = 0.53) at stage 1 between the groups (<10 h/week=49% vs. ≥ 10 h/week=42%). However, the results indicate that training volume ≥ 10 h/week significantly compromised iron status at stage 2 (39% vs. 17%, p=0.02) and 3 (3% vs. 0%, p=0.05) compared to lower training volume.

CONCLUSIONS: A similar prevalence of ID, IDE, and IDA suggests that female athletes competing in volleyball, handball, soccer, and judo are at a similar risk of disturbance in iron metabolism. A weekly training volume ≥ 10 h has an impact on iron status, promoting a higher prevalence of IDE and IDA in female athletes.

 (No relevant relationships reported)

Studies with animals have demonstrated that estrogens contribute to limit exercise-induced muscle damage. However, this effect is not entirely clear in humans, despite some benefits have been observed. For instance, estrogen replacement therapy

WEDNESDAY, MAY 27, 2020

has shown to increase strength and reduce exercise-induced muscle damage in postmenopausal women. **PURPOSE:** To evaluate the influence of sex hormones on creatine kinase (CK) response after an eccentric squat-based workout in well-trained females with different hormonal profiles. **METHODS:** Nineteen eumenorrheic females (28.6±5.9 years, 163.4±6.1 cm, 59.6±5.8 kg) and thirteen postmenopausal females (51.7±3.7 years, 161±5.31 cm, 56.6±8.1 kg) participated in this study. A resistance-based workout was performed by the eumenorrheic females in the early follicular phase (EFP), late follicular phase (LFP) and mid-luteal phase (MLP) of their menstrual cycle, in a counterbalanced and randomized order. Postmenopausal females performed the protocol in a single visit. Blood samples were obtained at baseline and 2h, 24h and 48h after the eccentric workout to analyse serum CK. An unpaired t-test was performed to compare CK values between postmenopausal and eumenorrheic females. **RESULTS:** At baseline, postmenopausal showed higher CK concentrations (136.2±45.5 U·L⁻¹) in comparison to eumenorrheic women in the LFP (105.7±33.1 U·L⁻¹, p=0.039) and MLP (100.7±29.8 U·L⁻¹, p=0.012). However, these differences were not observed between postmenopausal and eumenorrheic women in the EFP (108.6±48.0 U·L⁻¹, p=0.114). No differences were observed in post-exercise time-points between postmenopausal and eumenorrheic women in any of the menstrual cycle phases analysed. **CONCLUSION:** Lower estrogen and progesterone concentrations may elicit higher CK values at rest. However, the lack of post-exercise differences between groups may indicate that the supposed protective role of sex hormones is not as determinant as other factors like intensity or training status. The IronFEMME Study is supported by the Ministerio de Economía y Competitividad (Contract DEP2016-75387-P).

Influence Of Aerobic Exercise On Select Cytokine And Hormone Levels In Pregnant Women.

Samantha Michelle McDonald, Cody Strom, Mary Remchak, Alec Chaves, Nicholas Broskey, Linda May, FACSM. *East Carolina University, Greenville, NC.* (Sponsor: Linda E May, FACSM)
 Email: mcdonaldsa18@ecu.edu
 (No relevant relationships reported)

PURPOSE: To determine the effects of prenatal aerobic exercise on select maternal cytokines and hormones.

METHODS: Data from an ongoing, 24+ week aerobic exercise intervention trial were used. Thirty-one participants of 128 randomized to aerobic (150 min of moderate weekly aerobic exercise) or control (no exercise) groups had fasted blood samples drawn at 16 and 36 weeks gestation and were eligible for analysis. Levels of NGF, IL-1 α , IL-6, IL-8, TNF- α , IL-10, Leptin, Insulin, Glucagon and GLP-1 Active were analyzed.

RESULTS: At baseline, women in the aerobic group had lower levels of TNF- α (p=0.01). At 36 weeks of gestation, aerobic-trained women had higher levels of IL-1 α (p=0.04) and lower levels of IL-10 (p=0.01). No statistical differences in the change of these biomarkers were found.

CONCLUSIONS: Prior to prenatal exercise, participants in the aerobic exercise group possessed lower inflammatory cytokines, however at 36 weeks of gestation, aerobic-trained women had higher levels of different inflammatory cytokines. The complexity of these biomarkers and their differing patterns of change during pregnancy may explain the null and unanticipated findings of higher inflammatory biomarkers following chronic exercise.

Sex Difference On Arterial Stiffness And Measures Of Pulse Wave Reflection Response To Weight Machines

Rebecca Schmidt, Erica M. Marshall, Jason C. Parks, Derek J. Kingsley, FACSM. *Kent State University, Kent, OH.*
 (No relevant relationships reported)

PURPOSE: To evaluate sex-specific responses to acute bout of machine weight resistance exercise on arterial stiffness and measures of pulse wave reflection.

METHODS: Resistance-trained men (n=21; Mean±SD: Age: 23±3yrs) and women (n=20; Age: 22±3yrs) volunteered to participate in the study. Arterial stiffness, measured via pulse wave velocity, and measures of pulse wave reflection, were evaluated at rest, and 10 minutes following an acute bout of weight machine exercise composed of 3 sets of 10 reps at 75% 1RM on the chest press, leg press, lat pulldown, leg flexion and leg extension. Two minutes of rest was given between sets and exercises. A 2x2x2 ANOVA was used to analyze the effects of sex (men, women) across condition (acute resistance exercise, control) and time (rest, recovery (Rec)).

RESULTS: There were no significant three-way interactions for any variable, as well as no sex specific responses. Acute resistance exercise had no effect on arterial stiffness (p=0.07), or augmentation pressure (p=0.16). A significant condition by time interaction (p=0.001) was noted for Alx@75 (Alx@75: Men: Rest: 7.0±8.1%; Rec: 19.4±9.2%; Women: Rest: 11.0±16.0%; Rec: 14.0±6.0%) such that it was increased in response to the acute resistance exercise, but not the control. A

significant (p=0.0001) condition by time effect was also noted for the subendocardial viability ratio (SEVR: Men: Rest: 141.0±24.0%; Rec: 82.1±38.0%; Women: Rest: 136.0±13.4%; Rec: 91.3±28.0%) in that the acute resistance exercise reduced SEVR during recovery, but not the control. There was also a significant (p=0.007) main effect of time for myocardial workload (Ew: Men: Rest: 809.0±639.2 dynes s/cm²; Rec: 984.0±896.0 dynes s/cm²; Women: Rest: 985.0±965.0 dynes s/cm²; Rec: 364.0±540.0 dynes s/cm²) in that it was reduced during recovery from the acute resistance exercise compared to rest, as well as the control.

CONCLUSIONS: These data suggest that weight machines may not significantly alter arterial stiffness or measures of pulse wave reflection differently between the sexes. However, an acute bout of resistance exercises consisting of weight machines may reduce function of the left ventricle for at least 10 minutes.

789 Board #4 May 27 3:15 PM - 5:15 PM
Effects Of Menstrual Cycle Phases On Measures Of Body Composition

Abigail R. Champion, Lauren E. Coleman, Heather E. Webb. *Texas A&M Corpus Christi, Corpus Christi, TX.* (Sponsor: Edmund O. Acevedo, FACSM)
 (No relevant relationships reported)

Many women complain about weight fluctuation across the span of a month as a result of hormonal changes that accompany their menstrual cycle (MC). Specific research regarding the menstrual cycle phases of females and their effects on body composition measures have been limited to examining these changes as a subset of other variables. As water makes up approximately 73% of lean body tissue, fluctuations in body water due to changes in a women's MC may impact measurements of body composition

PURPOSE: To investigate whether phases of the MC have an impact upon common measures of body composition **METHODS:** 51 apparently healthy females between the ages of 18-45 participated in data collection sessions held weekly, at the same time of day, seven days apart, for a month. Each week, participants self-reported the presence or absence of menses during that week, including starting or ending days. Participants completed three body composition assessments: bioelectrical impedance analysis (BIA), dual-energy X-ray absorptiometry (DXA), and air displacement plethysmography (ADP) according to manufacturer's instructions, and also reported their exercise habits for the previous week. **RESULTS:** RMANOVA revealed no differences in physical activity levels between sessions for participants and that total body water amounts in participants did not change across time when measured via BIA. A 3 (device) x 4 (MC phase) RMANOVA demonstrated no significant device by phase interaction effects, nor were changes in body weight, body fat percentage, or lean body mass seen across time. However, significant differences in lean body mass measures (p = .001) between DXA and BIA (\bar{x} difference = 1.62 ± 0.4 kg) and DXA and ADP (\bar{x} difference = 1.74 ± 0.36 kg) measures were seen. **CONCLUSION:** Although there were no changes in body composition across the MC phases, there were differences in body composition values among the three types of devices used to quantify body composition. These findings suggest that differences in the technology used to quantify body composition may explain varying results across studies.

790 Board #5 May 27 3:15 PM - 5:15 PM
Transitioning From Daytime To Nighttime Operations During Military Training Negatively Impacts Dynamic Balance And Vertical Jump Performance In Elite Male Army Soldiers

Bradley M. Ritland¹, Jacob A. Naylor², Ashlee B. McKeon³, Janna Mantua³, Walter J. Sowden³. ¹United States Army Institute of Environmental Medicine, Natick, MA. ²2d Battalion, 75th Ranger Regiment, JBLM, WA. ³Walter Reed Army Institute of Research, Silver Spring, MD.
 (No relevant relationships reported)

PURPOSE: Investigate the impact transitioning from daytime to nighttime operations during military training has on dynamic balance and vertical jump performance in elite Army Soldiers. **METHODS:** This study was part of a larger study investigating the impact sleep loss and circadian desynchrony during military training have on the health and performance of elite Army Soldiers. Elite Army Soldiers (all male) performed a cognitive/motor battery (pre-test), including the Y-Balance Test (YBT) and a vertical jump assessment, approximately 2 weeks prior to switching from daytime to nighttime operations during military training (getting on a "reverse sleep cycle"). After the first night into the nighttime operation training (after a full night of sleep loss), the Soldiers were reassessed (post-test) on the YBT (n=74, 26.0 ± 4.1 years) and vertical jump (n=75, 26.2 ± 3.9 years). **RESULTS:** Compared to pre-test, the elite Army Soldiers demonstrated a significant decrease during the posteromedial reach bilaterally (Right = -2.4 ± 6.5 cm, p = .003; Left = -2.9 ± 7.1 cm, p = .001), and a significantly lower composite score bilaterally (Right = -4.4 ± 15.8 cm, p = .018; Left = -4.6 ± 14.7 cm, p = .009) on the YBT at post-test. In addition, at post-test, asymmetry in the posterolateral direction was significantly worse (1.3 ± 3.9 cm, p =

.004) compared to pre-test. No other significant pre- to post-test differences were noted on the YBT. The vertical jump height was also significantly lower (-1.0 ± 3.0 inches, $p = .004$) at post-test, compared to pre-test. **CONCLUSION:** Transitioning from daytime to nighttime operations during military training negatively impacts dynamic balance and vertical jump performance in elite male Army Soldiers. Considering the post-test was conducted after the first night into the nighttime operation training, where Soldiers missed their normal sleep opportunity, sleep loss and fatigue were likely contributing factors to the decreased performance. Investigating strategies that may limit these physical impairments during the transition from daytime to nighttime operations is warranted. Future research should also to investigate whether the noted impairments have any impact on this population's injury risk considering impaired dynamic balance has been associated with injury risk in other athletic populations.

Effect Of Sex And Neuromuscular Training On Lower Limb Stiffness Characteristics And Jump Performance

Mengru Huang¹, Jiaxin Cai¹, Zhihai Wang¹, Eamonn Delahunty², Dan Wang¹. ¹Shanghai University of Sports, Shanghai, China. ²University College Dublin, Dublin, Ireland.

Email: huangmengru33@163.com

(No relevant relationships reported)

Stiffness is potentially related to sports injury and athletic performance. Higher stiffness within a certain range may represent lower sports injury risk and better athletic performance. It is not clear whether a sex difference existed in lower limb stiffness changes induced by neuromuscular training.

PURPOSE: To investigate the effect of neuromuscular training on lower limb stiffness in both male and female young recreational athletes.

METHODS: Eleven recreational athletes (5 females: 24.4 ± 3.4 yr; 6 males: 24.0 ± 3.9 yr) underwent neuromuscular training 3 times a week for continuous 6 weeks, including plyometric training (e.g. squat jump, wall jump et al.) and strength training (e.g. barbell squat, bench press et al.) with progression every two weeks. Pre- and post-intervention measurements included: gastrocnemius lateralis (GL), gastrocnemius medialis (GM), soleus muscle and the Achilles tendon (AT) stiffness on both lower limbs by Myometer; vertical stiffness (Kvert), jump height and reactive strength index (RSI) by force plate during drop vertical jump from a 40 cm step.

RESULTS: Two-way repeated measures ANOVA was conducted and found no significant interaction between time and sex in all the variables mentioned above, but significant results on time in left GL stiffness ($p=0.021$), left GM stiffness ($p=0.008$), right AT stiffness ($p=0.040$), Kvert ($p=0.019$), jump height ($p=0.012$), and RSI ($p=0.008$). Paired-T test was further conducted and identified jump height in females increased significantly from pre (0.14 ± 0.04 m) to post (0.18 ± 0.05 m) intervention ($p=0.037$). After intervention, left GL stiffness had a downward tendency in males ($\Delta=39.69 \pm 68.24$ N/m) and females ($\Delta=70.00 \pm 60.46$ N/m); left GM stiffness tended to increase in males ($\Delta=34.17 \pm 82.22$ N/m) and decrease in females ($\Delta=29.60 \pm 63.53$ N/m); right AT stiffness ($\Delta=52.17 \pm 215.48$ N/m) and Kvert ($\Delta=199.33 \pm 207.36$ N/m) tended to decrease in males; RSI in males ($\Delta=0.16 \pm 0.15$ m/s) and females ($\Delta=0.162 \pm 0.146$ m/s) tended to increase.

CONCLUSIONS: Males and females may achieve similar benefits from neuromuscular training. Neuromuscular training can improve jump performance in females, with a tendency to decrease lower limb stiffness in males and females.

Cardiorespiratory Variables During A Maximal Running Test In Well-trained Females With Different Hormonal Profiles

Beatriz Rael, Victor M. Alfaro-Magallanes, Laura Barba-Moreno, Nuria Romero-Parra, Eliane A. de Castro, Miguel Angel Rojo-Tirado, Rocio Cupeiro, Ana B. Peinado.

Universidad Politecnica de Madrid, Madrid, Spain.

Email: beanad16@gmail.com

(No relevant relationships reported)

Differences in estrogen and progesterone levels along a natural menstrual cycle and an oral contraceptive (OC) cycle may influence female's performance. Previous literature reported lower strength, maximal oxygen consumption (VO₂ max) and systolic volume in OC users. According to postmenopausal women, their low and stable levels of sex hormones may affect them in a different way than in young women.

PURPOSE: To elucidate the effect of different hormonal profiles on maximal VO₂, heart rate (HR) and ventilation (VE) in well-trained females. **METHODS:** Thirty-three eumenorrheic females (30.1 ± 6.2 years, 59.3 ± 8.4 kg, and 164.1 ± 6.3 cm), twenty-three monophasic OC users (24.8 ± 4.3 years, 58.6 ± 5.8 kg, and 163.3 ± 5.1 cm) and thirteen postmenopausal women (51.0 ± 3.7 years, 54.9 ± 4.1 kg, and 161.5 ± 5.4 cm) participated in the study. A maximal graded test with a computerized treadmill was performed. Expired gases were measured breath-by-breath with the gas analyser Jaeger Oxygen Pro. HR was continuously monitored with a 12-lead ECG. Participants began with a

warm-up of 3 minutes at 6 km/h. Then, the speed was set at 8 km/h, increasing 0.2 km/h every 12 seconds until exhaustion. **RESULTS:** One way ANOVA reported lower values in post-menopausal females compared to the other two groups (eumenorrheic and OC users) for all variables measured: VO₂ max (2924.2 ± 389.7 ml/min for the eumenorrheic; 2808.8 ± 366.7 ml/min for the OC; and 2455.15 ± 281.04 ml/min for the postmenopausal; $p=0.001$), maximal HR (184.2 ± 10.3 ; 189.9 ± 8.4 ; and 172.1 ± 12.9 bpm respectively; $p<0.001$) and maximal VE (111.8 ± 17.5 ; 114.7 ± 15.1 ; and 96.4 ± 10.4 l/min, respectively; $p=0.003$). Nonetheless, no significant differences in VO₂max, HR and VE were found between eumenorrheic females and OC users. **CONCLUSION:** The drastic decrease of sex hormones in postmenopausal females, along with other hormonal and physiological changes caused by the age, may explain the drop in VO₂ max, HR and VE in this population. In terms of young women, despite literature reported lower values in OC users, the lack of difference observed in this study may be due to the lower concentrations of sex hormones that OC pills have nowadays, or because of the fact that all were well-trained participants.

Work-matched High-intensity Interval And Moderate-intensity Continuous Training Adaptations On 17 Lactate Threshold Methods In Females

Felipe Mattioni Maturana¹, Manuel Widmann¹, Barbara Munz¹, Ansgar Thiel², Andreas M. Nieß¹. ¹University Hospital of Tübingen, Tübingen, Germany. ²Eberhard Karls University Tübingen, Tübingen, Germany.

Email: felipe.mattioni@med.uni-tuebingen.de

(No relevant relationships reported)

PURPOSE: to compare exercise training effects on 17 lactate threshold methods to 6 weeks (3x/week) of high-intensity interval training (HIIT) or moderate-intensity continuous training (MICT) in females. **METHODS:** 24 healthy sedentary females (mean \pm SD: peak oxygen uptake 30.0 ± 3.2 mL·kg⁻¹·min⁻¹, peak power output 151 ± 21 W, body mass index 23.4 ± 2.6 kg·m⁻²) were randomly assigned to either HIIT or MICT. Participants performed a step-incremental test on a cycle ergometer (3-min stages of 25-W increments, starting at 25 W) pre- and post-training. The HIIT group (N = 12) performed a 10-min warm-up (power output (PO) at 70% of the maximal heart rate (HR_{max})), and four 4-min intervals (PO at 90% HR_{max}) interspersed with 4-min recovery at 30 W. The MICT group (N = 12) performed 60-min continuous cycling (PO at 90% of the first lactate turning-point (LT1)). Lactate thresholds were analyzed as: Log-log, onset of blood lactate accumulation (OBLA, N = 5), fixed value above baseline (Bsln+, N = 3), D_{max} and its modified versions (N = 5), lactate turning-points (LT1 and LT2), and the minimal lactate-intensity ratio (LT_{ratio}). A two-way analysis of variance was used to test differences within (post versus pre) and between groups. Additionally, the width of confidence intervals (CI_{width}) from the delta change was calculated for each method and group. **RESULTS:** In the HIIT group, the intensity derived from all the methods significantly increased after training ($p < 0.01$), except for LT_{ratio} ($p = 0.6$). In the MICT group, the intensity from OBLA, Bsln+, and the modified D_{max} methods significantly increased after training ($p < 0.05$), whereas Log-log, D_{max}, LT1, LT2, and LT_{ratio} did not improve significantly ($p > 0.05$). The HIIT group showed a higher increase in intensity from the D_{max} methods, and in LT1 and LT2 compared with the MICT group ($p < 0.05$). No differences were observed between the groups in the improvements of Log-log, OBLA, Bsln+, and LT_{ratio}. OBLA at 3.5 and 4.0 mM, and D_{max} presented the narrowest CI_{width} (range 7 - 12 W), while Bsln+ 0.5 mM, Bsln+ 1.0 mM, and Log-log had the widest CI_{width} (range 24 - 32 W). **CONCLUSIONS:** In healthy sedentary females, improvements of the D_{max} methods, LT1, and LT2 were superior in the HIIT group. The lowest intra-individual variability in response to training was observed in the D_{max} and OBLA at 3.5 and 4.0 mM methods.

The Separate And Combined Effects Of Acute Simulated Altitude And High Ambient Temperature On Cycling Time Trial Performance

Jos J. de Koning, FACSM¹, Stefan M. van Meurs¹, Dominique W. H. Ebben¹, Carl Foster, FACSM², Dionne A. Noordhof³.
¹Vrije Universiteit, Amsterdam, Netherlands. ²University of Wisconsin - La Crosse, La Crosse, WI. ³NTNU, Trondheim, Norway.
 Email: j.j.de.koning@vu.nl
 (No relevant relationships reported)

Simulated altitude and high ambient temperature independently compromise endurance performance, although there is limited evidence on the combined exposure to both stressors. In addition, the effect of corresponding underlying key mechanisms has yet to be quantified. **PURPOSE:** To investigate the separate and combined effects of acute simulated altitude and high ambient temperature on time trial (TT) performance, VO_{2max} , the ventilatory threshold (VT) and gross efficiency (GE). **METHODS:** Ten trained male cyclists performed 4 maximal incremental exercise tests (GXT) and GE-tests, both at sea-level (0 m; 20.93% O_2) and simulated altitude (2000 m; 16.3% O_2) in high environmental temperature (36.00 ± 1.4°C, 42.58 ± 0.8% RH) and temperate conditions (16.00 ± 0.32°C, 40.20 ± 1.2% RH). The GXT included 3 min at 100 W, followed by 25 W·min⁻¹ until volitional fatigue. GE was determined at 50% of the power attained at VO_{2max} in relative conditions, prior to and following 4000m TT performances. **RESULTS:** Although average PO was significantly reduced during TT performance at simulated altitude (31 ± 18 W, $p < .001$, $n_p^2 = .795$) and high ambient temperature (9 ± 16 W, $p = .007$, $n_p^2 = .570$), no significant interaction was found ($p = .137$). At simulated altitude, VO_{2max} (3.77 ± 2.1 ml·kg⁻¹·min⁻¹, $p < .001$, $n_p^2 = .925$), VT (3.39 ± 2.9 ml·kg⁻¹·min⁻¹, $p < .001$, $n_p^2 = .795$) and GE (0.72 ± 0.97%, $p = .021$, $n_p^2 = .555$) were significantly reduced compared to sea level. However, VO_{2max} (3.33 ± 3.1 ml·kg⁻¹·min⁻¹, $p = .005$, $n_p^2 = .608$) and VT (2.05 ± 3.1 ml·kg⁻¹·min⁻¹, $p = .021$, $n_p^2 = .462$) were significantly increased at high ambient temperature, although no effect on GE ($p = 0.240$) was found. **CONCLUSION:** The reduction in TT performance at acute simulated altitude is associated with a decline in VO_{2max} , VT and GE, likely because a lower SpO_2 . VO_{2max} and VT are significantly higher at acute high ambient temperature, likely because the metabolic cost of physiological heat stress increases relative exercise intensity at similar absolute PO. GE was unaffected by acute high ambient temperature, likely because heat exposure during the GE-test was too short to increase T_{core} . VO_{2max} , VT and GE were not compromised during combined exposure, which corresponds with the absence of a significant interaction effect in endurance performance.

796 Board #2 May 27 3:15 PM - 5:15 PM
Impact Of Heat Acclimation On Steady-State Exercise And Time-Trial Performance In Hypobaric Hypoxia (3500m)

Beau R. Yurkevicius, Kirsten E. Coffman, Karleigh E. Bradbury, Adam J. Luippold, Katherine M. Mitchell, Thomas A. Mayer, Nisha Charkoudian, FACSM, Charles S. Fulco, Robert W. Kenefick, FACSM, Roy M. Salgado. *USARIEM, Natick, MA.*
 (No relevant relationships reported)

Heat acclimation (HA) has been reported to improve endurance exercise performance in normobaric hypoxia. However, the impact of prior HA on exercise performance in hypobaric hypoxia (HH) is unclear. **PURPOSE:** To determine whether HA alters steady-state (SS) exercise responses and time-trial (TT) cycle performance during a 30 hour exposure to HH. **METHODS:** Thirteen sea level (SL) resident men (mean ± SD; age: 21 ± 3 years; height: 173 ± 8 cm; weight: 75 ± 12 kg; SL cycle ergometer VO_{2peak} : 43 ± 5 ml·kg⁻¹·min⁻¹) participated in two 30 hour HH exposures in a hypobaric chamber (496mmHg or ~3500m, 20°C, 20% RH). The HH exposures were separated by a 14 day washout period during which volunteers completed an 8-day exercise-HA protocol (2 hours of treadmill walking: 5km·h⁻¹, 2% grade; 40°C, 40% RH). During each HH exposure, volunteers completed 30 min of SS exercise followed by a 15 min cycle TT at ~2 and

24 hours of exposure. SS exercise consisted of cycling at ~50% SL VO_{2peak} while gas exchange (oxygen consumption (VO_2), minute ventilation (V_E), end tidal partial pressure of oxygen ($P_{ET}O_2$), and oxygen saturation (SpO_2)) were recorded. For the TT, volunteers completed as much work (kJ) as possible in 15 min, with heart rate (HR), SpO_2 , and Rating of Perceived Exertion (RPE, Borg Scale) recorded at the end of exercise. A two way repeated measures ANOVA was used to compare the effects of condition (Pre HA and Post HA) and time (~2 and 24 hours).

RESULTS: There were no condition x time interaction effects among the SS or TT variables. For main effect of condition, from Pre HA vs. Post HA, SS VO_2 tended to be lower (1.63 ± 0.00 L·min⁻¹ vs. 1.60 ± 0.01 L·min⁻¹; $p = 0.05$), $P_{ET}O_2$ was higher (75.7 ± 1.0 mmHg vs. 76.8 ± 0.7 mmHg; $p < 0.01$), and V_E and SpO_2 did not differ ($p > 0.05$ for both). For the TT, there was no main effect of HA on total work completed (106.8 ± 23.0 kJ vs. 103.8 ± 21.3 kJ), HR (159 ± 13 bpm vs. 158 ± 13 bpm), SpO_2 (83 ± 3% vs. 83 ± 3%), or RPE (17 ± 2 vs. 17 ± 2) ($p > 0.05$, for all).

CONCLUSIONS: Our results suggest that although HA may augment some aspects of ventilation during low-intensity SS exercise, exercise performance measured by a 15 min cycle TT in HH is not affected by HA.

Effects Of Short-term Heat Exposure On Time Trial Performance In Moderate Hypoxia With Trained Athletes

Alexander B. Maycock, Shelby S. Dickey, Geoffrey L. Hartley.
Nipissing University, North Bay, ON, Canada.
 (No relevant relationships reported)

PURPOSE: To examine the effect of a 5-day training protocol in the heat on physiological acclimation, perceptual responses, and 16 km time-trial performance in moderate hypoxia. **METHODS:** Twelve well-trained, healthy male participants (age = 27 ± 8 years; VO_{2peak} = 66.52 ± 4.94 ml·kg⁻¹·min⁻¹) were randomly assigned to a hot (HOT; 40°C, 35% RH) or control (CON; 18°C, 35% RH) group, and completed five consecutive days of cycling for 60 min at 50% VO_{2peak} . Participants completed a 16 km time-trial in hypoxia ($F_{O_2} = 0.165$; $S_{pO_2} = 86.00 ± 2.64$), pre- (TT1) and post-training (TT2), to determine if heat training enhanced hypoxic cycling performance. Rectal core temperature (T_{re}), heart rate, and rating of perceived exertion were assessed through the training protocol. **RESULTS:** Time to completion from TT1 (HOT = 1637 ± 110 s, CON = 1684 ± 117 s) to TT2 (HOT = 1617 ± 118 s, CON = 1671 ± 109 s) was reduced ($p = 0.029$); however, there was no interaction between groups ($p = 0.599$). There was no difference in mean ($p = 0.443$) or peak heart rate ($p = 0.651$) between TT1 and TT2 across both groups. Training resulted in a reduction in resting heart rate (Day 1: HOT = 61 ± 14 beats·min⁻¹, CON = 72 ± 4 beats·min⁻¹ vs. Day 5: HOT = 58 ± 11 beats·min⁻¹, CON = 66 ± 6 beats·min⁻¹; $p = 0.049$) and rating of perceived exertion (Day 1: HOT = 4 ± 1, CON = 3 ± 2 vs Day 5: HOT = 3 ± 1, CON = 2 ± 1; $p = 0.001$); however, there was no interaction between the groups. There was no significant difference in T_{re} ($p = 0.836$), mean exercising T_{re} ($p = 0.127$), or peak exercising T_{re} ($p = 0.152$) responses between Day 1 and Day 5 of the training protocol. **CONCLUSION:** This study found that the 5-day training protocol improved time-trial performance in hypoxia; however, there was no perceptual, physiological or performance benefits associated with training in the heat compared to normoxic conditions.

Heat Acclimation Does Not Alter Cutaneous Blood Flow During Steady-state Cycling Exercise At 3500 M Altitude

Billie K. Alba, Katherine M. Mitchell, Karleigh E. Bradbury, Beau R. Yurkevicius, Kirsten E. Coffman, Thomas A. Mayer, Adam J. Luippold, Nisha Charkoudian, FACSM, Robert W. Kenefick, FACSM, Roy M. Salgado. *US Army Research Institute of Environmental Medicine, Natick, MA.*
 (No relevant relationships reported)

Cutaneous vasodilation is attenuated when exercise is performed in a hypoxic environment, which may impair convective heat loss. Heat acclimation (HA) improves cutaneous blood flow in response to an increase in core temperature; however, the effect of HA on cutaneous blood flow during exercise in hypobaric hypoxia has not been examined. **PURPOSE:** The aim of this study was to test the hypothesis that cutaneous blood flow would be augmented during steady-state exercise at 3500 m altitude (hypobaric chamber) following 8 days of exercise-HA. **METHODS:** Thirteen healthy men (21 ± 3 yr; ht: 173 ± 8 cm; wt: 75.1 ± 12.2 kg; sea-level VO_{2peak} : 42.9 ± 4.6 ml/kg/min) participated in two 30 h altitude exposures (495 mmHg / ~3500 m, 20°C, 20% RH) separated by a 14 day washout period in which they completed 8 days of exercise-HA (2 h of treadmill walking in 40°C, 40% RH). At hour ~24 of each altitude exposure, subjects performed a 30-min bout of steady-state submaximal cycling exercise (~50% sea-level VO_{2peak}). Red blood cell flux (laser-Doppler flowmetry) was continuously measured during a 5 min seated baseline period and minutes 20-25 of exercise. Cutaneous vascular conductance (CVC = red blood cell flux/mean arterial

pressure) was calculated and normalized to a percentage of maximum (local skin heating to 42°C). **RESULTS:** Compared to Day 1 of HA, core temperature (Day 1: 38.1 ± 0.3 vs Day 8: 37.8 ± 0.3 °C; p<0.01) and heart rate (Day 1: 134 ± 17 vs Day 8: 121 ± 13 bpm; p<0.01) were significantly lower at min 120 of exercise on Day 8, indicating HA was achieved. Baseline cutaneous blood flow at altitude was reduced after HA (pre: 7.3 ± 1.2 vs post: 5.1 ± 0.7 %CVCmax; p=0.03). During steady-state exercise at altitude, cutaneous blood flow was not different pre- and post-HA (pre: 23.5 ± 4.4 vs post: 20.9 ± 4.4 %CVCmax; p=0.53). **CONCLUSION:** These data suggest that HA does not alter cutaneous blood flow during steady-state exercise at 3500 m altitude. However, while the magnitude of the blood flow response is unchanged, cutaneous blood flow may be elevated relative to core temperature following HA. Future studies examining potential benefits of HA on the relation between cutaneous blood flow and core temperature during exercise at altitude are warranted.  Email: sh0114ef@ed.ritsumei.ac.jp
 (No relevant relationships reported)

Hypoxia causes nitric oxide-induced vasodilatation and increases muscle blood flow during exercise as intensity dependent, which may mediate promoted training adaptations. On the other hand, exposure to heat stress also increases muscle blood flow during exercise. However, combined effects of heat and hypoxia on muscle metabolic responses to repeated sprint exercise are unclear. **PURPOSE:** To determine the effects of combined heat and hypoxic condition on muscle blood flow and muscle oxygen consumption following repeated sprint exercise. **METHODS:** Eleven male athletes (19.4 ± 0.4 years, 173.0 ± 2.3 cm, 72.8 ± 2.0 kg) completed repeated sprint exercise (three sets of 5 × 6 s maximal pedaling) under 3 different conditions, consisting of normoxia (NOR; 23 °C, FiO₂ = 20.9%), hypoxia (HYP; 23 °C, FiO₂ = 14.5%), and combined heat and hypoxia (HH; 35 °C, FiO₂ = 14.5%) with single blind, randomized crossover design. Power output, arterial oxygen saturation, skin and rectal temperature were monitored during the exercise. We also measured muscle blood flow and muscle oxygen consumption in vastus lateralis immediately after the exercise using venous/arterial occlusion and near infrared spectroscopy. **RESULTS:** Average power output was not different significantly among three conditions (NOR: 692 ± 18 W, HYP: 679 ± 17 W, HH: 685 ± 20 W). Arterial oxygen saturation was significantly lower in HYP and HH compared with NOR (NOR: 92.4 ± 0.7%, HYP: 82.6 ± 1.3%, HH: 82.2 ± 1.5%, p<0.05), while skin (NOR: 31.9 ± 0.3 °C, HYP: 31.7 ± 0.2 °C, HH: 34.7 ± 0.1 °C) and rectal temperature (NOR: 37.2 ± 0.1 °C, HYP: 37.2 ± 0.1 °C, HH: 37.4 ± 0.1 °C) were significantly higher in HH than in NOR and HYP (p<0.05). HH showed significantly greater muscle blood flow immediately after the first set of exercise compared with NOR (NOR: 0.61 ± 0.10 mL/min/100g, HYP: 0.81 ± 0.13 mL/min/100g, HH: 0.99 ± 0.16 mL/min/100g, p<0.05). However, muscle oxygen consumption did not differ significantly among conditions (NOR: 0.36 ± 0.04 mL O₂/min/100g, HYP: 0.42 ± 0.07 mL O₂/min/100g, HH: 0.44 ± 0.06 mL O₂/min/100g). **CONCLUSIONS:** Combined heat and hypoxic condition augmented exercise-induced increase in muscle blood flow during the initial phase of repeated sprint exercise in spite of similar power output compared with thermoneutral normoxic and hypoxic conditions.

Effect Of Heat Acclimation-induced Plasma Volume Expansion On Arterial Oxygen Content During Exposure To Hypobaric Hypoxia
 Myra L. Jones, Roy M. Salgado. *U.S. Army Research Institute of Environmental Medicine, Natick, MA.*
 (No relevant relationships reported)

INTRODUCTION: Exposure to high altitude results in a loss in plasma volume (PV) which augments hemoglobin (Hb) and thus arterial oxygen content (CaO₂). Conversely, heat acclimation (HA) results in plasma volume (PV) expansion. However, it is unclear whether HA-induced PV expansion impacts the change in PV and CaO₂ during a hypobaric hypoxia (HH) exposure. **PURPOSE:** To determine whether HA-induced PV expansion alters CaO₂ during HH exposure. **METHODS:** Thirteen sea-level natives (mean ± SD; men, age: 21 ± 3 yr; ht: 172 ± 0.8 cm; wt: 76 ± 13 kg; sea level VO_{2peak}: 42.9 ± 4.6 ml·kg⁻¹·min⁻¹) participated in a three phase study consisting of: a) 1) 30 hour HH exposure (HH1; 3,500 m, 495mmHg), 2) 14-day washout period in which volunteers completed an 8-day exercise-HA protocol (treadmill walking: 5 km·hr⁻¹, 2% grade; 40°C and 40% RH), and 3) second 30 hour HH exposure (HH2). After 20 minutes of seated postural control, venous and

arterialized capillary blood samples were collected pre- and post-HA and after 22 hours of HH1 and HH2. Samples were analyzed for Hb, Hct, arterialized oxygen saturation (SaO₂), and arterialized partial pressure of oxygen (PaO₂). The percent change in plasma volume (%ΔPV) was calculated in accordance with the Dill and Costill equation while CaO₂ was calculated using the following formula: CaO₂ = (1.34*Hb*SaO₂/100) + (0.0031*PaO₂). A t-test was used to assess differences in the %ΔPV, Hb, SaO₂, PaO₂, and CaO₂ between HH1 and HH2. **RESULTS:** The %ΔPV from pre- to post-HA was 7 ± 9%. From HH1 to HH2, the %ΔPV decreased to a greater extent (-12 ± 3 vs -17 ± 5; P < 0.01). From HH1 to HH2, Hb (16.1 ± 0.9 vs 16.0 ± 0.9 mg/dl), SaO₂ (89 ± 4% vs 90 ± 4%), PaO₂ (56.7 ± 2.8 vs 57.6 ± 3.2 mmHg) and CaO₂ (19.4 ± 1.1 vs 19.4 ± 1.3 ml/l) were not different (P > 0.05). **CONCLUSION:** Our results suggests that although HA induced a PV expansion; and there was a greater change in PV during HH2, CaO₂ was not affected. High Intensity Intervals Expands Plasma And Improves Cycling Performance In Acute Hypoxia
 Felipe Gorini Pereira, Trevor Gillum. *California Baptist University, Riverside, CA.*
 Email: felipegorinilienert.pereira@calbaptist.edu
 (No relevant relationships reported)

Introduction: Hypoxia cause decrements in submaximal and maximal exercise performance. Hypervolemia may improve O₂ delivery to the metabolically active tissue, thus lowering physiological and cardiovascular strain during moderate exercise at altitude. Since two weeks are needed to acclimate to exercise in hypoxia, we sought to expand plasma volume (PVE) through a single bout of high intensity intervals (HI) to attempt to expedite improvements in aerobic performance. **Purpose:** To determine if the hypervolemic response to a single bout of HI intervals was sufficient to mitigate the hypoxia associated declines in exercise capacity. **Methods:** In our randomized counterbalanced study, 7 males (24.4 ± 5.8 years, VO_{2max} 46.9 ± 5.8 ml·kg⁻¹·min⁻¹, 12.8 ± 4.4% body fat) performed two 15km cycling time-trials (TTs) in normobaric hypoxia (FiO₂ = 15%) before and 48 hours following HI (8x4 minutes at 85% VO_{2max} with 4 minutes rest between rounds) or a control bout (CON) performed at 50% VO_{2max}, in which duration was extended in order to assure workloads were matched between conditions (identical kilojoules between conditions). Pre-exercise blood samples were collected to quantify changes in plasma volume, while hemodynamic data were collected utilizing PhysioFlow. **Results:** Increased PVE was observed 24 hours (6.96% ± 4.84%) and 48 hours (9.77% ± 4.26%) (p<0.05) following the HI bout while the CON condition decreased plasma volume 48 hours post (-3.75% ± 2.62%). Under the HI condition, participants showed an improvement in TT performance (Time: 1880 ± 215s to 1840 ± 203s, Power: 164.8 ± 41.2W to 171 ± 39.5W) (p < 0.05) and lowered HR (164.5 ± 9.5 bpm to 161.9 ± 8.8bpm) (p < 0.05). SV and Q manifested an upwards trend during TT performance within the HI condition (p = 0.09 and p = 0.08, respectively). There was no difference in performance, Q, or SV in the CON condition. Hydration, RPE, SaO₂, and blood lactate were similar in both TTs in hypoxia. **Conclusion:** A single bout of HI intervals resulted in increased cycling performance in acute hypoxia, accompanied by an enhanced PVE both 24 and 48 hours following exercise. This observed enhancement in cardiac efficiency following intense exercise may be desirable in military populations or individual desiring to complete physical tasks at moderate altitude without the means or time to fully acclimatize.

 (No relevant relationships reported)

INTRODUCTION: Adaptations gained from heat acclimation (HA) can induce protective responses to a different stressor, such as hypoxia. Rapid ascent to altitude (hypobaric hypoxia, HH) increases the risk for acute mountain sickness (AMS). However, it is unknown whether HA can protect against the development of AMS during exposure to HH. **PURPOSE:** To determine if prior HA reduces the incidence of AMS during a 30 hour exposure to HH (3,500 m). **METHODS:** Thirteen unacclimatized healthy men (mean ± SD; age: 21 ± 3 yr; ht: 172 ± 8 cm; wt: 75.1 ± 12.2 kg; sea level VO_{2peak}: 42.9 ± 4.6 ml·kg⁻¹·min⁻¹) participated in three study phases consisting of: Phase 1) baseline (pre HA) 30 hour HH exposure (HH1; 3,500 m), Phase 2) 14-day washout period during which volunteers completed an 8-day exercise-HA

protocol (treadmill walking: 120 minutes at 5 km·hr⁻¹, 2% grade; 40°C and 40% RH), and Phase 3) post HA 30 hour HH exposure (HH2). During the HA protocol, heart rate (HR) and core temperature (T_c) were recorded throughout exercise. AMS was assessed using the Environmental Symptoms Questionnaire after ~12, ~21, and ~23 hours of exposure during each HH phase. HR and pulse oxygen saturation (SpO₂) were measured at rest immediately after assessment of AMS. A t-test was used to assess difference in HR and T_c from Day 1 and Day 8 of HA. For the HH exposures, HR and SpO₂ data were analyzed by fitting a mixed effects model as implemented by GraphPad Prism 8.1.2. **RESULTS:** Heat acclimation was achieved as indicated by a lower T_c (Day 1: 38.1 ± 0.3 vs Day 8: 37.8 ± 0.3 °C; p<0.01) and HR (Day 1: 134 ± 17 vs Day 8: 121 ± 13 bpm; p<0.01) at the end of exercise on Day 8 compared to Day 1. Three of 13 volunteers developed AMS during HH1 but not during HH2. A fourth volunteer only developed AMS during HH2. From HH1 to HH2, resting HR (84 ± 6 vs 83 ± 7 bpm) and SpO₂ (87 ± 2 vs 88 ± 2%) were not different (both p >0.05). **CONCLUSION:** Our results suggest that in unacclimatized individuals, HA may be an effective, though not perfect training strategy for reducing the incidence of AMS during rapid exposure to 3,500 m. Changes in AMS incidence could not be explained by alterations in HR or SpO₂. Supported by USAMRDC; author views not official US Army or DoD policy.

B-48 Thematic Poster - Spine

Spinal Range Of Motion And Back Pain In Female Artistic Adolescent Gymnasts

Emily A. Sweeney¹, Morgan N. Potter², Richard E. Pimental³, James J. Carollo⁴, David R. Howell¹. ¹Children's Hospital Colorado, University of Colorado School of Medicine, Aurora, CO. ²University of Delaware, Newark, DE. ³University of North Carolina at Chapel Hill, Chapel Hill, NC. ⁴University of Colorado School of Medicine, Aurora, CO. (Sponsor: James MacDonald, FACSM)
Email: emily.sweeney@childrenscolorado.org
(No relevant relationships reported)

PURPOSE: Back pain is a common complaint among female gymnasts, but it is unknown if gymnasts with back pain demonstrate different movement patterns during gymnastics skills compared to those gymnasts without back pain. Our purpose was to evaluate gymnasts' movement patterns in their native environment using wearable sensors. Specifically, we examined three-dimensional spine range of motion (ROM) during back walkovers (BWOs) and back handsprings (BHSs) on the floor and balance beam. **METHODS:** Female artistic gymnasts ages 8 to 18 years were divided based on presence or absence of self-reported back pain within the last 12 months. Gymnasts performed BWOs and BHSs on floor and balance beam while wearing APDM Opal V2 sensors. Valid spine sagittal plane maximums, minimums, and ROM during trials for each skill were compared between groups via Kruskal Wallis analysis of variance. **RESULTS:** Seventeen participants (n=6 with back pain, mean age=13.9±2.6 years; n=11 without back pain, mean age=13.3±1.7 years) completed BWOs and BHSs. There were no demographic differences between groups for age, height, weight, competition level, or years of experience. Gymnasts with back pain had a greater maximum back extension (45.0±15.4° back pain vs. 34.6±7.1° no pain; p=0.011, Cohen's d=1.46) and range of motion (94.6±18.9° back pain vs. 80.9±19.6° no pain; p=0.032, Cohen's d=0.70) during BWOs compared to gymnasts without back pain. There were no differences between groups in peak extension, peak flexion, or ROM during BHS skills. **CONCLUSION:** Gymnasts with a history of back pain had increased spinal motion when performing BWO skills. To perform a BWO, gymnasts must have higher levels of shoulder, spine, and hip flexibility, which may relate to back pain. This study suggests the need for future studies to evaluate if increased spinal motion during gymnastics is a contributing factor to the development of back pain.

How Does The Dancer's Spine Move? Application Of A Multisegmented Model.

Marijeanne Liederbach¹, Christopher T.V. Swain², Ian J. Kremenic³, Karl F. Orishimo³, Marshall Hagins¹. ¹NYU Langone Orthopedic Hospital, New York, NY. ²Australian Catholic University, Melbourne, Australia. ³Lenox Hill Hospital, New York, NY. (Sponsor: Malachy McHugh, PhD, FACSM)
(No relevant relationships reported)

How does the dancer's spine move? Application of a multisegmented model.
Purpose: Historically, most biomechanical studies of the spine used a rigid single segment model. However, recent studies show that spinal segments do not move together predictably and that a multi-segmental model improves discrimination between patients and healthy controls. Although professional dancers experience low back pain equal to or more than the general and sporting population, to date, no study has described multi-segmented spinal motion of the dancer during any dance specific tasks which may place unique mechanical demands on the spine. The purpose of this study was to describe spinal motions of professional dancers during a common dance task, the arabesque, using a multi-segmented spinal model. **Methods:** As part of larger study, 25 professional dancers (ages 24.8 +/-6.2; 5 males) performed two trials each of a right and left arabesque at their own pace while spinal kinematics were captured using a five-segment model (pelvis (PEL), lower lumbar (LL), upper lumbar (UL), lower thoracic (LT) and upper thoracic (UT). Motion was captured from initiation of vertical foot movement and ended at maximal foot height. Two trials were averaged and all values were time normalized. **Results:** Means and standard deviations of motion in all segments in three planes were identified. In all three planes, the two upper segments (UT-LT and LT-UL) contributed 69-87% of the total spinal motion. In the coronal plane, side-bending of all segments occurred ipsilateral to the lifted leg with 54% of all motion occurring at a single segment (LT-UL). In the sagittal plane the spine generally extended, however the upper segment (UT-LT), began and remained in a flexed position throughout the motion, although it extended during the motion. In the transverse plane all segments rotated contralateral to the lifted leg. However, the lower two spinal segments contributed almost no motion. **Conclusion:** This study demonstrated that segmental motion was not uniform in degree or direction across multiple spine segments during an arabesque. Most spinal motion occurred in the upper spine. Using a multi-segmental model may improve understanding of the biomechanical stressors experienced by professional dancers.

Appropriate Neck Flexion Without Head-hitting Decreases The Thrown Player'S Risk Of Brain Injury In Judo

Haruo Murayama¹, Masahito Hitosugi², Yasuki Motozawa³, Masahiro Ogino¹, Katsuhiko Koyama⁴. ¹Dokkyo Medical University, Shimotsuga, Japan. ²Shiga University of Medical Science, Otsu, Japan. ³Teikyo University, Utsunomiya, Japan. ⁴University of Yamanashi, Kofu, Japan.
Email: hmurayam@dokkyomed.ac.jp
(No relevant relationships reported)

PURPOSE: Judo is one of the worldwide sports and its competitive athletic events have been held in Olympic Games. Serious brain injuries, however, have been occasionally noted in judo practices and/or competitions. Since the patterns and severities of brain injuries largely depend on the kinematics of the thrown players, it is essential to investigate the mechanism of brain injury from the biomechanical viewpoint in popular throwing techniques. The aim of this study is to evaluate the brain injury criterion (BrIC), an indicator of brain injury, with measuring the presence or absence of head-hitting on the anthropomorphic test device (ATD) in judo throwing technique Ouchi-gari.

METHODS: A male judo expert (thrower) threw an ATD for 6 times by Ouchi-gari with or without head-hitting, respectively. The ATD with a straight neck component necessarily hit the occipital region on the mat, whereas an angled component was designed for preventing the ATD's head-hitting. A 3-axis angular rate sensor, mounted in the gravity center of the ATD's head, assessed head axial angular velocity in each trial. To evaluate the ATD's head impact quantitatively, we calculated the BrIC from the head axial angular velocity. High-speed digital video cameras also recorded the kinematics of the ATD's whole body during trials.

RESULTS: In all trials, the largest angular velocities were recorded in the phase of the initial head (with head-hitting) or back (without head-hitting) contacting to the mat. The peak BrIC values of ATD ranged from 0.94 to 2.27 (with head-hitting) and 0.54 to 0.91 (without head-hitting). The average BrIC value with head-hitting (1.62 ± 0.22, mean ± S.E.) trials was significantly higher than those without head-hitting (0.73 ± 0.08) trials (p<0.05). Four out of six trials with head-hitting scored BrIC values larger than 1.0, which implies the human tolerance limit for serious brain injury. However, BrIC values were less than 1.0 in all other trials without head-hitting.

CONCLUSIONS: These results suggested that thrown player's break-fall technique, with appropriate neck flexion to avoid head-hitting, decreases the BrIC value effectively and the risk of serious brain injuries in judo.

The Effectiveness Of Electromyography Biofeedback At Improving The Upper Trapezius To Serratus Anterior Activation Ratio

Julia E. Holton, Robert D. Clark, Cory J. Greever, Heather Smith. *California Polytechnic State University, San Luis Obispo, CA.*
 (No relevant relationships reported)

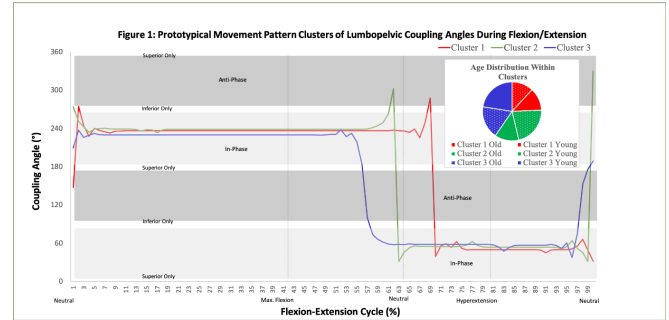

The upper trapezius (UT) to serratus anterior (SA) muscle activation ratio is essential for optimal shoulder function. An alteration of this ratio is a main area of focus in shoulder rehabilitation. Electromyography (EMG) biofeedback has been shown to be an effective technique used during rehabilitation but there is limited research on the retention of improvements. **Purpose:** To determine if EMG biofeedback can be used to improve scapular control by decreasing the UT to SA activation ratio. A secondary purpose was to determine if the predicted improvements can be retained beyond the treatment period of four weeks. **Methods:** 20 college aged (21.75±1.77 yrs) subjects participated in this study. Subjects were randomized to the exercise only (EO) group or EMG biofeedback group. Both groups performed 30 repetitions of three exercises twice a week for four weeks under supervision. The EMG biofeedback group performed them with the addition of EMG biofeedback. They were given the instructions to decrease the UT and increase the SA activation by adjusting the corresponding EMG trace on the monitor. The percent maximal voluntary contraction for each muscle during each exercise was measured on visit one, visit nine (after the four weeks) and visit 10 (after a two-week retention period) and presented as a percent change value. **Results:** There was no statistically significant effect of group on the ratio comparing visit one to visit nine (p=0.084), nor when comparing visit nine to visit 10 (p=0.065). The EMG biofeedback group had a significant decrease in UT activation (-10%) compared to the EO group (+27%) (p=0.007) at the end of the four weeks with no effect seen after the retention period (p=0.358). There was a significant increase in SA activation in the EMG biofeedback group (+196%) compared to the EO group (+29%) (p=0.000) comparing visit one to nine. There was a significant increase in SA activation comparing visit nine to visit 10 in the EMG biofeedback group (+14%) compared to the EO group (-12%) (p=0.001). **Conclusion:** EMG biofeedback was not found to decrease the UT to SA activation ratio, but the individual muscle activation changes indicate that EMG biofeedback can be effective at altering muscle activation rates in individual muscles and that those changes can be retained beyond the timeframe of the intervention.

Lumbopelvic Rhythm Prediction Using Machine Learning And Its Use As A Biomarker For Low Back Pain Identification

Ashudeep Singh¹, Joshua Tome², Yumeng Li³, Zachary Doig², Rumi Singh Kakar². ¹Cornell University, Ithaca, NY. ²Ithaca College, Ithaca, NY. ³Texas State University, San Marcos, TX.
 Email: ashudeep@cs.cornell.edu
 (No relevant relationships reported)

Lumbopelvic (LUM-PEL) rhythm has the potential be used as biomarker for diagnosis and rehabilitation of athletes predisposed to mechanical low back pain (LBP). Studies till date have mostly focused on discrete variables from the time series to explain movement patterns. Machine learning algorithms provide opportunity to analyze continuous time series data for predictive classification of movement patterns into pathological and non-pathological, adding value to early diagnosis and clinical decision making for conditions such as LBP. **Purpose:** Use of machine learning to categorize healthy LUM-PEL rhythm. **Methods:** 79 participants with no LBP (Young: n=42; 18-40yr; 27.6±6.5yr; Older: n=37; 41-65yr; 51.7±7.3yr). 3D segmental kinematics of lumbar (LUM: L1-L5) and pelvis [PEL] were calculated for maximum trunk flexion-extension. Coordination patterns were divided into in-phase, anti-phase, superior and inferior-only based on the coupling angles of LUM and PEL. K-means clustering, an unsupervised machine learning algorithm, was employed to create clusters of movement patterns of the coupling and segmental angles based on dynamic time warping similarity. Sample distribution within each cluster was compared for different age groups. **Results:** LUM-PEL rhythm fell under k=3 major movement pattern clusters (Fig. 1). No difference between age groups was observed. Non-pathological LUM-PEL rhythm clusters suggest flexion movement initiation and return from hyperextension typically have segments in anti-phase (LUM leading: 40.4%), PEL/ LUM only (35.3%) and in-phase (LUM leading: 24.3%). The 2 segments predominantly move in-phase except at start and end of movement. Patterns were not apparent when using segment angles

or through discrete variable of mean coupling angles. **CONCLUSIONS:** Using the discovered movement pattern clusters, individuals with LBP could be identified and training prescriptions can be based on healthy segmental coordination.

Back pain is linked to alterations in movement behaviour. Yet, the interaction between pain intensity and movement is not fully understood. In particular, it remains unknown if the movement quality differs between (chronic) pain intensities. **Purpose:** To compare trunk movement behaviour, assessed by lumbar/pelvic and conjunct lateral flexion contributions to the total range of motion (RoM) during trunk flexion, between people with low and moderate to high back pain intensities. **Methods:** A multi-centre study on 607 people with back pain was performed. Chronic pain intensity scores (INT [0-100]; sub-score of the Graded Chronic Pain Scale) were used to group participants into comparably low (LP; Score <30 points) and moderate to high pain intensity (HP; Score ≥ 30 points). Accordingly, 211 participants (49% f; 37±13y; 73±15kg; 174±9cm; INT 18±7) were allocated to LP and 393 participants (57% f; 41±14y; 75±16kg; 173±9cm; INT 46±13) were allocated to HP. Motion was assessed during maximal trunk flexion in upright standing. A mobile IMU system (six sensors), distinguishing between total, lumbar and pelvic motion in all three movement planes, was used. Outcome measures were total RoM, lumbo-pelvic ratio (LPR) and amount of conjunct lateral motion (CLM; sum of angular changes in lateral flexion, RoM-normalized). Between-group comparisons using adjusted unpaired t-tests/Mann-Whitney U test for RoM and LPR and two-way ANOVAs for CLM were performed. **Results:** Significant between-groups differences in trunk flexion movement were found for LPR (LP 0.92±0.65; HP 0.72±0.49; p<0.0001) but not for RoM (LP 101±27°; HP 104±25°; p=0.28). CLM differed significantly between groups during downward movements in lumbar (LP 8.0±3.1; HP 7.1±2.7; p<0.01) but not in pelvic segments (LP 7.6±3.5; HP 8.3±3.4; p=0.06). No significant difference was found (lumbar: LP 8.7±3.3 HP 8.5±3.2; p=0.62; pelvic: LP 8.5±4.1; HP 9.2±4.0; p=0.08) during upward movements of the trunk. **Conclusion:** Though total RoM between subclinical and clinical back pain patients is not different, lumbar contribution on total trunk flexion movement is reduced and conjunct lateral movements at the lumbar area are increased with higher pain intensities. This might reflect a strategy to reduce potential pain at the lumbar back during flexion movements of the trunk.

 (No relevant relationships reported)

PURPOSE: Machine learning-based methods, which include Artificial Neural Networks [ANN], have been used successfully in varied classification problems. If these methods can successfully classify those vulnerable to musculoskeletal problems such as low-back pain [LBP], they may have utility in screening and management of such conditions and aid in identifying what assessment methods provide optimal information for practitioners. We examined whether ANN techniques could correctly classify whether subjects experienced LBP in a convenience sample of dancers. **METHODS:** 60 subjects [48 women], 36 of whom [24 women] reported an episode of back pain in the past two months, were instrumented with a multi-segment spine marker set [Swain et al., 2019] and recorded [Motion Analysis Corp Eagle, 250 Hz] while performing standing and seated rotations, walking and several functional and dance-related movements [step-over task, arabesque, passe]. The multi-segment model has five segments: pelvis, lower and upper lumbar [L/L], lower and upper thoracic [L/UT]. 3D rotations were computed both between adjacent segments, and with respect to the lab coordinate system. To determine variables of interest, 1-dimensional statistical parametric mapping [SPM1D; Pataky, 2008] analysis was performed. Features [min, max, time to min/max, and side-side difference] were extracted from these variables and used to train an ANN pattern recognition tool [MATLAB]. Approximately 75% of the data were used for training, with the remainder used for validation and testing. Because of the dearth of men, analysis was performed on the entire cohort, and of women only. **RESULTS:** Based on the SPM1D analysis, only approximately 10% of data were used for training the ANN. For example, for walking trials, LL and LT axial and UT coronal plane rotations were used. The ANN classifier was able to correctly identify incidence of LBP with approximately 65% accuracy. **CONCLUSIONS:** Based on our small sample, ANN techniques show promise for identifying subjects with LBP based on their movement patterns. A larger training set of data is needed for better results. Future work should optimize feature selection by focusing on areas of difference between data rather than by selecting fixed features [e.g., max value] and examine the effect of different ANN architectures.

 (No relevant relationships reported)

Trunk modification (TM) is associated with reduced knee adduction moment during gait in both healthy and symptomatic individuals. Reported reductions are dependent on the magnitude of modification implemented. Evidence however suggests that increased trunk motion augments structural loading at the spine. Despite the positive adaptations at the knee, potential unanticipated changes in spinal load are yet to be investigated. **PURPOSE:** To investigate changes in trunk joint reaction force (JRF) during ipsilateral (IP) and contralateral (CT) stance phases subsequent to implementing unilateral subject-specific TM. **METHODS:** 19 healthy participants (26.7±4.8 years; 1.69±0.17 m; 72.3±11.8 kg) were recruited. Trunk lean was implemented towards the side of the preferred kicking limb. Participants average trunk angle (TA) was assessed during 10 baseline trials using a motion capture system (200Hz) and force plates (1000Hz). Subject-specific TA range was determined by adding 1-3 standard deviations (small), and 3-5 standard deviations (large) to baseline value. Participants completed 5 trials using both small and large subject-specific TM angles. Real-time TA projected as a line graph which was visible to participants during TM trials reinforced performance. Visual 3D was used to deliver feedback and determine trunk JRF (N/kg). Changes to trunk JRF was assessed using a Friedman test with Wilcoxon signed-ranked test and Bonferroni-adjusted significance level. Analyses were conducted using a significance level of p<0.017. **RESULTS:** Peak lateral JRF during IP and CT stance were significantly greater during TM trials ($\chi^2(2) = 32.9$, and 30.7 , p<0.001 respectively). Participants experienced increased lateral JRF during both IP (d=1.5,

and d=1.7, small and large TM respectively), and CT (d=1.6, and d=1.7, small and large TM respectively) compared to baseline. **CONCLUSION:** Changes in trunk JRFs are indicative of elevated spinal loads. During CT stance, lateral JRF in the direction of the modified side persisted which is indicative of continued asymmetric trunk load. Findings suggest TM could result in detrimental adaptations and may be contraindicated for certain individuals. Further research employing longitudinal design is needed to investigate if observed acute changes are transient in nature.

B-49 Free Communication/Slide - Health Interventions in Youth

 (No relevant relationships reported)

Physical Activity (PA) guideline recommendations for young people are intended to increase fitness and prevent overweight and obesity. However, little is known about the heterogeneity in health-related outcomes experienced by guideline concordant children.

PURPOSE: To prospectively investigate the associations between PA intensity and unfavorable health trajectories among physically active children aged between 6 and 12 yrs.

METHODS: This prospective study (2.5 yrs) included 391 students (8.1 ± 1.4 yrs) from ten public schools participating in the Childhood Health, Activity, and Motor Performance School Study Denmark (CHAMPS-dk). All children performed a daily minimum of 60-min of moderate-to-vigorous physical activity (MVPA), measured by accelerometers, at baseline and 30 months. Trajectories of body mass index (BMI), waist circumference, and aerobic fitness were constructed with a group-based multi-trajectory model and associations between PA measures and health trajectories were modeled with logistic regression.

RESULTS: Overall, 9.1% of guideline-concordant children were classified as members of an unfavorable health trajectory with BMI and waist circumference indicating overweight/obesity, and lower aerobic fitness. Time in sedentary [OR 0.98 95%CI (0.94-1.02)] and moderate intensity activity were not associated with membership in an unfavorable health trajectory [OR 0.86 95%CI (0.71-1.04)]. Each 5-min in MVPA was associated with a 23% reduction [OR 0.77 95%CI (0.66-0.91)] in the odds of being in the unfavorable health trajectory group. For every 5-min spent in vigorous PA, there was a 39% reduction in the odds of being classified as a member of the unfavorable health trajectory [OR 0.61 95%CI (0.46-0.80)].

CONCLUSION: Additional 5-min in MVPA and vigorous PA are associated with better health-related outcomes among children who adhere to PA guideline recommendations. Vigorous PA was the strongest predictor of health outcomes. PA guidelines should place greater emphasis on vigorous intensity PA.

An Intervention For Fundamental Motor Skills And Physical Activity In Pre-schoolers: A Cluster-randomized Controlled Trial

Carolyn Broderick¹, Alexander C. Engel¹, Louise Hardy², Natalie Kwai¹, Nancy Van Doorn¹, Rachel E. Ward¹, Belinda J. Parmenter¹. ¹University of NSW, Sydney, NSW, Australia. ²University of Sydney, Sydney, NSW, Australia.
 Email: c.broderick@unsw.edu.au
 (No relevant relationships reported)

PURPOSE: Physical activity (PA) is important for health and development in preschool-aged children yet only 34% of Australian pre-schoolers achieve the

recommended levels. Fundamental motor skill (FMS) interventions have been shown to improve FMS proficiency and PA levels, however, whether these changes are maintained post-intervention is unknown. We aimed to determine if a 12-week FMS program improved FMS and PA in pre-schoolers; and if so, whether these improvements were maintained 12 weeks post-intervention. **METHODS:** The Physical Activity and Fundamental Motor Skills in Pre-schoolers (PLAYFun) Program was a cluster randomized controlled trial. Participants were recruited from 4 University pre-schools. The PLAYFun Program was a 12-week, games-based, FMS program delivered directly into the centers by an exercise physiologist. Primary outcomes included FMS proficiency, objective PA and parent perceived PA assessed at baseline, 12 weeks and 12 weeks after the completion of the intervention (week 24). Differences within and between groups were assessed via a one-way analysis of variance.

RESULTS: Forty-nine participants (mean age 4.0±0.6; 54% male) were recruited. Children attended on average 2.0±1.0 sessions per week for 40 minutes per session. Participants in the PLAYFun Program demonstrated a significantly greater increase in object control ($p=0.003$) and total FMS ($p=0.019$) proficiency at week 12 compared to controls. Locomotor skills score (M 14.83 95% confidence interval (95%CI) [3.90 to 25.75]; $p=0.012$), object control skills (M 24.11 [9.93 to 38.29]; $p=0.003$) and gross motor quotient (M 20.14 [8.33 to 31.96]; $p=0.003$) all significantly improved when children attended twice a week, but these improvements were not maintained at 24 weeks. Girls in PLAYFun significantly increased objective moderate to vigorous PA after the intervention ($P=0.015$), but not boys. This increase was also not maintained 12 weeks post-completion of PLAYFun. No significant relationships between FMS and PA outcomes were identified.

CONCLUSIONS: Motor skill programs delivered directly to preschool children by an exercise physiologist within their preschool is effective at improving FMS proficiency in boys and girls and PA in girls. However, these improvements are not maintained when the practice is not ongoing.

Effectiveness Of School-based Program To Reducing Sedentary Behavior And Improving Physical Activity In Brazilian Students

Sueyla Ferreira da Silva dos Santos¹, Drenya Bordin², Elaine Fernanda Dornelas de Souza³, Thiago Ferreira de Sousa⁴, Ismael Forte Freitas, Jr.². ¹Federal University of Amazonas, Parintins, Brazil. ²São Paulo State University, Presidente Prudente, Brazil. ³University of West Paulista, Presidente Prudente, Brazil. ⁴Recôncavo da Bahia Federal University, Amargosa, Brazil. Email: sueylaf.silva@gmail.com

Reported Relationships: S.F. Santos: Other (please describe); This study was funded by The São Paulo Research Foundation (FAPESP Process: 2016/09260) and Coordination of Superior Level Staff Improvement – Brazil (CAPES Process: 88881.187941/2018-01)..

Regular high intensity physical activities have been associated with healthy outcomes in adolescents. Previous studies have reported positive changes on physical activity (PA) level and sedentary time (SED) in participants of multicomponent school-based programs. The main research question was whether School in Action program is effective on promote active life style in Brazilian adolescents. **PURPOSE:** To examine the effects of a multicomponent school-based program on students' PA and SED. **METHODS:** A cluster randomized controlled trial with 370 adolescents (aged 11.7 years, SD=0.6) from four public schools from Presidente Prudente-SP, Brazil, were randomized to either an intervention or control group. School in Action program was based on ecological and self-determination theory principles and strategies consisted of: (a) 15 minutes of PA program in physical education (PE) class, (b) PA practice during the lunch break, (c) active breaks during theoretical classes, (d) monthly participation of school's health education project, (e) parent's counseling during school meeting and (f) school playground adaptation and acquisition of material resources to improve moderate-to-vigorous physical activity (MVPA). Changes in PA and SED were measured. PA level was evaluated by wrist-worn accelerometers (Actigraph, gt3x+), and Chandler's cut-points were considered. Generalized linear mixed models were used and pre-specified interactions were tested (i.e., group*time). All analyses were adjusted by sex, peak height velocity, baseline data and social economic level on SPSS, 25.0 version, 95% of significance. **RESULTS:** Total of 70.27% (n=260) of data accelerometer was valid at baseline (600 minutes per day, minimum 3 days). The proposed intervention presents decreased SED (Δ intervention group 'baseline to post-test' = -3.8; Δ control group 'baseline to post-test' = 6.3; $p=0.04$) and minimize the reduction of vigorous PA (Δ intervention group of 'baseline to follow-up' = -0.2; Δ control group 'baseline to follow-up' = -0.4; $p=0.03$). Time spent in MVPA did not differ between the groups over time. **CONCLUSION:** The multicomponent program was effective to decrease SED and can maintain students' vigorous PA level.

Effect Of A School-based Physical Activity Intervention On Academic Performance In Norwegian Adolescents: The School In Motion Study - A Cluster Randomized Controlled Trial

Runar Solberg¹, Jostein Steene-Johannessen¹, Ulf Ekelund, FACSM¹, Øystein Lerum², Andreas Åvitsland³, Tommy Haugen⁴, Sveinung Berntsen⁴, Elin Kolle¹. ¹Norwegian School of Sports Sciences, Oslo, Norway. ²Western Norway University of Applied Sciences, Sogndal, Norway. ³University of Stavanger, Stavanger, Norway. ⁴University of Agder, Kristiansand, Norway. (Sponsor: Ulf Ekelund, FACSM) Email: r.b.solberg@nih.no

(No relevant relationships reported)

There is increasing evidence of a positive association between physical activity (PA) and academic performance. However, few studies include adolescents.

PURPOSE: To investigate the effect of a nine-month, school-based PA cluster-randomized controlled trial, School in Motion (SciM), on academic performance in 14-year-old adolescents.

METHODS: 29 secondary schools (N=2084) in Norway were cluster-randomized into three groups A) the Physical active learning (PAL) intervention group (n = 10), B) the Don't worry - Be Happy (DWBH) intervention group (n = 9) or C) control (n = 10). Target dose in the PAL and DWBH group was 120 min/week of additional PA and physical education. Academic performance (secondary outcome) was assessed by standardized national tests in reading and numeracy at baseline (September 2017) and at the end of the intervention (May 2018). Test scores are reported as t-scores (mean = 50, standard deviation (SD) = 10). We used a linear mixed model with the means as a function of time and group-by-time interaction, with schools as random effects. Participants (n = 1682) from 27 schools with valid data at both timepoints were included in the analysis. **RESULTS:** At baseline, mean values in reading were 57 (SD 9.5) and 54 (SD 10.2) points for girls and boys respectively and 56 (SD = 9.7) points for numeracy in both genders. Performance in numeracy increased in both intervention groups. In favor of the PAL group, the mean difference in change in numeracy were 1.1 points (95% confidence interval (CI) 0.3-1.8, $p = 0.024$) and 2.6 points (95% CI 1.7-3.5, $p < 0.001$) for girls and boys respectively, when compared with controls. Similarly, in favor of the DWBH group, the mean difference in change in numeracy compared to the control group was 1.4 points (95% CI 0.5-2.2, $p = 0.005$) for girls and 2.8 points (95% CI 1.8-3.8, $p < 0.001$) for boys. A significant intervention effect for reading were only observed among boys in DWBH intervention with mean difference in change of 1.8 points (95% CI 0.6-2.9, $p = 0.008$) in favor of the intervention group.

CONCLUSIONS: The findings from the SciM intervention support the notion that additional PA in school is beneficial for students' academic performance especially in numeracy.

817 May 27 4:15 PM - 4:30 PM

Effects Of A Teacher Training Program To Promote Physical Activity Among Preschoolers With Autism

Ellyn M. Schmidt¹, Jessica A. Hoffman¹, Christina Mulé², Amy Briesch¹. ¹Northeastern University, Boston, MA. ²Floating Hospital for Children at Tufts Medical Center, Boston, MA. Email: schmidt.el@husky.neu.edu

(No relevant relationships reported)

Children with Autism Spectrum Disorder (ASD) are disproportionately impacted by childhood obesity, with one contributing factor being low levels of physical activity (PA). There is a paucity of interventions for promoting PA that are responsive to the unique needs of young children with ASD. One promising approach designed for teachers working with typically developing preschoolers is WE PLAY (Wellness Enhancing Physical Activity for Young Children), an online-based training system. It was adapted to be responsive to the needs of children with ASD through a stakeholder-engaged approach. **PURPOSE:** To determine the impact of WE PLAY-Autism on the moderate-to-vigorous PA (MVPA) of preschoolers with ASD during school hours.

METHODS: A multiple baseline design across participants was used, which allowed for a rigorous experimental evaluation of the impact of WE PLAY-Autism through the repeated measurement of children's MVPA as the intervention was implemented sequentially across classrooms. Children's (N = 5) MVPA was measured daily during school hours using accelerometers (ActiGraph GT9X Link) worn at the iliac crest. Data were analyzed using validated accelerometer count cut-points for preschoolers, with min/hour of MVPA as the dependent variable. **RESULTS:** Following current best practices in single case designs, visual analysis and effect size calculations were used, indicating higher average min/hour of MVPA among preschoolers with ASD in the intervention phase (Tau- $U_{A vs. B} = .53$, $p < 0.001$, Hedges' $g = 0.99$, 95% CI [0.56, 1.43]) and post-training phase (Tau- $U_{A vs. B} = .55$, $p < .001$, Hedges' $g = 1.17$, 95% CI [0.73, 1.60]) in comparison to the baseline phase. The average increase in min/hour of MVPA from baseline to post-training was 2.51 (range = 1.35 - 4.32), which translates to approximately 38 additional minutes of MVPA across the 15-hour preschool week.

CONCLUSION: This study is, to our knowledge, the first to implement and report the impact of a preschool PA intervention adapted to be responsive to the needs of preschoolers with ASD. The results provide preliminary evidence that WE PLAY-Autism increases MVPA among preschoolers with ASD to a similar magnitude as preschool-based interventions for typically developing children.

818 May 27 4:30 PM - 4:45 PM

Dearborn SHINES: The Impact Of A Comprehensive School Health Intervention

Erin E. Centeio¹, Jeanne M. Barcelona², Christine Pedder², Hayley B. McKown¹, Kowsar A. Hijazi². ¹University of Hawaii at Manoa, Honolulu, HI. ²Wayne State University, Detroit, MI. Email: ecenteio@hawaii.edu

(No relevant relationships reported)

PURPOSE: Arab Americans account for almost 3.7 million people in the U.S., however, limited health data is available on youth and adult populations. In order to better understand the health behaviors of Arab Americans and aid in the push for healthy lifestyles in children, more research should be conducted. Therefore, the purpose of this study was to implement a culturally relevant healthy eating (HE) and physical activity (PA) intervention known as D-SHINES in a primarily Arab-American school district and understand the impact it had on students' overall PA, attitude toward PA and HE, as well as PA and HE knowledge, and perceived social support. **METHOD:** Eight schools participated in the D-SHINES intervention over one school year, with 264 (Mage=11.1; Male = 106) randomly selected students participating in pre-post testing. The intervention consisted of physical education utilizing SPARK, PA afterschool clubs, gardening and nutrition programming, and classroom physical activity breaks. Students participated in a pre-post survey with validated measures for overall PA level, HE and PA attitude, knowledge, and perceived social support. Implementation of the garden, HE, and PA curriculum tools were also tracked for fidelity. **RESULTS:** T-tests were used to determine differences among students from pre-post intervention. Results showed that students significantly increased their HE and PA knowledge over the course of the year ($p < .001$), as well as their PA attitude ($p = .021$). There was no significant difference observed in overall PA levels ($p = .92$), vigorous PA ($p = .08$), and perceived social support. Additionally, MANCOVA's showed significant differences among the variables between grade and gender ($p < .001$). **CONCLUSIONS:** Although limitations exist, the results show that while the D-SHINES program was implemented in the school, students' significantly improved their attitudes and knowledge toward HE and PA, yet, failed to show a significant increase in overall PA. Additionally, great strides were made with teachers and schools to build and implement the garden curriculum. Additional research should be conducted to better understand successful comprehensive school programming among urban Arab American youth, a population that is often understudied.

819 May 27 4:45 PM - 5:00 PM

CHANGES IN PHYSICAL ACTIVITY, PHYSICAL FITNESS AND WELL-BEING FOLLOWING A SCHOOL-BASED HEALTH PROMOTION PROGRAM

Sabrina Krogh Schmidt, Michael Sæther Reinboth, Solfrid Bratland-Sanda. University of South-Eastern Norway, Bø in Telemark, Norway. (Sponsor: Jorunn Sundgot-Borgen, FACSM) Email: sabrina.k.schmidt@usn.no

(No relevant relationships reported)

Purpose: School-based physical activity (PA) has mostly been examined in a preventive perspective. The purpose of this study was to examine the changes in physical activity, physical fitness and psychosocial well-being in early adolescents after the implementation of a school-based health promotion program in secondary school.

Methods: Four municipalities with 15 secondary schools in Telemark County, Norway, were recruited into an intervention or a control group. A total of 644 pupils participated in the study (response rate: 79%). The schools in the intervention group implemented the Active Healthy Kids program, where the physical activity component consisted of: (1) 120 min/week of physically active lessons (PAL), (2) 25 min/week of physical active breaks during classroom lessons and (3) 135 min/week of curriculum based normal physical education. Primary outcome was physical activity assessed by accelerometer and expressed as counts per minutes. Secondary outcomes were sedentary time, physical fitness, vitality, school effort and health-related quality of life in the five domains; physical health, psychological wellbeing, parent, peers and school environment.

Results: There was a Group X Time effect for school-based, but not full-day, physical activity ($p = 0.005$), and for cardiorespiratory fitness ($p = 0.02$) and vitality ($p = 0.008$). A Group effect was found for the perceived exerted effort in class ($p < 0.001$) and the health-related quality of life domains "psychological well-being" ($p = 0.04$) and "school environment" ($p < 0.001$).

Conclusions: A multi-component, school-based, health-promotion intervention with emphasis on the use of PAL led to positive changes in school-based physical activity,

cardiorespiratory fitness, vitality and health-related quality of life among early adolescents in a county with poor public health profile. This might have implications for the development and promotion of general health and well-being throughout adolescence.

Trial registration: Approved by the Norwegian Data Protection Services (ID 54327), and registered in ClinicalTrials.gov, (ID NCT03906851).

Keywords: School-based physical activity, adolescents, Physical activity, physical fitness, Health Related Quality of Life, Norway

Aadland³, Einar Ylvisaker³, Jan Morten Loftnes³, Eivind Aadland³. ¹Norwegian School of Sport Sciences // Western Norway University of Applied Sciences, Sogndal, Norway. ²Norwegian School of Sport Sciences, Oslo, Norway. ³Western Norway University of Applied Sciences, Sogndal, Norway.

Email: adakn@hvl.no

(No relevant relationships reported)

PURPOSE: The direction of the longitudinal relationship between physical activity (PA) and fundamental motor skills (FMS) remains unclear. We evaluated the bi-directional, prospective relationships between intensity-specific physical activity (PA) and domain-specific fundamental motor skills (FMS) over two years in young children. **METHODS:** A sample of 235 children (mean age at baseline 4.7 yr, 52 % boys) from the Sogn og Fjordane Preschool Physical Activity Study was measured two years apart. PA was assessed using ActiGraph accelerometers (GT3X+). FMS were evaluated by a test battery inspired by the "Test of Gross Motor Development 3" and the "Preschooler Gross Motor Quality Scale". PA outcomes were total PA (TPA [counts per minute]) and intensity specific PA and sedentary behaviour (SED) (min/day). FMS outcomes were total FMS score, locomotor-, object control-, and balance skills. Linear mixed model adjusting for potential co-variables was used to evaluate the bi-directional prospective associations between these variables, including the moderating effect of sex and age. **RESULTS:** Baseline total PA, moderate-to-vigorous PA (MVPA), and vigorous PA predicted higher total FMS score, locomotor-, object control-, and balance skills at follow-up (standardized regression coefficient (β): 0.15 to 0.26, $p = 0.002-0.031$). SED predicted lower FMS in all domains except balance (β : -0.10 to -0.27, $p = 0.008-0.026$). Baseline light PA did not predict FMS at follow-up. Baseline object control- and balance skills were not associated with PA or SED at follow-up. Total FMS score at baseline predicted lower light PA at follow-up (β : -0.14, $p = 0.041$), and locomotor skills at baseline predicted higher TPA in boys relative to girls (p for interaction=0.044). **CONCLUSIONS:** PA, especially MVPA, were positively associated with development of FMS in young children. In contrast, FMS was largely unrelated to future PA levels. Our results suggest promotion of MVPA is important for FMS development in young children.

Influence Of Maternal Exercise And DHA Levels During Pregnancy On Maternal Lipids

Cody J. Strom, Kimberly Kew, Samantha McDonald, Christy Isler, Kelly Haven, Ed Newton, Linda May. East Carolina University, GREENVILLE, NC. (Sponsor: Dr. Linda May, FACSM)

(No relevant relationships reported)

Elevated levels of Total Cholesterol (TC), low-density lipoprotein (LDL) and triglycerides (TG) during pregnancy have been associated with risks of gestational diabetes, preeclampsia, fetal macrosomia and cardiovascular disease. Exercise is

known to decrease TC, LDL and TG, while increasing HDL within normal ranges. Similarly, Supplementation of polyunsaturated fatty acids (PUFA), such as DHA, help control and mitigate excessive triglycerides, while increasing HDL. Research has not investigated the potential relationship of maternal exercise and PUFA levels on maternal lipid profiles. **PURPOSE:** To determine the relationship between maternal exercise and plasma levels of DHA on maternal lipid levels at 16 and 36 weeks.

METHODS: 22 women with a singleton pregnancy (<16 weeks) were randomized to either aerobic (n=9) or non-exercising control (n=4) group. Participants exercised 3x50 minutes per week at moderate intensity for ~24 weeks, with average weekly METmins/wk calculated based on standard MET values*average minutes. Maternal plasma was collected at 16 and 36 weeks of gestation and analyzed for DHA and lipid levels. Multiple linear regression and Spearman correlation models were performed to determine relationships between maternal METmins/wk, DHA levels, and lipid levels. **RESULTS:** There is a significant negative correlation between DHA levels on HDL (-0.692, p=0.01) at 36 weeks. There are trends of significance with METmins/wk with DHA (0.500; p=0.08) and TG (-0.440, p=0.13) at 36 wks. There was not a significant regression equation found for TC (F=0.690, p=0.52) and TG (F=2.092, p=0.174), however METmins/wk showed a negative relationship to TC (-0.094, p=0.307) and trended to significantly predict TG (-0.185, p=0.081) while DHA Levels showed a positive relationship with TC (0.059, p=0.331) and TG (0.105, p=0.125).

CONCLUSION: The current suggests a potential relationship between exercise and DHA levels during pregnancy on maternal lipids. These findings showed a negative and stronger relationship with METmins/wk compared to DHA levels, thus suggesting exercise may be more important to control excessive increases in TC and TG during pregnancy.

823 May 27 3:30 PM - 3:45 PM

Physical Activity Knowledge And Sources Of Advice During Pregnancy

Ciara O'Hagan¹, Louise Turner². ¹Institute of Technology Carlow, Carlow, Ireland. ²Sheffield Hallam University, Sheffield, United Kingdom.

Email: ciara.ohagan@itcarlow.ie

(No relevant relationships reported)

Physical activity (PA) during pregnancy is known to be beneficial for the health of both the mother and foetus, but most pregnant women do not engage in the recommended volume of activity. Lack of personal and healthcare-professional knowledge is frequently cited as a barrier to PA participation during pregnancy in both low-activity and athletic populations.

PURPOSE: To explore the sources of advice used by women to guide their PA participation during pregnancy.

METHODS: Women who had recent experience of pregnancy in Ireland (n = 102, age 35±4 years) completed an online survey with questions regarding their activity type immediately pre-pregnancy (activities of daily life only (DAILY), recreational exercise (EXERCISE) or competitive sport (SPORT)), knowledge of PA guidelines, experiences of receiving PA advice from healthcare professionals during pregnancy, and perceptions regarding different sources of advice. Between-group comparisons were made by Chi-square analysis.

RESULTS: Knowledge of the recommended volume of activity for health was significantly poorer in EXERCISE than DAILY or SPORT ($X^2_8 = 16, p = 0.037, V = 0.283$); there were no differences in knowledge of recommended intensity or type. Women in the EXERCISE and SPORT groups were significantly more likely to have felt that they needed to initiate discussion about PA with their healthcare providers than those in the DAILY group, for whom the professional was more likely to initiate the discussion ($X^2_6 = 19, p = 0.004, V = 0.310$). While 48% of respondents perceived their healthcare professionals to be their most useful source of PA advice during pregnancy; the other 52% cited sources such as friends, exercise professionals or online media, with no between-group differences. Furthermore, many women reported that they never received PA advice during their pregnancy from their general practitioner (27% of women), midwife (45%) or obstetrician (46%).

CONCLUSION: Knowledge of guidelines for PA during pregnancy is low among pregnant women in Ireland; low levels of guidance from healthcare professionals may be a contributing factor.

824 May 27 3:45 PM - 4:00 PM

Maternal Physical Activity Correlates With Fasted And Postprandial Insulin Resistance And Lipids During Late Pregnancy

Rachel A. Tinius¹, Maire M. Blankenship¹, Kevin J. Pearson², W. Todd Cade³, Elizabeth Altizer⁴, Nikki B. Zite⁴, Jill M. Maples⁴.

(No relevant relationships reported)

PURPOSE: Physical activity (PA) has been shown to be effective for lowering insulin resistance and blood lipid profiles during pregnancy. Recent evidence indicates sedentary time is also associated with poor pregnancy outcomes. The purpose of this study was to determine the relationships between sedentary time and moderate PA, assessed during late pregnancy, and insulin resistance (HOMA-IR) and triglycerides in fasting and postprandial conditions. Postprandial conditions are important to study as humans spend the majority of their time in a fed-state.

METHODS: Healthy pregnant women (N=61, 32-36 weeks gestation) were recruited for this study. Sedentary time and moderate intensity PA were objectively assessed using a wrist-worn Actigraph GT9X Link Accelerometer. The device was worn 24 hrs/day for 7 days. Fasting blood lipids, insulin, and glucose were assessed. A standardized high-fat breakfast was consumed and these measures were collected again 120-minutes post-meal (postprandial). All relationships were analyzed with Pearson Product Moment Correlation Coefficients while controlling for pre-pregnancy BMI.

RESULTS: Sedentary time was positively correlated with fasting and postprandial insulin resistance (fasting HOMA-IR: $r = -0.471, p = 0.001$; postprandial HOMA-IR: $r = -0.433, p = 0.002$), while these measures were negatively correlated with light PA (fasting HOMA-IR: $r = -0.395, p = 0.005$; postprandial HOMA-IR: $r = -0.364, p = 0.010$) and moderate PA (fasting HOMA-IR: $r = -0.520, p < 0.001$; postprandial HOMA-IR: $r = -0.477, p = 0.001$). Sedentary time was positively correlated with fasting triglycerides ($r = 0.296, p = 0.039$). Moderate PA was negatively correlated with fasting triglycerides ($r = -0.403, p = 0.004$) and postprandial triglycerides ($r = -0.343, p = 0.016$).

CONCLUSIONS: Decreasing sedentary time and adding any intensity PA may positively impact metabolic health during pregnancy by reducing fasting and postprandial insulin resistance, as well as reducing fasting and postprandial triglycerides. This is important as, during pregnancy, insulin resistance is associated with poor pregnancy and neonatal outcomes and increased triglycerides are associated with increased risk of preeclampsia, pre-term birth, and increased maternal cardiovascular risk later in life.

Influence Of Physical Activity And Sedentary Behavior During Pregnancy On Labor And Delivery Type

Melissa A. Jones¹, Janet Catov¹, Kara Whitaker², Bethany Barone Gibbs¹. ¹University of Pittsburgh, Pittsburgh, PA.

²University of Iowa, Iowa City, IA.

Email: maj133@pitt.edu

(No relevant relationships reported)

Physical activity (PA) during pregnancy is known to be safe and does not increase risk of medical intervention during labor and delivery. While it is known that sedentary behavior (SED) and PA have independent health effects, whether higher SED during pregnancy increases risk for medical intervention in labor and delivery is unknown.

PURPOSE: To examine the relationship of SED and PA patterns across pregnancy with labor and delivery outcomes. **METHODS:** In this prospective cohort study, objective SED (thigh-worn activPAL micro3) and physical activity (waist-worn ActiGraph GT3X-BT) were assessed in women for ≥ 4 days with ≥ 10 hours in each trimester of pregnancy. This secondary analysis includes women with available labor and delivery records, and PA and SED measures in ≥ 1 trimester (n=99). Trajectory analysis was used to identify patterns of PA and SED across pregnancy and assign women to the groups most closely related to their dominant activity patterns. Labor and delivery information was abstracted from participant medical records. Labor types were categorized as: spontaneous, induced-elective, or induced-medical. Delivery types were categorized as: vaginal, c-section-elective, c-section-medical. Differences in labor and delivery type by SED and PA trajectories were analyzed using Fisher's exact tests due to small cell sizes. **RESULTS:** Trajectory analysis resulted in and assigned women to high, medium, and low groups for PA and SED across trimesters of pregnancy. Approximately 60% of labor was spontaneous, followed by 27% medical induction, and 13% elective induction. Deliveries were 79% vaginal, 13% medically indicated c-section, and 8% elective c-section. Type of labor (L) or delivery (D) did not significantly differ by SED (L: $p = 0.185, D: p = 0.134$) or PA (L: $p = 0.756, D = 0.120$) trajectories. When elective induction and c-sections were removed to only consider risk for medical intervention, differences remained insignificant by SED (L:

p=0.136, D: p=0.088) or PA (L: p=0.527, D: p=0.128) trajectories. **CONCLUSION:** Objectively-measured patterns of SED or PA across pregnancy were not related to type of labor or delivery, including risk of medical intervention. Future research with larger samples could expand to the entire birth experience including duration of labor, medication use, or fetal complications.

826 May 27 4:15 PM - 4:30 PM
Effect Of Exercise During Pregnancy And Lactation In Obese Wistar Rats On Offspring Glycemic Control

Peter M. Magyari, FACSM, Ruth Capistrano, Elizabeth Piazza, Leila Ninya, Alireza Jahan-Mihon. *UNF, Jacksonville, FL.*
 Email: p.magyari@unf.edu
 (No relevant relationships reported)

PURPOSE: To determine the effect of maternal exercise in pregnant and lactating obese Wistar rats on the glycemic control of their offspring at time of weaning. **METHODS:** Two days following impregnation, 24 obese Wistar rats were separated into 2 groups. One group received 30 minutes of treadmill exercise (E) at 15-20 m/min each day while the other group received no exercise (NE). The groups were maintained after the birth of the offspring (21 days) through lactation (21 days) for a total of 6 weeks. At weaning an oral glucose tolerance test (OGTT) was performed on 12 randomly selected pups from each group. A t-test was utilized to determine differences in total glucose area under the curve (t-AUC) (mean and standard error) between groups ($p \leq 0.05$). **RESULTS:** There was an effect of maternal exercise on the glycemic control of the offspring. The ability to dispose of glucose following a glycemic load was significantly greater in the offspring of E dams (513.1 ± 11.7 mmol/L) compared to the offspring of NE dams (542.7 ± 7.1 mmol/L) ($p \leq 0.05$). **CONCLUSIONS:** Initiating moderate exercise early during the pregnancy of obese rats and maintaining exercise through lactation can positively impact glycemic control in offspring.

827 May 27 4:30 PM - 4:45 PM
The Effects Of An Antenatal Lifestyle Intervention On Pregnancy Outcomes In Overweight And Obese Pregnant Women

Jihong Liu, Sara Wilcox, FACSM, Ellen Wingard, Brent Hutto. *University of South Carolina, Columbia, SC.* (Sponsor: Sara Wilcox, FACSM)
 Email: jliu@sc.edu
 (No relevant relationships reported)

Three reviews of antenatal behavioral lifestyle interventions did not find significant intervention effects on maternal complications and adverse neonatal outcomes, perhaps due to the inclusion of low to medium quality studies. **PURPOSE:** To evaluate the effect of a lifestyle intervention program on pregnancy outcomes in overweight and obese pregnant women. **METHODS:** This study was a randomized controlled trial. Overweight and obese pregnant women were recruited from Columbia, South Carolina and were randomized to a behavioral intervention group (n=110) or to a standard care group (n=104). The antenatal intervention was designed to target weight self-monitoring, increasing physical activity, and increasing healthy dietary behavioral practices. Intervention contents were delivered through one in-depth counseling session, followed by phone counseling, behavioral podcasts, and social media support. Standard care women received monthly mailings and a match number of podcasts on non-weight related topics. **RESULTS:** Our study population was racially diverse (56% white, 44% African American) with a mean prepregnancy BMI of 32.2 ± 5.9 and was 12.7 ± 2.4 wks gestation at baseline. Compared to standard care women, women in intervention group had lower percentages of gestational hypertension (9.1 vs. 21.2%, $p=0.01$) and delivering a low birth weight baby (<2500g) (1.9 vs. 10.6%, $p=0.009$). These women also had lower percentages of gestational diabetes (7.3 vs. 12.5%) and delivering a preterm baby (<37 wks of gestation) (2.8 vs. 7.7%), although these differences were not significant at the 0.05 level. No group differences were found in other outcomes (i.e., cesarean deliveries, macrosomia births (birthweight ≥ 4000 g), and Apgar scores). **CONCLUSIONS:** An antenatal behavioral lifestyle intervention designed to reduce gestational weight gain was beneficial in improving pregnancy outcomes in overweight and obese pregnant women. Future analyses will examine mechanisms for this effect.

828 May 27 4:45 PM - 5:00 PM
Change In Physical Activity In The Health In Pregnancy And Postpartum (HIPP) Randomized Controlled Trial (RCT)

Sara Wilcox, FACSM, Jihong Liu, Brent Hutto, Ellen Wingard. *University of South Carolina, Columbia, SC.*
 Email: wilcox@mailbox.sc.edu
 (No relevant relationships reported)

Despite the known benefits of physical activity (PA) in pregnancy, PA is consistently shown to decrease from early to late pregnancy. Very few antenatal interventions have targeted PA and included sensor-measured outcomes in overweight and obese pregnant women.

PURPOSE: To examine whether a lifestyle intervention increased moderate- to vigorous-intensity PA (MVPA), light PA, and steps or reduced their decline from early to late pregnancy compared to a standard care condition. **METHODS:** HIPP is a RCT comparing the effects of a lifestyle intervention vs standard care on gestational weight gain (primary outcome) and health behaviors including PA (secondary outcomes) among women entering pregnancy overweight or obese. The lifestyle intervention was grounded in social cognitive theory and, during pregnancy, included an introductory behavioral counseling session followed by telephone counseling calls, behavioral podcasts, and a private Facebook group. Usual care participants received usual care from their obstetrician and received mailings and podcasts focused on a healthy pregnancy. Participants wore a SenseWear armband ≥ 21 hrs/d for ≥ 5 d at baseline (early pregnancy, n=205) and 32-wk gestation (n=167). We tested Randomization x Time interaction effects (SAS PROC MIXED) for min/d of MVPA, min/d of light PA, and steps/d. **RESULTS:** Participant demographics were: 30 ± 5 years, 44% African American, 56% white, 60% college graduate, 61% employed full-time, 67% married, 42% nulliparous, and 13 ± 2 wk gestation at baseline. While the time main effects indicated that MVPA ($p=0.07$), light PA ($p=.04$), and steps ($p<.0001$) decreased significantly, intervention effects (Randomization x Time) were not significant for these PA variables (see Table).

Table. Changes in MVPA, Light PA, and Steps Over Time, by Randomization Group, Least Square Means (SEs)

	Intervention		Standard Care		p
	Baseline	32-wk	Baseline	32-wk	
MVPA, min/d	38 (2)	36 (3)	35 (2)	28 (3)	.17
Light PA, min/d	219 (8)	206 (8)	200 (8)	194 (8)	.43
Steps/d	5574 (196)	5041 (209)	5114 (196)	4363 (211)	.34

CONCLUSION: A behaviorally based lifestyle intervention did not significantly lessen the decline in PA typically seen from early to late pregnancy. Assessments will be repeated at 6- and 12-mo postpartum.
 Funded by NIH/NICHD.

829 May 27 5:00 PM - 5:15 PM
A Healthy Lifestyle Intervention During Pregnancy: Key To Preventing Chronic Disease Risk?

Roberta Bgeginski¹, Taniya S. Nagpal², Harry Prapavessis¹, Barbra de Vrijer¹, Christina G. Campbell³, Karishma Hosein¹, Stephanie Paplinski¹, Mollie Manley¹, Michelle F. Mottola, FACSM¹. ¹University of Western Ontario, London, ON, Canada. ²University of Ottawa, Ottawa, ON, Canada. ³Iowa State University, Ames, IA. (Sponsor: Michelle F. Mottola, FACSM)
 Email: robertabg@gmail.com
 (No relevant relationships reported)

Gestational hypertension disorders and diabetes affect 6-15% of all pregnancies worldwide and are associated with adverse maternal and neonatal outcomes that can have a programming effect on future chronic disease risk. Pregnant women who receive lifestyle interventions, including healthy eating and/or physical activity, may have a decreased risk of developing complications. **PURPOSE:** To analyze the effects of a supervised healthy lifestyle intervention (nutrition and exercise) during pregnancy on diagnosis of gestational diabetes, hypertension, caesarean delivery, stillbirth, macrosomia (babies > 4500g), and low birth weight (babies < 2500g) in a cohort in London, Canada. **METHODS:** From 2016 to 2019, 111 women were enrolled at 12-18 weeks gestation in the Nutrition and Exercise Lifestyle Intervention Program (NELIP; Clinical Trials #NCT02804061) up to delivery. The nutrition goals for the intervention were: 1) Submit a weekly 24 hour-food intake record; 2) Consume approximately 1800-2200 kcal/d; and 3) Consume 200-250 g carbohydrates/d (40-55% of total energy intake). The exercise goals were: 1) Duration of session: Walk for 25 minutes and add 2 minutes each week until 40 minutes were achieved and then maintain this walking duration until delivery; 2) Frequency: 3-4 times per week; and 3) Submit a weekly step log (pedometers were provided to each participant). **RESULTS:** As of October 2019,

the average duration of the intervention was 20.9 ± 3.9 wks. Out of the 75 participants that completed the intervention, maternal age was 32.2 ± 3.3 yrs, self-reported pre-pregnancy weight was 71.2 ± 15.3 kg, and gestational age at delivery was 278.1 ± 9.0 days. No participants were diagnosed with gestational diabetes or hypertension. Data from 52 babies indicated: birth weight was 3456.0 ± 442.4 g and length was 50.7 ± 3.1 cm. None were born with low birth weight and there were no cases of stillbirth. The rate of macrosomia was 1.9% (n = 1) and caesarean delivery was 27% (n = 14). **CONCLUSION:** A healthy lifestyle intervention during pregnancy may help to prevent gestational diabetes and hypertension, and help to reduce the prevalence of stillbirth, macrosomia, low birth weight, and caesarean deliveries. Taken together, these findings may have major positive implications for the long-term health of both mothers and babies.

B-51 Clinical Case Slide - Cardiovascular

Wednesday, May 27, 2020, 3:15 PM - 4:35 PM

Cardiovascular-Track And Field
 Mitchell J. Odom. *University of Michigan, Ann Arbor, MI.*
 (Sponsor: Robert Kinningham, FACSM)
(No relevant relationships reported)

HISTORY: A 21-year old senior male track and field athlete who competes in mid-distance running events in a Division I university was evaluated for a family history of hypertrophic cardiomyopathy. During his pre-participation physical exam, he denied history of dizziness, syncope, or chest pain. There was no family history of an abnormally thickened heart or early sudden cardiac death. However, his father was recently diagnosed with hypertrophic cardiomyopathy by his primary care provider. There is no other known history of hypertrophic cardiomyopathy in the family. **PHYSICAL EXAMINATION:** There were no abnormalities during his cardiac exam. There were no murmurs on standard exam or with provocative maneuvers. **DIFFERENTIAL DIAGNOSIS:** 1. Family history of hypertrophic cardiomyopathy. 2. Physiologic hypertrophy response to exercise. **TEST AND RESULTS:** 1. Standard electrocardiogram: Sinus bradycardia with a heart rate of 55, PR interval 152, QRS duration 94, QT/QTc interval 442/422, evidence of left ventricular hypertrophy, and non-specific ST-T wave changes in leads V2 and V3. 2. Stress electrocardiogram: Asymptomatic during exercise. Interpretation: decreased sensitivity of the test due to baseline left ventricular hypertrophy, non-diagnostic study. 3. Resting echocardiogram: No valvular abnormalities, normal size of right and left atria, normal size of right and left ventricles. Concentric left ventricular hypertrophy present and marked right ventricular hypertrophy present. Impression: Consider hypertrophic cardiomyopathy. 4. Stress echocardiogram: normal hyperdynamic response to exercise. Return to baseline following rest. 5. Cardiac MRI: Left ventricle size normal, maximal left ventricular wall size 11mm, normal left ventricle indexed mass, mildly dilated right ventricle. **FINAL DIAGNOSIS:** Normal physiologic response to exercise. False positive resting echocardiogram. **TREATMENT AND OUTCOMES:** 1. After discussion with a sports cardiologist, a cardiac MRI was ordered as his resting echocardiogram was concerning for hypertrophic cardiomyopathy. 2. Cardiac MRI showed no evidence of hypertrophic cardiomyopathy. 3. No restrictions were placed on activity or participation

834 May 27 3:35 PM - 3:55 PM
Incidental Cardiac Arrhythmia Identification With Consumer Grade Heart Rate Monitors: A Case Study
 Neal C. Phifer, Dale D. Brown, FACSM, Kelly R. Laurson, Skip M. Williams, Emily Jones, Karen K. Dennis, Megan Smith, Ryan Swenson. *Illinois State University, Normal, IL.* (Sponsor: Dale Brown, FACSM)
 Email: ncphife@ilstu.edu
(No relevant relationships reported)

HISTORY: A 19-year-old sophomore NCAA Division I female volleyball player was identified, via a consumer-grade heart rate (HR) telemetry system, as having what would be considered a high heart rate (123% of age predicted max HR or 233 bpm) during practice. **PHYSICAL EXAMINATION:** Athlete was observed without interaction for signs of distress, excessive heavy breathing, pallor changes, or any sort of balance issues that would indicate dizziness or syncope. After approximately 5 minutes, HR returned to a normal level that would be commensurate with the exercises/drills being performed. Once a more in-depth analysis of the collected data was performed it was determined that consultation with team physician and cardiologist was needed. Retrospective analysis of data recorded prior to this episode was undertaken and identified approximately 40% of recorded session contained a similar episode. Further clarification of both HR, and R-R interval data aided in identification of episodes. **DIFFERENTIAL DIAGNOSIS:** 1. Supraventricular tachycardia (SVT) 2. Wolf-Parkinson-White Syndrome 3. Atrioventricular Nodal Reentrant Tachycardia (AVNRT) **TEST AND RESULTS:** Electrocardiogram: --No noticeable abnormalities Holter Monitor: --identified an exercise induced SVT episode with no other abnormalities when episode was not present. --HR data was used to assist in identifying duration, initiation and termination of the episode. **FINAL/WORKING DIAGNOSIS:** Exercise induced SVT **TREATMENT AND OUTCOMES:** Athlete continued participation with continuous real time heart rate monitoring for episodic activity. When episodes of tachycardia occurred, the athlete was removed from practice/play until a return to normal HR was achieved. After conclusion of academic year an ablation was attempted to correct the problem. The remaining athletes using the HR telemetry system have performance data analyzed on a daily basis for possible identification of arrhythmic signatures. Currently development and implementation of a policy to address identified athletes is underway and will streamline addressing future instances.

Cardiovascular-Football
 Sabrina P. Sawlani, Joshua T. Goldman, Kevin Shannon. *University of California - Los Angeles, Los Angeles, CA.* (Sponsor: Aurelia Nattiv, FACSM)
(No relevant relationships reported)

HISTORY
 A 19-year-old football offensive lineman with history of SVT (treated in infancy with propranolol and adenosine) presented during his annual pre-participation exam with palpitations for 3 months. Episodes occurred during exercise, lasting 30 seconds to 5 minutes. He admitted associated difficulty breathing and chest tightness. He denied dizziness or syncope. **PHYSICAL EXAMINATION**
 BP 133/79, HR 96, SpO2 98%/RA, BMI 35. Exam in training room: Regular heart rate and rhythm, no murmurs sitting/lying/standing, lungs clear to auscultation bilaterally, 2+ pulses throughout. **DIFFERENTIAL DIAGNOSIS**
 1. Supraventricular tachycardia
 2. Wolff-Parkinson-White syndrome
 3. Cardiomyopathy
 4. Hyperthyroidism
 5. Anemia
 6. Anxiety or panic disorder **TESTS AND RESULTS**
 CBC, CMP, TSH, A1c normal, except: AST 53, ALT 68, Ferritin 505
 CXR: No acute cardiopulmonary abnormalities
 EKG: NSR, pre-excitation in V3
 ECHO: Normal
 Treadmill stress test: Excellent exercise tolerance (92% of HRmax), limited by shortness of breath and leg fatigue. Exercise-induced chest pressure present. Pre-excitation difficult to see at peak exercise, no sudden change to suggest abrupt loss of pre-excitation. **FINAL/WORKING DIAGNOSIS**
 Wolff-Parkinson-White syndrome **TREATMENT/OUTCOMES**
 1. Urgent referral to Cardiology, EKG and ECHO (see results), outpatient cardiac ambulatory monitor placed, and treadmill stress test completed.

WEDNESDAY, MAY 27, 2020

2. Concern for high-risk pathway as pre-excitation persisted at higher heart rates on stress test. Cardiology recommended electrophysiology study and ablation.
3. Underwent uncomplicated catheter ablation of left posterior accessory pathway.
4. 1 week post-ablation, some degree of pre-excitation noted on follow-up EKG (however, similar to post-elimination and initial EKG).
5. 2 weeks post-ablation, ambulatory monitor with no events.
6. 6 weeks post-ablation, remained asymptomatic and received cardiac clearance to return to sport.

836 May 27 4:15 PM - 4:35 PM

Chest Pain - Football

Courtney Nicole Hintz. *UCLA Health, Los Angeles, CA.*
(Sponsor: Aurelia Nattiv, FACSM)
Email: courtney.hintz@gmail.com
(No relevant relationships reported)

HISTORY: A 23-year old male division I football linebacker developed acute-onset exertional chest pain 30 minutes into practice. The pain was substernal, radiated to his back and was associated with shortness of breath. He was immediately transferred to the ED and after two hours had resolution of his pain with intravenous ketorolac. The patient admitted to suffering from a viral upper respiratory infection with mild unreported chest pain for two weeks prior to the episode. He has a past medical history of well-controlled asthma and sickle cell trait. He denied previous episodes of chest pain or syncope and also denied family history of sudden cardiac death.

PHYSICAL EXAMINATION: Initial vital signs were BP 141/85, HR 74, O₂ saturation 96%, T 97.8°F. Athlete was in visible distress in right lateral decubitus position, clutching chest. Cardiac examination revealed regular rate and rhythm, no murmurs or rubs. Chest pain was not reproducible on palpation of anterior chest. Pain was positional and worse with leaning forward. Lungs were clear to auscultation bilaterally with no wheezing or rhonchi, and good air movement.

DIFFERENTIAL DIAGNOSIS: 1. Myocarditis/Pericarditis 2. Acute coronary syndrome 3. Anomalous coronary artery with myocardial infarction 4. Pulmonary embolism 5. Aortic dissection

TEST AND RESULTS: Emergency Department: Labs: Troponin 2.9, CBC: 9.3 > 15.2/45.6 < 234, BMP: 141/4.3/104/23/1.4 < 102. Imaging: CXR with no cardiopulmonary disease. Bedside ultrasound with no pericardial effusion, no evidence of acute right heart strain. EKG: Sinus rhythm, rate 69, nonspecific T-wave inversions and diffuse ST-segment elevation. Cardiac Unit: Labs: Troponin trend: 2.9->6.4->11.9->13.3->9.7, D dimer 650, CRP 0.4, ESR 10. Imaging: Normal CT pulmonary angiogram. TTE with normal LV and RV size and systolic function, EF 60-65%, no valvular abnormalities. Cardiac MRI: Mild hypokinesis in the basal septum with associated patchy mesocardial delayed enhancement and transmural delayed enhancement in the basal anterior wall and mid septum with mild hypokinesis.

FINAL WORKING DIAGNOSIS: Myocarditis **TREATMENT AND OUTCOMES:** 1. Colchicine and high dose ibuprofen taper over 3 weeks 2. Avoidance of physical activity for 3-6 months per AHA guidelines 3. Resting and stress TTE and EKG, 24-hour Holter monitor prior to RTP.

Left Foot Injury In A Female Gymnast

George Ceremuga¹, Elena Jelsing². ¹*Mayo Clinic, Rochester, MN.* ²*Mayo Clinic Square, Minneapolis, MN.* (Sponsor: Jonathan Finnoff, FACSM)
Email: ceremuga.george@mayo.edu
(No relevant relationships reported)

HISTORY: A 17-year-old female high level gymnast presented for evaluation of left heel pain and ecchymosis. Two days prior to her presentation, she was sprinting in preparation for a roundoff prior to vault take-off and felt her heel shift when she went to push-off. She fell and was immediately unable to bear weight secondary to heel pain. Pain was exacerbated by any weight-bearing activity and improved with rest. She had been wearing a walking boot and using crutches for ambulation. **PHYSICAL EXAMINATION:** Healthy-appearing female with a muscular build in no apparent distress. Antalgic gait favoring left foot, avoiding pressure on heel. Ecchymosis along both the medial and lateral aspects of the calcaneus. Tenderness to palpation and associated swelling at the plantar aspect of the calcaneus and along the subtalar joint. Ankle range of motion was full and pain-free. Pain with resisted eversion. Talar tilt and calcaneal squeeze tests were positive. No pain with plantar fascia stretching or palpation along the mid to distal plantar fascia. Achilles tendon was intact. Anterior drawer was negative. Strength was full and light touch sensation was intact. **DIFFERENTIAL DIAGNOSIS:** 1. Calcaneal stress fracture 2. Subtalar joint subluxation 3. Plantar fascia tear **TEST AND RESULTS:** Left ankle and foot radiographs were negative for acute fracture or dislocation. Left ankle MRI revealed a focal tear involving the lateral margin of the lateral cord of the plantar aponeurosis. **FINAL WORKING DIAGNOSIS:** Lateral cord plantar fascia rupture **TREATMENT AND OUTCOMES:** 1. Walking boot for 6 weeks with gradual wean out of boot during the 6th week and ankle range of motion exercises when out of the boot. 2. Once out of boot, supportive shoes with ankle brace and dorsiflexion night splint at night. 3. Physical therapy focusing on Achilles stretching, ankle range of motion and strengthening until pain and tenderness resolved. Slowly advanced to more sports-specific tasks once pain-free. 4. At 10 weeks post injury, she was pain free while performing plyometric and balance/proprioceptive exercises and had a normal exam with full pain-free range of motion. 5. Functional return to sport given her normal exam and pain-free activity with physical therapy.

(No relevant relationships reported)

HISTORY: 17 year-old male with fascioscapulohumeral muscular dystrophy who developed acute left heel pain while skiing. He was alpine skiing when he struck his heel on a mogul and felt immediate heel pain. He was able to reach the bottom of the ski slope but was unable to continue skiing due to severe heel pain. He denied any popping sensation. He had no bruising, numbness, tingling, weakness or mechanical symptoms. **PHYSICAL EXAMINATION:** There was no swelling or obvious deformity on inspection of his left heel. He was tender on palpation over his left heel, distal Achilles tendon, and medial malleolus. He had limited range of motion of his foot due to pain. Negative Thompson's test although left had 15 degrees compared to 30 degrees of plantar flexion on the right.

DIFFERENTIAL DIAGNOSIS:

1. Bone spur
2. Partial tear of Achilles tendon
3. Bursitis
4. Hindfoot fracture

TEST AND RESULTS:

X-ray AP and lateral views of left ankle were normal.

MRI left ankle revealed a nondisplaced fracture of the calcaneus. There was no signal abnormality involving the Achilles tendon and it appeared intact.

FINAL/WORKING DIAGNOSIS:

Nondisplaced calcaneus fracture

TREATMENT AND OUTCOMES:

Placed in a pneumatic boot with weight bearing as tolerated.

Out of pneumatic boot at 8 weeks.

Began physical therapy at 7 weeks.

Planning to return to skiing this winter as injury occurred in the spring.

MRI Sagittal T2 FS

Bimalleolar Fracture In Athlete With Negative Ottawa Ankle Rules

Bilal Ittiq, Kaiser Permanente Fontana, Fontana, CA. (Sponsor: Dr. Robert E. Sallis, FACS, FACS)

(No relevant relationships reported)

HISTORY: A 16-year-old senior high school football wide receiver sustained an ankle injury while getting tackled after catching a pass. During the last few minutes of the game, he sustained an inversion ankle injury while falling to the ground during a tackle. He reported pain at the lateral malleolus during the on-field examination and was able to bear weight on the leg while walking off of the field, even though he was limping. He denied any previous ankle injuries, numbness, tingling, or radiation of pain.

PHYSICAL EXAMINATION: Examination on the field revealed full range of motion, no gross deformities, and tenderness along the anterior lateral malleolus. Further evaluation on the sideline revealed pain at the lateral ankle with inversion and eversion against resistance. The athlete was tender to palpation along the anterior lateral malleolus but he denied pain with palpation of the posterior distal 6 cm of the tibia and fibula, navicular, and base of the 5th metatarsal.

DIFFERENTIAL DIAGNOSIS: 1. Ligamentous sprain (most likely ATFL). 2. Peroneal tendon injury. 3. Fracture of the lateral malleolus. 4. Osteochondral defect.

TEST AND RESULTS: Ankle anterior-posterior and lateral radiographs: bimalleolar fracture and soft tissue edema

FINAL WORKING DIAGNOSIS: Bimalleolar fracture

TREATMENT AND OUTCOMES: 1. Immobilization in CAM boot. 2. Transitioned to lace-up ankle brace once pain resolved. 3. Range of motion, proprioceptive, and balance exercises initiated. 4. Returned to play once he achieved full, pain-free range of motion.

843 May 27 4:15 PM - 4:35 PM

A Rare Case Of Ankle Pain In An Adolescent Male Athlete

Ike Hasley, Edward Laskowski, Mayo Clinic, Rochester, MN.

(No relevant relationships reported)

History 12-year-old healthy male presents for evaluation of progressive left lateral ankle pain for 3 weeks. Denies recent injury, trauma, change in activity, prior history

of similar pain, radicular pain, weakness/sensory symptoms. Pain present at rest and at night. Increases with walking and twisting activities. Mild improvement with ice, Tylenol, ibuprofen, compression wrap.

Physical examination Gait: Non-antalgic gait with normal cadence and stride. Strength: Bilateral lower extremity strength intact. Inspection/palpation: Significant focal edema noted at the left distal fibula which is tender to palpation correlating with area of most significant pain. Range of motion: Within functional limits. Sensation: Normal. Provocative maneuvers: Mild tenderness in the area of the left anterior talofibular ligament. Bilateral ankle drawer test, squeeze test, external rotation stress tests are negative/unremarkable.

Differential Diagnosis Osteoid osteoma, Intracortical hemangioma, Nonossifying fibroma, Distal fibula physeal injury, Chondromyxoid fibroma, Ewing sarcoma, Langerhans cell histiocytoma, Osteosarcoma, Stress fracture

Tests and results: Initial plain films Focal lucency in distal left fibular metaphysis abutting the physis. Periosteal reaction and overlying soft tissue swelling.

MRI Oval well-circumscribed area in distal left fibular metaphysis crossing the physis with surrounding bone marrow edema and periosteal reaction. No evidence of abscess.

Final working diagnosis Suspected Brodie's abscess

Treatment and Outcomes Orthopedics service was consulted and patient underwent debridement of left ankle and curettage of the distal fibula. Admitted overnight for administration of IV vancomycin and cefazolin. Infectious disease service was consulted. He was discharged with one month of oral antibiotics (cefadroxil) following operation. Cultures from tissue taken remained negative. However, the patient did have a positive nares MSSA swab. He was able to return to activity and he recovered well, without significant events or issues.

B-53 Clinical Case Slide - Oncology I

Wednesday, May 27, 2020, 3:15 PM - 4:35 PM

A 26 Year Old Pregnant Woman With Growing Wrist Pain

Keyur Desai, University of Chicago (NorthShore), Glenview, IL. (Sponsor: Carrie A. Jaworski, FACS) Email: KeyurD@gmail.com

(No relevant relationships reported)

HISTORY: A 26 year old G1P1001 right-hand dominant woman presents 4 weeks after delivery for insidious onset right ulnar-sided wrist pain. Pain was initially present 6 months prior to visit during pregnancy. Her symptoms were initially intermittent but eventually progressed to constant pain. Pain is localized to the distal ulna without radiation. Patient endorses swelling. Patient has no previous history of wrist and hand pain or injury. Patient denies any mechanism of injury or trauma. Patient denies numbness and tingling.

PHYSICAL EXAMINATION: Vital signs: 133/77, HR79, T 97.5degF, 1.68m, 75.3kg, BMI 26.62

Inspection: Right wrist swollen medially

Palpation: Tender over volar aspect of distal ulna

Range of motion: Full AROM of wrist flexion, extension, supination, pronation, ulnar deviation, radial deviation. Pain with resisted flexion, end-range supination and pronation, and with ulnar deviation.

Strength testing: Strength 5/5 of wrist flexors, extensors, supination, pronation.

Special testing: Sensation preserved over C5-T1 dermatomes. Negative Tinel's. Negative Phalen's.

DIFFERENTIAL DIAGNOSIS:

1. ECU Tendonitis
2. TFCC Tear

3. DRUJ Instability
4. Ulnocarpal arthritis or abutment syndrome
5. Giant cell tumor
6. Chondrosarcoma
7. Bone cyst

TEST AND RESULTS: Right wrist X-ray:

Expansile lucent septated bony lesion in the distal ulna. The findings may reflect an aneurysmal bone cyst.

Right wrist MRI:

Expansile, enhancing, solid lesion within the distal ulna extending to the subarticular bone surface, with appearance most suggestive of giant cell tumor. Less likely considerations include chondroid lesions such as chondromyxoid fibroma or a clear cell/low-grade chondrosarcoma. Consider bone biopsy or surveillance follow-up imaging. **FINAL WORKING DIAGNOSIS:** Distal right ulna giant cell tumor. **TREATMENT AND OUTCOMES:** 1. Patient was referred to orthopedic oncology. 2. Patient underwent biopsy with curettage and allograft of distal right ulna. 3. Frozen specimens during procedure confirmed giant cell tumor. 4. Patient has followed up with orthopedic oncology with good improvement in pain and return of function.

848 May 27 3:35 PM - 3:55 PM

Toe Pain - Softball

Miguel Lopez, Angel Lazu, Peter Seidenberg, FACSM. *Penn State University, State College, PA.* (Sponsor: Peter Seidenberg, FACSM)

(No relevant relationships reported)

HISTORY: An 18-year-old collegiate softball player started noticing right great toe pain in March of her freshman season. Pain was unrelenting throughout the day but temporarily responded to anti-inflammatories. She denied fevers, chills, night sweats, or unexpected weight loss. She did not report her pain to the team physician. However, after seeing an outside physician for continued pain, she was placed in a walking boot and provided a bone stimulator. After an additional three weeks of pain despite these therapies, she presented to the training room for re-evaluation of her toe. **PHYSICAL EXAMINATION:** Examination revealed exquisite tenderness to palpation of the dorsal-fibular aspect of the proximal portion of the distal phalanx of the right first toe, with mild swelling but no plantar tenderness. There was full passive and active range of motion of the MTP and IP joints. Skin of the right foot was intact, without erythema or induration. Tendon function was intact. The foot was neurovascularly intact. **DIFFERENTIAL DIAGNOSIS:** 1. Stress Reaction of right first toe distal phalanx 2. Subacute/Chronic Osteomyelitis 3. Bony Tumor **TEST AND RESULTS:** Right toe AP, lateral, and oblique radiographs- bony alignment is unremarkable, no acute fracture; joint spaces well preserved. MRI of right foot without contrast - diffuse marrow edema throughout the first distal phalanx; no corresponding focal signal hyperintensity in the distal phalanx. Nuclear medicine bone marrow imaging - mild increased radiotracer uptake in the region of the distal first phalanx suggesting increased regional blood flow. The above studies were reviewed by the team physicians and there was a concern for bony mass of the proximal portion of the dorsal fibular distal phalanx. MRI with contrast confirmed this suspicion. CT right foot without contrast with 3D reconstruction - ill-defined sclerosis in the medial aspect of the base of the first distal phalanx measuring 7 mm x 4 mm x 5 mm with faint lucency proximal to the sclerosis. **FINAL WORKING DIAGNOSIS:** Osteoid Osteoma **TREATMENT AND OUTCOMES:** 1. Continued anti-inflammatories with COX2 inhibitors for symptomatic treatment. 2. Surgical curettage and excisional biopsy of the 7 mm x 4 mm x 5 mm nidus; deferment of radiofrequency ablation due to proximity to the joint. 3. Anticipated return to play in 4-6 weeks.

849 May 27 3:55 PM - 4:15 PM

New Mole In A College Football Athlete

Kathleen Roberts, Robert Hosey, FACSM, Kyle Smoot. *University of Kentucky, Lexington, KY.* (Sponsor: Robert Hosey, FACSM)

Email: karoberts6@gmail.com

(No relevant relationships reported)

Skin Cancer – Football

History: A 19-year-old male college sophomore football defensive lineman noted a pigmented lesion on the sole of his right foot with the appearance of a blood blister at the end of his freshman year. Over the next weeks to months the lesion grew in size and also became painful with activity. Because the pain was limiting him with football activity he presented to be seen by a dermatologist.

Physical exam: Right foot without soft tissue swelling, area on the plantar surface of the first metatarsal approximately 1.5cm in size with dark coloration, black in appearance, negative signs of infection. Tender to palpation over this area. Range of motion intact at the first metatarsal in flexion and extension without pain. Plantar and dorsiflexion, inversion and eversion intact at the ankle. Pain with ambulation when weight bearing on the area. Sensation intact to light touch. Dorsalis pedis pulse 2+.

Differential Diagnosis:

1. Dysplastic Nevus
2. Melanoma
3. Benign Nevus

Test and Results:

Shave biopsy of the right plantar forefoot overlying the first metatarsal:

- Malignant Melanoma in situ, the deep biopsy margin being free in the tissue planes examined. Lesion involves the peripheral biopsy margin.

Lesion Excision

- Malignant melanoma, 3.3mm

Final/Working Diagnosis:

Acral Lentiginous Melanoma

Treatment and Outcomes:

1. Patient underwent resection of the right foot melanoma in situ with a total defect of 2x2cm, with subsequent adjacent tissue transfer 5x3cm.
2. Sentinel node sampling performed which identified microscopic foci of melanoma in both sentinel nodes resulting in Stage IIIB (T3a, N2a), genetic testing performed showing BRAF negative.
3. PET scan performed showing no evidence of residual disease or metastatic focus.
4. Started on Nivolumab 480mg IV monthly for 13 doses.
5. Patient able to return to football competition in the middle of November, competing in the last few games of his sophomore season.

850 May 27 4:15 PM - 4:35 PM

Atraumatic Knee Swelling - Runner

Bernadette Pendergraph, Bret Namihas, Jason Alvarado. *Harbor-UCLA, Harbor City, CA.*

Email: bpendergraph@lundquist.org

(No relevant relationships reported)

HISTORY: 38-year-old male runner with 4 months of left knee pain and swelling that he noticed worsened with running. He remembers no particular injury, increase in mileage, change in footwear, or systemic symptoms such as night sweats, weight loss, or other joint swelling. He was seen in urgent care with his exam showing an effusion and painful range of motion. He was diagnosed with a knee sprain, MRI ordered, and referred to sports medicine. In our clinic, he complained about anterolateral knee pain, persistent knee effusion, and inability to train because of pain and swelling. He denied locking or giving way.

PHYSICAL EXAMINATION: Left knee with 1-2+ non-warm effusion, range of motion 0-130 degrees, lateral patellar facet tenderness, medial joint line tenderness, Lachman negative, valgus/varus testing stable, McMurray negative for click.

DIFFERENTIAL DIAGNOSIS: 1. Medial meniscal tear 2. Patellar chondromalacia 3. Rheumatologic disorder 4. Pigmented nodular synovitis 5. Synovial chondromatosis

TEST AND RESULTS: X-ray: small joint effusion MRI without contrast:

large joint effusion, small medial meniscal tear, lateral patellar facet chondromalacia Arthrocentesis: 303,500 RBCs, 839 WBCs, no crystals; ESR 10, CRP 0.08, ANA negative, RF negative, Normal CBC; MRI with contrast: multiple round lesions on the medial posterior mid joint next to the proximal tibiofibular joint with peripheral enhancement consistent with pigmented villonodular synovitis vs infection

FINAL WORKING DIAGNOSIS: 1. Pigmented villonodular synovitis 2. Medial meniscal tear 3. Patellar chondromalacia

TREATMENT AND OUTCOMES: 1. Athlete was initially treated with physical therapy for the atraumatic meniscal tear. 2. Athlete had persistent effusion, with an aspiration that showed blood. This provoked review of prior MRI with concern of nodularity of synovium. Therefore an MRI with contrast was performed consistent with likely pigmented nodular synovitis. 3. Athlete evaluated by orthopedics for arthroscopy and synovial biopsy. Intraoperative findings included diffuse involvement of joint including anterior compartment, medial and lateral gutters, and the notch. Pathology consistent with pigmented villonodular synovitis. 4. Post op care complicated by poor progression of range of motion, current 10 to 70 degrees.

B-54 Rapid Fire Platform - Oxygen Uptake Kinetics

Residual Fatigue Does Not Affect Critical Power And W' Using A Single-visit Protocol

Christoph Triska¹, Astrid Reif¹, Barbara Wessner¹, Harald Tschan¹, James Hopker², Bettina Karsten³. ¹University of Vienna, Vienna, Austria. ²University of Kent, Kent, United Kingdom. ³LUNEX International University of Health, Exercise and Sports, Differdange, Luxembourg. (Sponsor: Prof. Dr. Juergen Scharhag, FACSM)
Email: christoph.triska@univie.ac.at
(No relevant relationships reported)

Traditionally, determining critical power (CP) and its related work above CP (W') requires exhaustive constant-power trials interspersed by at least 24 h rest. During the last decade several approaches were undertaken to make the protocol less time consuming and to use self-paced ecological time-trials (TT). However, it is debatable whether residual fatigue induced by a single-visit protocol might affect CP and/or W' . Parameters of oxygen uptake ($\dot{V}O_2$) kinetics and muscle deoxygenation can be suggested as suitable to assess the effects of residual fatigue. **PURPOSE:** Assessing fatigue-related parameters of $\dot{V}O_2$ kinetics and muscle deoxygenation between a single-visit and a multi-visit protocol. **METHODS:** Nine well-trained male triathletes (mean \pm SD; age: 27.7 \pm 4.3 yrs; body mass: 75.6 \pm 5.6 kg; $\dot{V}O_{2peak}$: 60.0 \pm 6.5 mL/min/kg) participated. Athletes had to perform a single-visit (2, 5 and 10 min TT, interspersed by 30 min passive rest) as well as a multi-visit determination of CP and W' (2, 5 and 10 min TT, interspersed by at least 24 h rest). During all tests, heart rate (HR) was recorded continuously, respiratory gases were measured breath-by-breath and deoxygenation was recorded at 10 Hz using near infrared spectroscopy (NIRS). The following parameters were assessed: maximal HR, $\dot{V}O_2$ during the first 2 min ($\dot{V}O_{2onset}$), mean response time (MRT), end-exercise $\dot{V}O_2$ ($\dot{V}O_{2peak}$), $\dot{V}O_2$ amplitude ($\text{ampl}\dot{V}O_2$), O_2 deficit, NIRS τ , amplitude (ampl_{NIRS}), and time-delay (TD). To compare the two protocols a paired sample t-test was used to assess the differences in CP and W' and a two-way ANOVA to assess the differences between trials and/or groups as well as and trials \times groups interactions.

RESULTS: No significant differences were found for CP or W' between protocols ($p > 0.05$). Significant main effects between trials were found for HR, $\dot{V}O_{2onset}$, $\text{ampl}\dot{V}O_2$, τ and ampl_{NIRS} ($p < 0.001$), but not for MRT, $\dot{V}O_{2peak}$, O_2 deficit and TD ($p > 0.05$). A post-hoc analysis of main effects did not reveal significant differences between corresponding trials ($p > 0.05$).

CONCLUSIONS: Due to non-significant differences in fatigue-related parameters results indicate that the determination of CP and W' using a single-visit protocol is not affected by residual fatigue. Consequently, the single-visit TT approach is a valid method to accurately determine CP and W' .

Influence Of Body Position On Pulmonary Oxygen Uptake And Muscle Deoxygenation Kinetics During Cycle Exercise

Richie P. Goulding¹, Dai Okushima², Simon Marwood³, Tze-Tuan Lei⁴, Narihiko Kondo⁴, David Poole, FACSM⁵, Thomas J. Barstow, FACSM⁵, Shunsaku Koga¹. ¹Kobe Design University, Kobe, Japan. ²Osaka International University, Osaka, Japan. ³Liverpool Hope University, Liverpool, United Kingdom. ⁴Kobe University, Kobe, Japan. ⁵Kansas State University, Kansas, KS.
Email: gouldingrichie@gmail.com
(No relevant relationships reported)

Whether pulmonary oxygen uptake ($\dot{V}O_2$) kinetics are limited by O_2 delivery remains contentious. Previous studies have demonstrated that the time constant of pulmonary $\dot{V}O_2$ kinetics ($\tau_{\dot{V}O_2}$) is greater during supine compared to upright cycle exercise, presumably reflecting the superimposition of an O_2 availability limitation. However, interpretation of these studies is compromised by their use of superficial single-site measurements using continuous-wave near-infrared spectroscopy (NIRS), which is unable to determine absolute [heme]. **PURPOSE:** To determine the impact of body position (i.e. upright [U] vs. supine [S]) on the kinetics of pulmonary $\dot{V}O_2$, as well as muscle deoxygenation (deoxy[heme]) kinetics and total[heme] using time-resolved

(TR-)NIRS. **METHODS:** 7 healthy men completed an incremental ramp test to determine $\dot{V}O_{2max}$ and the gas exchange threshold in the supine position. 4 visits followed whereby pulmonary $\dot{V}O_2$ and deoxy[heme] kinetics and total[heme] were determined via TR-NIRS at three muscle sites (deep [VLD] and superficial [VLS] vastus lateralis and superficial rectus femoris [RFs]) in two conditions: 1) during S heavy intensity constant work rate exercise at 40% Δ (between ventilatory threshold and $\dot{V}O_{2max}$); and 2) during U exercise at the same absolute work rate. **RESULTS:** $\tau_{\dot{V}O_2}$ was increased during S compared to U (S: 42 \pm 12 vs. U: 32 \pm 9 s, $P = 0.03$). The fundamental phase deoxy[heme] was greater (i.e. slower) in S compared to U for each muscle site (VLD S: 19 \pm 10 vs. U: 8 \pm 5 s; VLS S: 16 \pm 7 vs. U: 10 \pm 3 s; RFs S: 20 \pm 7 vs. U: 11 \pm 3 s, $P = 0.002$) and its amplitude was greater in S compared to U for RFs only (S: 27.4 \pm 12.1 vs. U: 9.1 \pm 2.5 μ M, $P = 0.008$). Total[heme] did not differ between U and S for any muscle site (all $P > 0.05$). **CONCLUSION:** The slowing of pulmonary $\dot{V}O_2$ kinetics for S versus U occurs concomitant with a depressed rate of muscle(s) deoxygenation. This finding suggests that supine exercise results in a relatively greater fall in muscle $\dot{V}O_2$ when compared to O_2 delivery kinetics at least for VLD and VLS. The increased amplitude of deoxy[heme] in S for RFs suggests an increase in O_2 extraction to compensate for impaired muscle perfusion in S compared to U.

854 May 27 3:35 PM - 3:45 PM
Skeletal Muscle Endurance And Oxygen Uptake Kinetics During Cycling In Patients With High Affinity Hemoglobin

Chad C. Wiggins¹, Paolo B. Dominelli², Jonathon W. Senefeld¹, John R.A. Shepherd¹, Sarah E. Baker¹, Koji Uchida¹, Michael J. Joyner, FACSM¹. ¹Mayo Clinic, Rochester, MN. ²University of Waterloo, Waterloo, ON, Canada. (Sponsor: Michael J. Joyner, FACSM)
Email: wiggins.chad@mayo.edu
(No relevant relationships reported)

Skeletal muscle oxygen (O_2) consumption is linked to the metabolic demand of the exercising skeletal muscle. In hypoxic conditions (e.g. high altitude) O_2 consumption may be the limiting factor of exercise tolerance. Patients with increased O_2 content, secondary to an increased oxygen affinity (HAH), provide an experiment of nature to investigate the effects of increased flux through the O_2 transport pathway on exercise tolerance. **PURPOSE:** To determine the effect of HAH on O_2 uptake kinetics and exercise tolerance during high-intensity exercise under normoxia (NORM) and hypoxia (HYP) conditions. **METHODS:** Five healthy controls (CTL); 4 men, 41 \pm 8 years, $P_{50} = 27 \pm 1$ mmHg; Hemoglobin concentration ([Hb]) = 14.2 \pm 1.3 g \cdot dL⁻¹; hematocrit (Hct) = 43 \pm 4% and five patients with high-affinity hemoglobin (HAH); 3 men, 37 \pm 12 years, $P_{50} = 15 \pm 2$ mmHg; [Hb]: 19.8 \pm 2.3 g \cdot dL⁻¹, Hct = 59 \pm 7% cycled during unloaded pedaling then at a power output that elicited 85% $\dot{V}O_{2max}$ until volitional exhaustion during two different environmental conditions: 1) NORM, ($F_{iO_2} = 0.21$), and 2) HYP, ($F_{iO_2} = 0.15$). O_2 uptake kinetics were modeled as a double-exponential rise to maximum from continuous measurements of inspired/expired gases. Two-way ANOVA with group (HAH, CTL) and inspire (NORM, HYP) as between-subjects factors were used to compare dependent variables. **RESULTS:** HAH patients had marked polycythemia (higher [Hb] and Hct, $P < 0.05$ for both). There was no effect of inspire on any of the parameters of O_2 kinetics, all $P > 0.175$). There was no main effect of group or inspire on $\dot{V}O_2$ during unloaded pedaling (A_p , $P > 0.24$), $\dot{V}O_2$ of the primary component (A_1 , $P > 0.13$), or the $\dot{V}O_2$ slow component ($P > 0.10$). HAH exhibited a trend towards slower O_2 kinetics (HAH = 64.3 \pm 17.7 s vs. CTL = 49.2 \pm 17.0 s, $P = 0.08$) and significantly lower primary component amplitude (HAH = 1.14 \pm 0.66 L \cdot min⁻¹ vs. CTL = 1.92 \pm 0.67 L \cdot min⁻¹, $P = 0.02$). There was a trend towards reduced time-to-exhaustion in HYP ($P = 0.09$), but no main effect of group ($P = 0.21$). **CONCLUSION:** Patients with HAH had slower and blunted $\dot{V}O_2$ kinetics, which may be due to 1) blunted O_2 off-loading to the contracting skeletal muscle or 2) adaptations of skeletal muscle (e.g. myosin heavy chain expression) to HAH.

855 May 27 3:45 PM - 3:55 PM

Influence Of Priming Exercise On Muscle Deoxygenation Kinetics During Upright And Supine Cycle Exercise

Shunsaku Koga¹, Dai Okushima², Simon Marwood³, Tze-Tuan Lei⁴, Narihiko Kondo⁴, David C. Poole, FACSM⁵, Thomas J. Barstow, FACSM², Goulding P. Richie¹. ¹Kobe Design University, Kobe, Japan. ²Osaka International University, Osaka, Japan. ³Liverpool Hope University, Liverpool, United Kingdom. ⁴Kobe University, Kobe, Japan. ⁵Kansas State University, Kansas, KS.
Email: gouldingrichie@gmail.com
(No relevant relationships reported)

A bout of prior heavy "priming" exercise typically reduces the time constant of fundamental phase oxygen uptake (VO_2) kinetics (τ_{VO_2}) in the supine position, an effect that is generally absent during upright exercise. This priming-induced speeding of pulmonary VO_2 kinetics has been attributed to increased muscle oxygenation at the onset of the second bout. However, the extent to which priming-induced improvements in muscle oxy/deoxygenation status differ across distinct muscle regions, as well as between deep vs. superficial muscle and with respect to body position, remains unknown. **PURPOSE:** To examine the impact of priming exercise on pulmonary VO_2 and muscle deoxygenation kinetics at three muscle sites (superficial rectus femoris [RFs], deep [VLd] and superficial [VLs] vastus lateralis) using time-resolved near-infrared spectroscopy during upright (U) and supine (S) exercise. **METHODS:** 7 healthy men completed an incremental ramp test to determine VO_2 max and the gas exchange threshold in S. 4 visits followed whereby participants performed two 6-min bouts of heavy exercise separated by 6-min unloaded pedalling in two conditions: 1) during constant power exercise at 40% Δ in S; and 2) during exercise at the same absolute work rate in U. Pulmonary VO_2 and muscle deoxy[heme] kinetics were determined during each test. **RESULTS:** τ_{VO_2} was reduced in bout 2 in S (bout 1: 42 \pm 12 vs. bout 2: 31 \pm 7 s, $P = 0.016$) but not in U (bout 1: 32 \pm 9 vs. bout 2: 28 \pm 5 s, $P = 0.32$). The fundamental phase tdeoxy[heme] was greater in bout 2 for RFs in both postures (S, bout 1: 20 \pm 7 vs. bout 2: 31 \pm 18 s; U, 1: 11 \pm 3 vs. bout 2: 23 \pm 9 s, $P = 0.021$), whereas it was increased in bout 2 for VLs during U only (bout 1: 10 \pm 3 vs. bout 2: 15 \pm 4 s, $P = 0.028$). The fundamental phase muscle deoxy[heme] amplitude was greater in bout 2 for RFs ($P = 0.001$) and VLs ($P = 0.024$) in both U and S. Both the fundamental phase tdeoxy[heme] and amplitude did not differ between bouts 1 and 2 for VLd in either position (both $P > 0.05$). **CONCLUSION:** Prior heavy exercise reduced τ_{VO_2} in S but not U. This was accompanied by a greater amplitude and slower rate of muscle deoxygenation in superficial but not deep muscle. The contrasting responses of deep and superficial muscle to priming exercise in both U and S suggests that these muscles rely on fundamentally different O_2 transport strategies.

Contrasting Patterns Of Respiratory And Locomotor Muscle Deoxygenation And Total Hemoglobin During Incremental Ramp Cycling

Dai Okushima¹, T. Scott Bowen², Thomas J. Barstow, FACSM³, David C. Poole, FACSM³, Harry B. Rossiter, FACSM⁴, Narihiko Kondo⁵, Shunsaku Koga⁶. ¹Osaka International University, Moriguchi, Japan. ²University of Leeds, Leeds, United Kingdom. ³Kansas State University, Manhattan, KS. ⁴The Lundquist Institute for Biomedical Innovation at Harbor-UCLA Medical Center, Torrance, CA. ⁵Kobe University, Kobe, Japan. ⁶Kobe Design University, Kobe, Japan.
Email: okushima@oiu.jp
(No relevant relationships reported)

Respiratory muscle demands during severe intensity exercise may constrain the blood flow increase to locomotory muscles, thereby limiting exercise tolerance. Muscle mitochondrial O_2 delivery depends on both perfusive and diffusive O_2 transport, the former reflecting the O_2 delivery-utilization balance and the latter exercise-induced changes in muscle total hemoglobin (THb). Resolution of changes in deoxygenation and THb simultaneously within these two muscle groups will provide novel insights into vascular and metabolic control. **PURPOSE:** We investigated absolute deoxygenated [Hb+Mb] (HHb, index of fractional O_2 extraction) and THb responses in respiratory and locomotor muscle using time-resolved near-infrared spectroscopy (TR-NIRS). **METHODS:** Ten males performed ramp incremental cycling (20 W \cdot min⁻¹) to exhaustion while measuring pulmonary VO_2 , HHb and THb (9-10th intercostal space for intercostal muscle and diaphragm, IC-DP, and vastus lateralis, VL). HHb and THb were corrected for adipose tissue thickness (ATT) at each optode site, using the THb-ATT regression. **RESULTS:** HHb increased systematically with power output (PO) in VL and plateaued above ~80% PO_{max} (Figure 1A). In contrast, HHb in IC-DP was unchanged from rest. THb in VL increased modestly and plateaued above ~50% PO_{max} ,

whereas THb in IC-DP declined gently from rest such that THb was greater in VL than IC-DP from 30 to 100 % PO_{max} (Figure 1B). **CONCLUSIONS:** These disparate HHb and THb profiles imply a muscle-specific regulation of perfusive and diffusive O_2 fluxes for respiratory versus locomotory muscle(s). Supported by JSPS-17J09854, 18K17875

Beneficial Effects Of Exposure To Mild Hyperbaric Oxygen On Microcirculation In Peripheral Tissues

Badur un Nisa¹, Hiroyo Kondo², Akihiko Ishihara³, Fujino Hidemi¹. ¹Kobe University, Kobe, Japan. ²Nagoya Women's University, Nagoya, Japan. ³Kyoto University, Kyoto, Japan.
Email: badurunnisa@yahoo.com
(No relevant relationships reported)

The intent of exposure to mild hyperbaric oxygen (mHBO) is to increase the oxygenation of a person's blood by forcing additional oxygen to dissolve into the blood plasma. There is a lack of substantial evidence regarding responses of exposure to mHBO on microcirculation in peripheral tissues, and this research will provide insight into it. **Purpose:** To determine the beneficial effects of exposure to mHBO on microcirculation in peripheral tissues. **Methods:** In this experimental study 15 healthy individuals were exposed to both normobaric (1.00 ATA with 20.9% oxygen) and mHBO (1.4 ATA, Oxygen Concentration 30.8% - 39.5%) in a mild hyperbaric oxygen chamber for 70 minutes in each condition. Peripheral capillary oxygen saturation (SpO_2) and blood flow in capillaries of muscles and skin were measured every 15 minutes during both exposures in the supine position. Repeated measures ANOVA and paired t-test were used for statistical comparisons. An analysis with a p-value < 0.05 was considered significant. **Results:** The mean age of participants was 24.6 \pm 4.9 years and mean BMI was 20.5 \pm 2.7. Average blood flow in capillaries was increased from 94 $\mu\text{m/s}$ to 105 $\mu\text{m/s}$ after exposure to normobaric condition whereas average blood flow was increased from 92 $\mu\text{m/s}$ to 126 $\mu\text{m/s}$ after exposure to mHBO. We found a significant effect of conditions ($p < .008$), time ($p < .001$) as well as interactional effect ($p < .001$). SpO_2 was increased from 97.6% to 99.5% after exposure to mHBO and it was unchanged after exposure to the normobaric condition. We found a significant effect of conditions ($p < .001$), time ($p < .001$) as well as interactional effect ($p < .001$). **Conclusion:** The results of this study confirm that exposure to mHBO increases oxygen saturation and blood flow in the capillaries of peripheral tissues.

Strengthening Knee Extensor Muscles In Healthy Individuals: Single-joint Or Multi-joint Exercises?

Steven Jeffery O'Bryan¹, David Michel Rouffet². ¹Victoria University, Footscray, Australia. ²University of Louisville, Louisville, KY.
Email: steven.obryan@vu.edu.au
(No relevant relationships reported)

Introduction

Increases in muscle strength from resistance training are maximized when the spatiotemporal recruitment of the muscle is full and the peripheral perturbation is high.

During maximal single-joint knee extension and multi-joint leg extension movements, activation of the *vastii* knee extensor muscles is similar, however, little is known of the magnitude and etiology of fatigue development when these movements are repeated.

Purpose

To compare the magnitude and etiology of fatigue in the *vastii* knee extensor muscles following repeated maximal contractions performed through single-joint (knee extension) or multi-joint (leg extension) exercises.

Method

On separate days, 16 participants completed 60 maximal unilateral: i) knee extensions on a dynamometer (K_{EXT}) or ii) leg extensions on a cycle ergometer (L_{EXT}). Knee range of motion ($\sim 120^\circ - 30^\circ$ flexion) and angular velocity ($\sim 80^\circ \cdot s^{-1}$) were matched. Maximal torque, *vastii* muscle EMG and M-wave amplitude (M_{max}) were calculated during the first and last three contractions of both exercises. Knee extensor isometric maximal voluntary force (IMVF), voluntary activation (VA) and resting twitch force ($RT_{10:100\text{ Hz}}$) were measured pre-exercise and 40-s post-exercise.

Results:

Similar torque (K_{EXT} : 152 ± 33 N·m vs. L_{EXT} : 165 ± 30 N·m, $P > 0.05$), EMG (K_{EXT} : $95 \pm 6\%$ vs. L_{EXT} : $96 \pm 8\%$, $P > 0.05$) and M_{max} (K_{EXT} : $95 \pm 5\%$ vs. L_{EXT} : $97 \pm 5\%$, $P > 0.05$) were measured at the start of the exercises. Larger reductions in torque (K_{EXT} : $-60 \pm 10\%$ vs. L_{EXT} : $-38 \pm 14\%$) and EMG (K_{EXT} : $-21 \pm 16\%$ vs. L_{EXT} : $-13 \pm 16\%$) were seen for K_{EXT} during the final part of the exercise ($P \leq 0.05$), whereas no differences were reported in M_{max} ($P > 0.05$). Larger reductions in VA were seen after K_{EXT} whereas greater reductions in $RT_{10:100\text{ Hz}}$ were seen after L_{EXT} (both $P \leq 0.05$). Ultimately, similar reductions in IMVF were seen following K_{EXT} ($-32 \pm 10\%$) and L_{EXT} ($-35 \pm 13\%$) ($P > 0.05$).

Conclusion:

A lower-limb resistance training program which adopts multi-joint exercises may induce superior strength gains in *vastii* knee extensor muscles compared to single-joint exercises, as it is possible to induce larger levels of peripheral fatigue with a smaller reduction in voluntary activation.

876 Board #2 May 27 1:30 PM - 3:00 PM Neural And Muscular Responses To Maximal Strength Training

(No relevant relationships reported)

PURPOSE: Maximal strength training (MST), performed with heavy loads ($\sim 90\%$ of one repetition maximum; 1RM) and few repetitions (4-5), yields large improvements in efferent neural drive and skeletal muscle force generating capacity. However, it is elusive how MST-induced neural adaptations may translate to muscular factors regulating excitation-contraction coupling. **METHODS:** Sixteen healthy young males (24 ± 4 years) were randomized to MST 3 times per week for 8 weeks ($n=8$), or a control group (CG; $n=8$). Measurements were taken of 1RM and rate of force development (RFD), and evoked potentials recordings (V-wave and H-reflex normalized to M-wave (M) in musculus soleus) applied to assess efferent neural drive to maximally contracting skeletal muscle. Biopsies were obtained from m. vastus lateralis and analyzed by western blot and mRNA isolation to investigate the protein expression of Sarcoplasmic Reticulum Ca^{2+} ATPase (SERCA) and mRNA expression of SERCA1 and SERCA2, myostatin, MuRF1 and Ryanodine receptor (RyR1). **RESULTS:** 1RM ($17 \pm 9\%$; $p < 0.05$) and early (0-100ms), late (100-200ms) and maximal RFD increased ($31-53\%$; $p < 0.01$) in the MST group, accompanied by increased maximal V-M wave ratio ($9 \pm 14\%$; $p < 0.05$), with no change in H-reflex to M-wave ratio. No changes were observed in the CG. No pre- to post-training differences were found in mRNA or protein expressions in either group ($p > 0.05$). **CONCLUSION:** MST increased efferent neural drive to maximally contracting skeletal muscle, and resulted in improved force generating capacity. The neural adaptations were not reflected in key muscular factors involved in excitation-contraction coupling, indicating that responses to high intensity strength training may predominantly be governed by neural adaptations.

877 Board #3 May 27 1:30 PM - 3:00 PM Ten Weeks Of Resistance Training Increased Total Hemoglobin Mass Without Increasing Maximal Oxygen Uptake

jun wang, Beijing Sport University, Beijing, China.

Email: wj430079@126.com

(No relevant relationships reported)

PURPOSE: Resistance training increases muscles mass whereas maximal oxygen uptake remains normally unchanged. The purpose of the present study was to investigate the effect of 10 weeks resistance training on total hemoglobin mass, lean mass and maximal oxygen uptake in young healthy males.

METHODS: Thirteen young male subjects (age: 22.2 ± 2.6 years; height: 177.7 ± 3.7 cm) completed 10 weeks of resistance training. The resistance training consisted of 5 weekly sessions of full body resistance training. The training program consisted of 13 exercises; for all exercises 3 sets with 12 repetitions were conducted. Each training session lasted 70-90 min. Body composition was measured with Dual-energy X-ray absorptiometry (DXA), total hemoglobin mass with CO rebreathing method, and maximal oxygen uptake was tested on treadmill.

RESULTS: Body mass did not increase significantly during the training intervention (before: 74.5 ± 7.9 ; after: 77.6 ± 6.2 kg; $p=0.30$), but fat free mass increased 8.8% ($p < 0.05$). Total hemoglobin mass (tHb) increased from 865.1 ± 70.6 to 981.2 ± 89.8 g ($p < 0.05$) during the training intervention and hematocrit was unchanged. Hemoglobin mass per kg body weight did not increase significantly (before: 11.0 ± 1.7 ; after: 13.4 ± 1.9 g/kg; $p=0.25$). Maximal oxygen was 3.32 ± 0.47 L/min before and 3.38 ± 0.52 L/min after the resistance training. Maximal oxygen uptake related to body weight did neither change during the training intervention (before: 44.4 ± 4.0 ; after 43.7 ± 5.9 ml \cdot kg $^{-1} \cdot$ min $^{-1}$).

CONCLUSIONS: Whole body resistance training for ten weeks increased fat free mass and tHb, but VO_{2max} did not increase. These data show that increased total hemoglobin mass is not sufficient to increase maximal oxygen uptake in young healthy males.

878 Board #4 May 27 1:30 PM - 3:00 PM Variation Of Resistance Exercise Intensity Versus Resistance Exercise Selection: The Effects On Strength And Power

Jonathan Hummel, East Stroudsburg University, East Stroudsburg, PA. (Sponsor: Shala Davis, FACSM)

(No relevant relationships reported)

Variation of resistance exercise intensity versus resistance exercise selection: the effects on strength and power

Jonathan W. Hummel, Gavin L. Moir, Matthew R. Miltenberger, Shawn N. Munford. East Stroudsburg University, East Stroudsburg, PA.

Purpose: To compare the effects of exercise selection variations versus exercise intensity variations on absolute strength and power measures across a 4-week training block for in-season collegiate athletes. **Methods:** 14 Division II collegiate track and field athletes ($n=5$ females; $n=9$ males; age: 20.7 ± 1.4 yrs; primarily anaerobic based track and field events) participated in one of two 4 week periodized exercise programs: 1) manipulation of resistance training intensity (INT group), 2) manipulation of resistance training exercise selection (EXE group). Exercise selection was held constant in the INT group while the intensity was varied (85%-90%). The EXE group held intensity at a constant but varied the selection of exercises (e.g. pin squat, box squat). The mean intensity and working repetitions across the 4-week block of training were equated across the groups. Absolute strength was assessed with a 1-repetition maximum (1RM) back squat and power was assessed in a vertical jump. **Results:** Both INT (mean improvement: 3.52 kg, $p < 0.05$) and EXE (mean improvement: 3.08 kg, $p < 0.05$) increased 1RM across the training period, but there were no significant differences between the groups ($p > 0.05$). Both groups produced an increase in jump height (INT mean improvement: 0.04 m, $p < 0.05$; EXE mean improvement: 0.04 m, $p < 0.05$) with no significant differences between the groups ($p > 0.05$). **Conclusion:** Variation in training applied through the manipulation of exercise intensity was as effective as that applied through the manipulation of exercise selection for improving strength and power in collegiate track and field athletes during a 4-week block. Both variables are equally important when considering implementation into programming for athletic populations.

879 Board #5 May 27 1:30 PM - 3:00 PM Diurnal Sensitivity Of Muscle Force And Acceleration Parameters Of The Upper Limb

Marie R. Acosta, J. Mark VanNess, Alexia E. Amo, Courtney D. Jensen. University of The Pacific, Stockton, CA.

(No relevant relationships reported)

Novel technology permits more precise investigation of motor function. Limited data exist on diurnal variation in force and acceleration parameters of the upper limb. **PURPOSE:** To detect the optimal time of day for maximum power output and development rate in unilateral row and press motions. **METHODS:** We tested 112 physically active male and female subjects on Proteus (Proteus Motion, USA). In total, they performed 2,750 unilateral, isotonic sets, evenly divided between rows and presses. Loads were applied through three-dimensional magnetic resistance at 10lb (862 sets), 15lb (646 sets), 20lb (612 sets), and 25lb (630 sets). Testing was performed at various times over a 14-hour span (6:00am to 8:00pm). For each individual set, Proteus calculated average peak power of all repetitions (PP_{max}), highest power achieved during any single repetition (PP_{max}), average peak force development rate across all repetitions ($PFDR_{max}$), and the highest rate achieved during a single repetition ($PFDR_{max}$). Mixed model ANOVA with repeated measures tested the differences in these parameters between push and pull motions, loads applied, and

times of day. Linear regression models isolated the effect of time on performance holding other influential factors constant. RESULTS: Across all movements, loads, and times, PP_{mean} was 235.2 ± 114.1 w; PP_{max} was 254.1 ± 120.0 w; $PFDR_{mean}$ was $1,036.1 \pm 631.6$ w/s; and $PFDR_{max}$ was $1,243.4 \pm 789.6$ w/s. Differences in both PP_{mean} and PP_{max} were detected by time of day ($p < 0.001$) and load ($p < 0.001$). The highest values were achieved between 2:00pm and 4:00pm. Similar relationships were found with time of day in $PFDR_{mean}$ ($p < 0.001$) and $PFDR_{max}$ ($p < 0.001$). Holding constant the subject performing the set, arm dominance, exercise being performed, and the load applied, linear regression analyses found that if performance occurred between 2:00pm and 4:00pm, there was a 139.6 w/s increase in $PFDR_{mean}$ (95% CI: 75.5-203.6), 164.7 w/s increase in $PFDR_{max}$ (95% CI: 79.7-249.8), 29.6 w increase in PP_{mean} (95% CI: 20.7 \pm 38.5), and 33.6 w increase in PP_{max} (95% CI: 24.4 \pm 42.8). CONCLUSIONS: Success in many athletic contexts depends on expressions of power and the rate of its development. Our findings demonstrate diurnal rhythms in power parameters of the upper limb, with optimal performance occurring in the afternoon.

880 Board #6 May 27 1:30 PM - 3:00 PM
Assessing True Variability And Mean Changes To Two Distinct Resistance Training Protocols

Scott J. Dankel¹, Zachary Bell², Robert Spitz², Vickie Wong², Ricardo Viana², Raksha Chatakondi², Samuel Buckner³, Matthew Jesse², Kevin Mattocks⁴, Grant Mouser⁵, Takashi Abe², Jeremy Loenneke, FACSM². ¹Rowan University, Glassboro, NJ. ²The University of Mississippi, Oxford, MS. ³University of South Florida, Tampa, FL. ⁴Lindenwood University, Belleville, IL. ⁵Troy University, Troy, AL. (Sponsor: Jeremy Loenneke, FACSM)

(No relevant relationships reported)

Millions of dollars are spent analyzing inter-individual differences in response to resistance exercise, but the lack of a non-exercise control group makes it possible that these studies may simply be examining random error. Furthermore, it has been hypothesized that the magnitude of variability may differ depending upon the exercise protocol employed, but this yet to be appropriately tested.

PURPOSE: To determine differences in two distinct resistance training protocols and whether true variability could be detected after accounting for random error.

METHODS: Individuals (n=151) were randomly assigned to one of three groups: (1) a traditional exercise group performing four sets of elbow flexion exercise to failure; (2) a one-repetition maximum (1RM) performing a 1RM elbow flexion test; and (3) a time-matched non-exercise control group. Both exercise groups performed 18 sessions over six weeks. A Bayesian ANCOVA was used to test for mean changes across groups while adjusting for pre-values. To assess whether the variability in response to each exercise intervention differed from that of the control group, Bayesian Levene's tests were computed. Bayes Factors (BF_{10}) were used to quantify evidence for or against the null hypothesis.

RESULTS: Both 1RM (2.3kg; $BF_{10} = 4.791e+6$) and traditional training groups (2.4kg; $BF_{10} = 11,915$) increased 1RM strength similarly ($BF_{10} = 0.21$), but only the 1RM group increased untrained arm 1RM strength (1.5kg; $BF_{10} = 271$). Only the traditional exercise group increased ultrasound measured muscle thickness (~0.23 cm across all sites; all $BF_{10} \geq 224$). Across both training groups, the only differential responses were found in the change in 1RM strength of the trained arm in the traditional training group ($BF_{10} = 5.381$). This resulted in a true variability of 1.8 kg after the removal of random error.

CONCLUSION: These findings demonstrate the importance of taking into consideration the magnitude of random error when determining response heterogeneity, as many studies may be classifying individuals based on random error. Additionally, our mean results demonstrate that strength is largely driven by task specificity, and the cross-over effect of strength may be load dependent.

881 Board #7 May 27 1:30 PM - 3:00 PM
Progressive Movement Training: An Analysis Of Its Effects On Muscular Strength And Power Development

Orrin Whaley, Abigail Larson, Mark DeBeliso, FACSM. Southern Utah University, Cedar City, UT. (Sponsor: Mark DeBeliso, FACSM)

(No relevant relationships reported)

Muscular strength and power are important attributes in many sports, so research on resistance training (RT) methods that may improve these attributes are of great interest. One such RT method is Progressive Movement Training (PMT) which incorporates a partial range of movement (ROM) with a supramaximal load. **PURPOSE:** This study compared the effects of PMT and traditional full ROM RT on the 1-RM back squat (BSQ), vertical jump (VJ) height, and power output (PO). **METHODS:** High school male participants were randomly assigned to either a PMT RT group (n=21, age: 17.4 \pm 0.7 yrs, height: 174.9 \pm 5.8 cms, mass: 84.7 \pm 26.5 kgs) or a full ROM RT group (n=15, age: 17.3 \pm 0.7 yrs, height: 175.9 \pm 8.8 cms, mass: 82.1 \pm 14.9 kgs). The experimental groups then engaged in a 7-week intervention period using either the

PMT or full ROM BSQ modality in order to target lower body strength and power. The participant's body weight, 1-RM BSQ and VJ were measured prior to and upon completion of the intervention period. PO was calculated using the Lewis formula. No additional lower body auxiliary movements were performed in the study. Dependent t-tests (two-tailed) were used to compare the dependent variables (DVs) from pre to post RT intervention within experimental groups. Independent t-tests (two-tailed) were used to compare the gain scores for each of the DVs between experimental groups. **RESULTS:** The PMT group improved significantly from pre to post intervention period for all DVs: 1-RM BSQ (pre: 96.0 \pm 37.8, post: 110.6 \pm 37.0 kg), VJ (pre: 55.8 \pm 8.0, post: 59.4 \pm 9.5 cm) and PO (pre: 1365.8 \pm 410.7, post: 1417.2 \pm 394.7 W) ($p < 0.01$). The full ROM group improved significantly from pre to post intervention period for the 1-RM BSQ only (pre: 91.3 \pm 23.3, post: 102.3 \pm 19.4 kg) ($p < 0.01$), VJ (pre: 59.3 \pm 9.8, post: 60.7 \pm 10.6 cm) ($p > 0.05$) and PO (pre: 1359.3 \pm 203.9, post: 1397.1 \pm 221.8 W) ($p > 0.05$). When comparing gain scores between each group there were no significant differences between the PMT and full ROM groups for any of the DVs ($p > 0.05$). **CONCLUSION:** Within the parameters of this study, PMT is as effective and may be more effective than full ROM RT for increasing lower body strength and power.

Strength Adaptions And Body Composition Changes Following High Vs. Low Volume Resistance Training And Detraining

Simon Gavanda¹, Sascha Schrey¹, Julia Christine Eyre², Stephan Geisler¹. ¹IST University of Applied Sciences, Düsseldorf, Germany. ²German Sport University Cologne, Cologne, Germany.

Email: sgavanda@ist-hochschule.de

(No relevant relationships reported)

Resistance training (RT) is used for improving strength and body composition. However, it is still under debate whether higher RT volume (HV) is necessary in novices, or if lower volume (LV) is equally effective. In addition, effects of detraining (DTR) following HV and LV RT are not well understood.

PURPOSE:

To determine the effects of a 12-week HV program (3 sets, 10 repetitions) compared to LV RT (1 set, 10 repetitions) to concentric muscle failure on strength and body composition, followed by four weeks of DTR in male and female subjects.

METHODS:

Forty-two untrained subjects were randomly assigned to either LV (female n=10; male n=10; age 32.9 \pm 11.8y, height 174.2 \pm 8.4cm; weight 70.3 \pm 13.5kg) or HV RT (female n=11; male n=11; age 33.0 \pm 9.6y, height 174.2 \pm 11.2cm; weight 72.4 \pm 18.1 kg). RT consisted of two RT sessions per week (squat, bench press, arm and leg flexion and extension). Measurements were taken prior to and post RT, and after DTR. Body composition was assessed using BIA. Strength measurement (10-RM) was done using the aforementioned exercises. Six subjects were eliminated from the study due to various reasons, resulting in 36 subjects included for further analysis (HV female n=10, male n=8; LV female n=9, male n=9). Compliance was 100%. Comparisons were made using two-way ANOVA with repeated measures.

RESULTS:

Both groups increased strength through RT with no difference between groups (squat HV 61.1% vs. LV 59.0%, $p < 0.001$; bench press HV 28.9% vs. LV 31.3%, $p < 0.001$; leg extension HV 54.6% vs. LV 50.2%, $p < 0.001$; leg flexion HV 30.9% vs. LV 30.3%, $p < 0.001$; arm extension HV 51.0% vs. LV 44.8%, $p < 0.001$; arm flexion HV 36.9% vs. LV 31.7%, $p < 0.001$). Body mass ($p = 0.182$), fat mass ($p = 0.238$), and fat-free mass ($p = 1.000$) was unaltered by RT. After DTR strength in arm flexion ($p = 0.007$), arm extension ($p = 0.001$), bench press ($p < 0.001$), and squat ($p = 0.039$) decreased to the same extend in both groups. Leg flexion and extension strength was unaltered following DTR, while fat-free mass increased ($p = 0.004$).

CONCLUSION:

HV and LV RT was equally effective in untrained subjects to increase strength. Novices could therefore save time with LV, with similar results. Yet, RT alone was not sufficient to change body composition. Following DTR strength gains were still elevated but in some measurements slightly lower than post RT.

Effect Of Gender And Body Type On Strength Gain From Different Modes Of Resistance Training

Jerry L. Mayhew¹, William F. Brechue, FACSM², Monica L. Hunter¹, Jana L. Arabas¹, Liz Jorn¹, Bryann Mann³. ¹Truman State University, Kirksville, MO. ²A. T. Still University, Kirksville, MO. ³University of Miami, Miami, FL.

Email: jmayhew@truman.edu

(No relevant relationships reported)

The discussion of the influence of body type on potential to gain strength from resistance training (RT) is a relatively new field of investigation. What has not been

explored is the degree to which body type might impact the potential for strength gains between men and women. **PURPOSE:** To determine the influence of sex and body type on changes in upper-body strength resulting from free-weight RT in college men and women. **METHODS:** College men and women were measured for fat mass (FM) and fat-free mass (FFM) determined from gender-specific skinfold equations. Body type was determined by regressing FFM/Ht² on FM/Ht² for each sex and partitioned into thirds as slender (SL), average (AV), and solid (SO). Men and women were matched for body type: SL (men = 40, women = 50), AV (men = 62, women = 44), and SO (men = 60, women = 43). RM bench press was measured before and after 12 weeks of linear periodization free weight RT performed 3 times/week in 3 sets of 6 overall body exercises. **RESULTS:** Sex x body type ANOVA on absolute strength revealed significantly greater ($p < 0.001$) gains by men (6.8 ± 8.4 kg) than women (4.2 ± 3.0 kg) but no significant difference ($p = 0.15$) across body types (SL = 6.5 ± 8.9 , AV = 5.3 ± 5.9 , SO = 5.2 ± 5.4 kg). The sex x body type interaction was not significant ($p = 0.60$). Absolute strength gains were poorly correlated with initial strength ($r = 0.01$, $r = -0.10$, respectively) and body type ($r = 0.00$, $r = -0.11$, respectively) in men and women. Sex x body type ANOVA on relative strength gain indicated a significantly greater ($p = 0.04$) gain by women ($14.0 \pm 14.2\%$) than men ($10.6 \pm 12.6\%$) but no significant difference among body types (SL = $13.8 \pm 15.3\%$, AV = $11.9 \pm 14.2\%$, SO = $11.0 \pm 11.1\%$). The sex x body type interaction was not significant ($p = 0.38$). Relative strength gains were significantly correlated with initial strength in both men ($r = -0.27$) and women ($r = -0.34$) as well with body type ($r = 0.06$ and $r = -0.07$ respectively). **CONCLUSIONS:** When following the same RT program, men make a greater absolute gain but women make a greater relative gain in upper-body strength. Body type does not seem to influence the degree of absolute or relative strength gain in RT in either sex. Initial strength level has little influence on the amount of strength to be gained during short-term training.

Acute Response Of Blood Glucose After Two Resistance Training Protocols With Different Execution Velocities

Jhonatan C. Peña Ibagón¹, Cristian Yanez¹, Lorena Benavidez², Jose Garcia³, William Martin¹, Carlos Castillo¹. ¹Fundación universitaria del área andina, Bogotá, Colombia. ²Corporación universitaria Cenda, Bogotá, Colombia. ³Corporación Universitaria Cenda, Bogotá, Colombia.
 (No relevant relationships reported)

PURPOSE: Studies have demonstrated that a single session of resistance training (RT) can reduce glycemia in subjects with or without diabetes. The aim of this study was to compare the acute response of blood glucose after 2 resistance training protocols with different execution velocities in amateur weightlifting athletes. **METHODS:** A randomized clinical trial was conducted in 24 amateur weightlifting athletes (23.5 ± 6.2 years). The participants were randomized into 2 groups: high velocity (MV, $n = 12$) or low velocity (LV, $n = 12$). The RT training protocol was based on a session with these characteristics: 3 sets of 12 repetitions at 60% of a maximum repetition in each of the exercises (bench press, squat and military press). The only difference between the training session was that the MV group performed all the repetitions at 100% of their maximum velocity and the LV group performed at 50%. This variable was controlled with the T-force system. An oral glucose tolerance test (OGTT) was conducted with metabolic measurements immediately after each RE protocol and every 30 min until 120 min of recovery. For the statistical analysis, the area under the blood glucose curve (AUC) was calculated at each time point. Cohen's d for effect size were also calculated to determine the magnitude of the group differences. The criteria to interpret the magnitude of the ES was as follows: trivial (< 0.2), small ($0.2-0.59$), moderate ($0.60-1.19$), large ($1.2-2.0$), or very large (> 2.0) **RESULTS:** The responses of blood glucose following each protocol and OGTT was similar in all groups, reaching the glycemic peak at 30 min of recovery. However, the MV group exhibited significantly lower values in the AUC when compared with LV group over two hours monitoring period ($P = 0.021$, $ES = 1.198$). **CONCLUSIONS:** The present study showed that RT at different velocities can generate different metabolic responses. In conclusion, the results of this study indicated that RT at a high velocity could be the optimum for postprandial glucose control.

 (No relevant relationships reported)

Discussion of the influence of body type on the potential to gain strength from resistance training (RT) is a relatively new field of investigation. What has not been

explored is the degree to which body type might impact the potential difference between men and women to make strength gains from RT. **PURPOSE:** To determine the influence of sex and body type on changes in upper-body strength resulting from free-weight RT in college men and women. **METHODS:** College men and women ($n = 903$) were measured for fat mass (FM) and fat-free mass (FFM) as determined from gender-specific skinfold equations. Body type was determined by regressing FFM/Ht² on FM/Ht² and partitioning into thirds for each sex as slender (SL), average (AV), and solid (SO). Sexes were matched within the 3 body types for SL (men = 47, women = 23), AV (men = 43, women = 18), and SO (men = 44, women = 16). Each participant was measured for 1RM bench press before and after 12 weeks of linear periodization RT in 3 sets of 6 exercises. **RESULTS:** Sex x body type ANOVA on absolute strength gain revealed no significant difference between sexes ($M = 6.3 \pm 5.7$ kg; $W = 4.5 \pm 5.0$ kg) or across body types (SL = 4.9 ± 5.8 , AV = 6.0 ± 5.7 , SO = 6.5 ± 4.9 kg). The sex x body type interaction was not significant. SO (36.6 ± 8.3 kg), SL (35.8 ± 8.0 kg), and AV (35.1 ± 8.4 kg) differed by $< 2\%$ in initial 1RM. Absolute strength gains had low correlations with initial strength in both men ($r = -0.16$) and women ($r = 0.12$) as well with body type ($r < 0.12$). **CONCLUSIONS:** Untrained men and women of comparable body types appear to make similar gains in upper-body strength when following the same periodized free-weight RT program. The level of initial strength seems to have little bearing on the amount of strength that can be gained during training.

Muscle Damage And Inflammatory Response From Resistance Exercise With Higher Vs Lighter Loads

Gilmar Weber Senna¹, Estevão Scudese², Paula Paraguassú Brandão¹, Matheus Baffi¹, Breno Vargas¹, Leandro Guimaraes¹, Gabriel Bronzeri¹, Flavia Soares Carrilho¹, Cristiano Queiroz de Oliveira¹, Fabiana Rodrigues Scartoni¹, Estélio Herinque Martin Dantas³. ¹Catholic of Petrópolis University, Petrópolis, Brazil. ²Federal University of State of Rio de Janeiro, Rio de Janeiro, Brazil. ³Tiratentes University, Petrópolis, Brazil.
 (No relevant relationships reported)

Resistance exercise is considered the most efficient strategy for strength, power, and muscle endurance enhancement. **PURPOSE:** The aim was to analyze the effects of different resistance exercise (RE) loads on inflammatory response and muscle tissue damage. **METHODS:** Ten trained men with at least one year of resistance training were selected (26.40 ± 4.73 years, 80.71 ± 8.95 kg, 176.03 ± 6.11 cm, $9.86 \pm 3.25\%$ body fat, bench press relative strength: 1.27 ± 0.27 kg/kg-1 of body mass), and alternately ordered to perform two separate visits. The first consisted of five submaximal sets of 10 repetitions at 80% of 10-RM, and the second consisted of five submaximal sets of 20 repetitions at 40% of 10-RM, for the horizontal bench press and leg press exercises with one-minute of rest, guaranteeing the volume equalization for both conditions. Circulating concentrations of creatine kinase (CK), lactate dehydrogenase (LDH), and leucocyte count were measured at pre-exercise (PRE) and post 3h, 6h, 12h, and 24h. **RESULTS:** The ANOVA presented increases in CK compared to the PRE moment, from 6h ($p < 0.0001$), to 24h after the higher 80% of the 10-RM load. The area under the curve differed significantly ($p = 0.009$) between 80% of 10-RM (4572.42 ± 1169.54 u/L) and 40% of 10-RM (3268.68 ± 1042.02 u/L). For the LDH concentration, a significant interaction effect (load x moment of the checks) was observed ($p = 0.019$). Specifically, for the main effect of verification moments ($p < 0.0001$), the data revealed that both loading protocols resulted in significant increases in LDH compared to PRE at 12 hours after exercise. The magnitude of the findings verified by the effect size showed large elevations of LDH from 6h to 12h for the higher load condition. For the 40% of 10-RM load, large elevations were observed in 3h, 6h, 12h, and 24h. For leucocyte count, the main effect of verification moments elevations ($p < 0.0001$), occurred from the time of 3h to 12h after exercise for both conditions. **CONCLUSION:** We found differences in tissue damage such an increase in the CK lesion marker with 80% 10-RM loading, which did not happen with 40% 10-RM loading, however with no differences on the inflammatory response concerning the total leucocyte count, neutrophils, lymphocytes and monocytes between different loads conditions. Supported by CAPES Brazil: 2.034.476.

Ischemic Preconditioning Of Thigh Muscles: Number Of Proper Repetitions And Effectiveness

Akeru Ishizawa¹, Koichi Okita¹, Hisato Tanaka¹, Kengo Tao¹, Noriteru Morita². ¹Hokusho University, Ebetsu, Japan. ²Hokkaido University of Education, Iwamizawa, Japan.
 Email: ishiake1438@outlook.jp
 (No relevant relationships reported)

Ischemic preconditioning (IPC) was introduced after it was demonstrated that repetitions of short-term ischemia and reperfusion of coronary arteries can reduce the myocardial damage following prolonged ischemia (direct IPC). It was later shown that the IPC of coronary arteries also protects remote cardiac tissue not directly exposed to IPC (remote IPC). Several studies suggested that the IPC of a limb may protect

remote organs against an ischemic incident. Because of the intermittent nature of blood flow during intense muscle actions, it was proposed that IPC prior to exercise could increase muscular performance. Although most of the prior exercise studies used an IPC protocol involving four cycles of 5-min circulatory occlusion followed by a 5-min reperfusion period, the optimal number of repetitions of IPC has been unknown. **PURPOSE:** We examined the effects of direct IPC on thigh strength and sought to determine the optimal repetitions of IPC for successful results. **METHODS:** In a randomized cross-over study, 12 healthy young males (19.8 ± 2.1 yrs, body mass index: 22.1 ± 2.7 kg/m²) performed maximal knee extension (Biodex System 3; New York, USA) of the right leg preceded by direct IPC at four different repetitions (1, 2, 3, and 4 sets) and a control intervention. One IPC consisted of 5-min circulatory occlusion by 1.3-times systolic blood pressure and 5-min reperfusion. **RESULTS:** There was no significant difference in the maximal voluntary torque of knee extension between the control and any number of repetitions of the IPC, as shown below.

MVT	Control	1 set	2 sets	3 sets	4 sets
60°/sec, Nm	287.3 ± 46.3	275.3 ± 46.3	276.4 ± 47.1	270.2 ± 52.0	262.6 ± 44.5
180°/sec, Nm	191.9 ± 25.2	198.0 ± 23.6	190.5 ± 20.4	199.3 ± 31.6	188.3 ± 22.7
300°/sec, Nm	144.7 ± 21.4	150.0 ± 17.4	144.7 ± 18.3	146.2 ± 16.7	141.7 ± 16.4

MVT, maximal voluntary torque; Nm, newton meter. Data are mean ± SD (n=12). **CONCLUSIONS:** These data indicate that direct IPC for the thigh muscles could not improve maximal strength regardless of the number of repetitions. The application of pre-exercise IPC for improving performance should be further carefully examined concerning the optimal protocol and its indications, such as exercise types and target muscles.

Effect Of Respiratory Training On Vas Pain Rating And Via Thickness In Patients Withrating And Via Thickness In Patients With Chronic Non-specific Lumber Pain

Li Huang, Li Peng. *College of Physical Education, South-West University, Chongqing, China.*
 (No relevant relationships reported)

PURPOSE: Non-specific low back pain(NLBP) is defined as a lumber pain that does not belong to an identifiable specific pathology. The probability of experiencing lumber pain in one's lifetime is as high as 84 %. According to the most accurate estimate, the prevalence of NLBP is 23 %, and 11 % of them have disabilities as a result. Compared with conventional physical therapy methods, core strength training can effectively relieve patients 'pain. Due to the overlap of the core muscle group and respiratory muscle in the anatomical structure, there is also a certain relationship in its function. But it is easy to ignore the training of respiratory muscle during the core force training. Therefore, this study compared the effect between respiratory training combined with core strength training and single core strength training in patients with NLBP, in order to confirm the effect of respiratory training on NLBP.

METHODS: 26 patients with NLBP were equitably distributed into observation group and control group according to random number table method. All the patients were taken in 3*40min exercise intervention for 8 weeks. The observation group adopted breath training combined with core strength training, while the control group only conducted core strength training. The VAS score measured with pain visual analog scale (VAS) and the thickness of transverse abdominis of patients were determined with Bone Ultrasound Instrument before and after the intervention.

RESULTS: The difference of VAS scores (4.40 ± 1.30 vs. 4.45 ± 1.29 , $P=0.92$) and thickness of transverse abdominis (0.35 ± 0.03 vs. 0.37 ± 0.03 , $P=0.12$) between groups were not obvious before intervention. But VAS score in observation group was significantly lower than that in the control group (3.20 ± 1.15 vs. 4.18 ± 1.17 , $P<0.05$), and the thickness in myalgia side of transverse abdominis was significantly higher than that in the control group (0.42 ± 0.03 vs. 0.39 ± 0.01 , $P=0.00$) after intervention.

CONCLUSIONS: The effect of respiratory training combined with core strength training on patients with NLBP is significantly better than that of the single core strength training, suggesting that respiratory training plays an important role in the treatment of NLBP.

Cross-validation Of A Prediction Equation For Energy Expenditure Of An Acute Resistance Exercise Bout.

Sean T. Stanelle¹, Jason R. Lytle¹, Bradley S. Lambert², Steven E. Martin¹, John S. Green¹, Stephen F. Crouse, FACSM¹. ¹Texas A&M University, College Station, TX. ²Houston Methodist Hospital, Houston, TX. (Sponsor: Stephen F. Crouse, FACSM)
 (No relevant relationships reported)

Previously, our laboratory introduced a regression equation for predicting net kcal consumption of a resistance exercise (RE) bout: Total net kcal = $0.874(\text{height, cm}) - 0.596(\text{age, years}) - 1.016(\text{fat mass, kg}) + 1.638(\text{lean mass, kg}) + 2.461(\text{total volume} \times 10^{-3}) - 110.742$ ($R^2 = 0.773$, $SEE = 28.5$ kcal).

PURPOSE: The purpose of this study was to validate this regression equation using the same variables as predictors.

METHODS: Forty-seven healthy, active subjects (23 men, 24 women, 20-58 yrs, 173.5 ± 10.5 cm, 85.5 ± 19.0 kg, $VO_{2max} 36.0 \pm 8.4$ ml/kg/min) were randomly divided into validation and cross-validation groups ($n_v = 24$, $n_{cv} = 23$). The validation group's data was used to develop an equation to predict net kcal consumption, which was applied to the cross-validation group's data to estimate net kcal consumption. Similarly, a prediction equation was derived from the cross-validation group's raw data and applied to that of the validation group. The strength of the relationship between each group's measured and estimated net kcal consumption was assessed via correlational analysis.

RESULTS: Multiple linear regression yielded the following estimates of net kcal consumption: validation net kcal = $1.125(\text{height, cm}) - 0.662(\text{age, years}) - 0.800(\text{fat mass, kg}) + 1.344(\text{lean mass, kg}) + 2.278(\text{total volume} \times 10^{-3}) - 144.846$ ($R^2 = 0.751$, $p < 0.0001$, $SEE = 29.7$ kcal); cross-validation net kcal = $0.515(\text{height, cm}) - 0.520(\text{age, years}) - 1.220(\text{fat mass, kg}) + 1.995(\text{lean mass, kg}) + 2.620(\text{total volume} \times 10^{-3}) - 59.988$ ($R^2 = 0.823$, $p < 0.0001$, $SEE = 29.2$ kcal). These equations had a cross-validation coefficient of 0.902 and a double cross-validation coefficient of 0.863.

CONCLUSION: The strong relationship between the measured and estimated net kcal consumption of both the cross-validation and validation group lead us to conclude that the regression equation derived by this laboratory is valid for estimating net energy expenditure for a total RE bout.

Effects Of High-Load And High-Volume Resistance Training On Maximal Strength, Peak Torque, And Mean Torque

Casey Lee Sexton¹, Christopher G. Vann¹, Shelby C. Osburn¹, Morgan A. Smith¹, Melissa N. Rumbley¹, Darren T. Beck², Kaelin C. Young³, Michael D. Roberts¹. ¹Auburn University, Auburn, AL. ²Edward Via College of Osteopathic Medicine - Auburn Campus, Auburn, AL. ³Edward Via College of Osteopathic Medicine-Auburn Campus, Auburn, AL.
 (No relevant relationships reported)

Purpose: This study was conducted to compare the effects of high-load, moderate-volume and high-volume, moderate-load resistance training on estimated one repetition maximum (Est. 1RM) on unilateral leg press and leg extension as well as isokinetic knee extension peak and mean torque.

Methods: Well-trained college-aged males ($n=15$; training age = 7 ± 3 years, mean squat relative to body weight = 1.9 ± 0.4), completed a 6-week (3 days per week) unilateral training program. Training involved exercising one leg with high loads at moderate volumes (HL: 82.5-95% Est. 1RM, 3 sets of 5 repetitions), and the other leg with moderate loads at high volumes (HV: 60% Est. 1RM, 5 - 10 sets of 10 reps). 3RM leg press, 3RM leg extension, and isokinetic knee extension at 60 and 120 deg/sec using an isokinetic dynamometer were collected on each leg prior to training (PRE), 72 hours following the last training bout (POST), and 10 days following passive recovery (POSTPR). Two-way repeated measures ANOVAs [condition (HL versus HV) x time (PRE, POST, POSTPR)] were performed for all dependent variables. Where appropriate, post-hoc analysis included Fisher's LSD and paired samples t-tests. Significance was set at ($p < 0.05$).

Results: There was a significant condition*time effect for leg extension ($p=0.017$). Both HV and HL significantly increased leg extension from PRE to POST ($p<0.001$) and PRE to POSTPR ($p<0.001$). However, HL was significantly greater than HV at both POST (mean difference 5 ± 6 kg, $p=0.007$) and POSTPR (5 ± 6 kg, $p=0.009$). There was a main effect of time for Est. 1RM leg press ($p<0.001$), with Est. 1RM being higher in both conditions from PRE to POST ($p<0.001$) and PRE to POSTPR ($p<0.001$). Similar trends were evident for mean knee extensor torque at 60 deg/sec ($p=0.041$) with mean knee extensor torque at 60 deg/sec being higher from PRE to POSTPR ($p=0.029$) and from POST to POSTPR ($p=0.43$). There were no significant interactions or main effects for isokinetic knee extension peak torque at 60 and 120 deg/sec or mean torque at 120 deg/sec.

Conclusion:

Our data suggest the effects of different unilateral loading schemes may be expressed to a greater extent in single joint movements. Additionally, isokinetic dynamometry may not be a valid method to detect strength changes to resistance training in a previously-trained population.

891 Board #17 May 27 1:30 PM - 3:00 PM
Men And Women Express Similar Power Profiles In Pull Motions But Not Push

Jacob M. Cunha, Alexia E. Amo, Cynthia Villalobos, J. Mark VanNess, Courtney D. Jensen. *University of the Pacific, Stockton, CA.*
 (No relevant relationships reported)

Pushing and pulling occurs in athletic and nonathletic settings. Weaknesses in either movement could compromise sport performance or daily functioning. Determination of optimal load may aid in sport performance and reduce the risk of injury. **PURPOSE:** To determine power output differences between men and women using colinear resistance. **METHODS:** We enrolled 32 recreationally active men (n=14) and women (n=18), ages 18-25, to evaluate power profiles in horizontal and vertical push and pull exercises using Proteus (Proteus Motion, USA), which applies continuous, three-dimensional, concentric resistance. Subsequent data collection involved 2 repetitions with the dominant arm at 7lb, 14lb, 21lb, and 28lb in each exercise (32 total repetitions). Proteus software computed power output in watts for each set performed. Analysis of variance (ANOVA) with repeated measures tested the differences in power output at each load. **RESULTS:** In both horizontal and vertical pull motions, there was a significant difference by load ($p < 0.001$) and an interaction effect by sex ($p < 0.001$). The expression of power was most similar between men and women at the lowest resistance horizontally ($p = 0.020$) and vertically ($p = 0.038$); both deviated more as weight increased. No plateaus were demonstrated in either motion; higher loads were required for both sexes to achieve peak power. In horizontal and vertical push motions, there was a significant difference by load ($p < 0.001$) and an interaction effect with sex ($p < 0.001$). Men and women were closest in power at 7lb horizontally ($p = 0.017$) and vertically ($p = 0.004$). Women experienced a plateau at 21lb; further change was insignificant both horizontally ($p = 0.147$) and vertically ($p = 0.519$). Men did not exhibit a plateau; power continued to increase from 21lb to 28lb ($p < 0.001$). **CONCLUSIONS:** In our population, the power produced between sexes was similar in press motions, but differed in pulls. By assigning sex-specific training loads, athletes can optimize performance.

892 Board #18 May 27 1:30 PM - 3:00 PM
Neuromodulation Does Not Enhance Neural Adaptations To Strength Training In Previously Trained Individuals

Carlos A. Estrada¹, Masoud Moghaddam², Micheal J. Luera², Tyler W.D. Muddle², Cameron S. Mackey², Cody L. Diehl², Jason M. DeFreitas², Bert H. Jacobson². ¹*Aurora University, Aurora, IL.* ²*Oklahoma State University, Stillwater, OK.*
 (No relevant relationships reported)

Introducing resistance training to an initially untrained population induces rapid, early strength increases due to neural adaptations and are thereafter increased due to morphological adaptations within the musculotendinous unit. However, transcranial direct current stimulation (tDCS) is a method of neuromodulation that has been speculated to elicit further neural adaptations in already trained individuals, though the efficacy of tDCS to do so remains unsubstantiated. **PURPOSE:** To examine the effect of tDCS on performance following a short-term resistance-training protocol. **METHODS:** Forty-three trained males and females (Age = 20.7 ± 1.4yrs) participated in this investigation and reported on 12 separate occasions for pre- and post-testing and lower-body resistance training. During the initial visit, participants performed submaximal lower-body strength (predicted-1RM) and power testing (countermovement jump height [CMJ], peak power [PP], and peak velocity [PV]), and were familiarized with isometric strength testing procedures (knee extensor maximal voluntary isometric contractions). Participants reported 48-72hrs later for isometric testing to evaluate knee extensor peak torque (PT) and peak rate of torque development (pRTD), and were randomly assigned to either a control (CON), stimulation (tDCS), or sham (S-tDCS) condition thereafter. Each condition engaged in an identical training protocol 2x/wk for four weeks. Individuals in the tDCS and S-tDCS condition received stimulation to the primary motor cortex for 21 minutes prior to training. Post-testing occurred within the 3-7 day period following the final training session. Six separate 2x3 (Time x Condition) repeated-measures ANOVAs were conducted to assess between-condition differences in pre- to post-training measures of strength and power. **RESULTS:** No significant Time x Condition interaction effects were observed within any of the dependent variables (DV). However, a main effect of Time was observed in measures of CMJ, PP, PV, PT, and predicted 1RM strength ($p < 0.05$). When collapsed across condition, significant improvements ($p = 0.000 - 0.048$) were observed in

these DVs. **CONCLUSION:** These results suggest that tDCS did not elicit superior improvements in lower-body strength and power compared to CON and S-tDCS conditions.

Agreement Between Kinovea And The Open Barbell System For Barbell Velocity And Range Of Motion

Christian Macarilla, Joseph P. Carzoli, Colby A. Sousa, Eric R. Helms, Michael C. Zourdos. *Florida Atlantic University, Boca Raton, FL.* (Sponsor: Michael Whitehurst, FACSM)
 Email: cmacarilla2018@fau.edu
 (No relevant relationships reported)

PURPOSE: The aim of this study was to examine the degree to which Kinovea video analysis software and a linear position transducer, the Open Barbell System (OBS), agree for measurements of average (ACV) and peak concentric velocity (PCV), as well as concentric range of motion (ROM) during the free-weight back squat and bench press exercises.

METHODS: Sixteen males (age: 23.6±2.8yrs, body mass: 82.0±12.2kg, height: 171.8±7.5cm, training age: 7.0±3.6yrs) performed a bench press and squat one-repetition maximum (1RM) in the first session. Then, in 3 different sessions subjects performed 3 (sets) X 1 (repetition) at 60% and 80% of 1RM. On each repetition, ACV, PCV, and ROM were assessed via both Kinovea and OBS. A smartphone was used to obtain videos from the lateral aspect that were later uploaded for analysis via Kinovea software, while the OBS was attached to the barbell via a cord and all outcomes were displayed on the unit in real time. Paired t-tests, intraclass correlation coefficients (ICCs), Bland-Altman plots, and folded empirical cumulative distribution plots (mountain plots) were used to analyze results.

RESULTS: Due to recording errors 348 out of a possible 352 repetitions were recorded. Paired t-tests revealed significant differences between measurement systems in all outcome variables for both the squat and bench press ($p < 0.01$). ICCs for the squat were: 0.929 (ACV), 0.913 (PCV), and 0.188 (ROM). ICCs for the bench press were: 0.930 (ACV), 0.929 (PCV), and 0.683 (ROM). Large limits of agreement were observed in all Bland-Altman plots and visual inspection of the mountain plots revealed deviation from the zero-difference line and long tails in all plots denoting a lack of agreement between devices.

CONCLUSION: In summary, the Kinovea software and OBS do not agree for measurement of ACV, PCV, and ROM during the squat and bench press. The OBS is a validated device versus a motion capture system, therefore we do not recommend Kinovea for these outcomes.

894 Board #20 May 27 1:30 PM - 3:00 PM
Sex Differences In Blood Lactate Concentration And Changes In Lifting Velocity During And After Resistance Exercise For Strength Gain And Muscle Hypertrophy.

Yukina Mochizuki, Hiroki Honma, Mika Saito, Naoki Kikuchi. *Nippon sport science University, Tokyo, Japan.*
 Email: 19pma35@gmail.com
 (No relevant relationships reported)

Strength training variants, such as load, repetition, and set, are manipulated for strength gain and muscle hypertrophy. However, there is little evidence of optimal training variants for women. **PURPOSE:** To investigate sex differences in blood lactate concentration and changes in lifting velocity during and after resistance exercise for strength gain and muscle hypertrophy, respectively. **METHODS:** Fourteen subjects (men=8, age 21.1±0.8 years, weight 70.9±7.2 kg, height 170.7±5.0 cm; women=6, age 20.7±1.1 years, weight 58.3±5.0kg, height 159.5±5.5 cm) with significant physical education and resistance training experience participated in this study. Participants performed four sets of parallel squats as part of two protocols, one for strength gain (four repetitions at 85% of 1RM) and one for muscle hypertrophy (10 repetitions at 70% of 1RM) using a cross over design. We measured blood lactate concentration before, during, and after the exercise. We also measured lifting velocity during exercise using a transducer (GymAware). **RESULTS:** Blood lactate concentration significantly increased after both protocols in both men (strength 1.4±0.7 to 4.1±1.7 mmol/l, $p = 0.001$, hypertrophy 1.6±0.5 to 8.3±2.0 mmol/l, $p < 0.001$) and women (strength 1.3±0.3 to 1.8±0.5 mmol/l, $p = 0.012$, hypertrophy 1.5±0.3 to 4.0±2.0 mmol/l, $p = 0.269$). The protocol for muscle hypertrophy, led to a more significant increase in blood lactate concentration in both men ($p = 0.001$) and women ($p = 0.040$) after exercise than the protocol for strength gain. After both protocols were applied, blood lactate concentration immediately after exercise was significantly higher in men than in women (strength $p = 0.008$, hypertrophy $p = 0.005$, respectively). Lifting velocity showed a decreasing tendency for both protocols, especially for muscle hypertrophy, in men, but without any significant differences between men and women. **CONCLUSIONS:** Our results suggest that there are no significant sex differences

in blood lactate concentration and lifting velocity during and after the application of the two protocols for strength gain and muscle hypertrophy. However, blood lactate concentration was significantly higher in men than in women.

895 Board #21 May 27 1:30 PM - 3:00 PM Distance Runners' Perceptions Of A Strength Training Intervention

Danielle Trowell¹, Aaron Fox¹, Natalie Saunders¹, Bill Vicenzino², Jason Bonacci¹. ¹Deakin University, Melbourne, Australia. ²University of Queensland, Brisbane, Australia.
Email: danielle.trowell@ausport.gov.au
(No relevant relationships reported)

PURPOSE: This study is one part of a Randomised Controlled Trial investigating the effect of strength training on distance runners' mechanics and performance. The aim of this study was to examine runners' perceptions of the strength training intervention. **METHODS:** Thirty distance runners (18 male, 12 female) were recruited for this study. In addition to their normal running training, the experimental group undertook strength training two days per week for 10 weeks. Total training time was matched, with the control group performing additional low-intensity running and body-weight exercises. Running performance and biomechanics during submaximal running (3.8 m/s) and maximal sprinting were assessed immediately before and after the intervention period. At the completion of the 10 week intervention period, the strength training group were also surveyed on their perceptions of the strength training intervention using an online questionnaire in Qualtrics.

RESULTS: Twenty-eight participants completed follow-up testing. Strength training significantly improved two kilometre running performance ($F(1,26) = 10.497, p = .003$, partial $\eta^2 = .288$) more than running training alone. The mean (95% CI) difference between groups was 11.31 (3.73 to 18.98) seconds. However, strength training did not change maximal aerobic capacity, running economy (3.3 m/s) or lower-limb joint kinematics or kinetics during running. Survey responses showed 64% ($n = 9$ of 14) of the experimental group believed the strength training program improved their running performance and 79% ($n = 11$) reported they would continue using strength training. Half ($n = 7$) of the experimental group believed strength training had a considerable effect on their running technique.

CONCLUSIONS: Strength training appears to improve runners' physical and task-specific self-efficacy, and increased confidence may facilitate faster running performance. This study also demonstrated a discrepancy between measured and perceived effects of strength training on running technique.

896 Board #22 May 27 1:30 PM - 3:00 PM Setting A New World Record: The Demands Of Running 833km On Treadmill In 7 Days

(No relevant relationships reported)

Ultra-running (UR) comprises running events longer than a marathon (>42.2km). Due to the prolonged duration of UR, decrements in most or all physiological parameters are to be expected, and include a decrease in body mass and dehydration, loss of skeletal muscle mass and increased total body water. **Purpose:** to present data on a female multiple world record holding ultra-runner, examining haematological and physiological perturbations, as well as nutritional strategies throughout a successful treadmill world record attempt for total distance completed in seven days on a treadmill (833.05km). **Methods:** Sharon Gayter (SG) 47 years, 162.5cm, 49kg, $\dot{V}O_{2max}$ 48 ml/kg/min⁻¹ ran continuously for 7 days on a treadmill located at Teesside University, UK. 3-hours of running were followed by 30-minute breaks, and night-time rest from 1am-5am. Heart rate (HR), oxygen uptake ($\dot{V}O_2$), weight (kg), blood lactate (La; mmol.L⁻¹), haemoglobin (Hb; g.DL⁻¹), haematocrit (hct; %), glucose (G; g.L⁻¹), and nutrition were recorded. **Results:** SG ran at approx. 7km/h for 17.5 hours/day, covering an average of 120km. Mean $\dot{V}O_2$ 1.2 ± 0.1 L.min⁻¹/24.7 ± 3.2 mL.kg.min⁻¹, RER 0.80 ± 0.03, HR 125 ± 5 b.min⁻¹. Weight increased from 48.6 to 49.5kg. Hb decreased from 13.7 to 11 g.DL⁻¹, and hct decreased from 40% to 33%. Average G was 6.3 ± 1.6 g.L⁻¹, (range 2.65-9.14 g.L⁻¹), and average blood lactate was 1.0 ± 0.5 mmol.L⁻¹, (range 0.4-3.3 mmol.L⁻¹). Energy expenditure (EE) for each 24-hour period was 6878 kcal, and energy intake (EI) was 2701 kcal. Hourly EE was 382 kcal, with 66.6% and

33.4% of the energy coming from fat and carbohydrate oxidation, respectively. 7-day EI was 26,989 kcal and EE was 48,147 kcal, resulting in a total energy deficit (ED) of 21,158kcal. **Conclusion:** The previous record of 753.24km was extended by 79km to a new world record of 833.05km. SG exhibits an enhanced fat metabolism through which she covered the large daily ED. The increase in body weight could be the result of protein catabolism. The corresponding development of hypoproteinaemic oedema, and increased plasma volume, likely lead to the reduced Hb and hct. Her success can be attributed to a combination of physiological and psychological factors, as she remained upbeat throughout the event and stated that she felt that the attempt was easy but became a bit 'tedious' towards the end.

897 Board #23 May 27 1:30 PM - 3:00 PM Prevalence Of Low Bmd Of High-level Kenyan Male And Female Distance Runners Compared To Kenyan Controls

Lauri Önnik¹, Diresibachew W. Haile², Anthony C. Hackney³, Robert Ojiambo², Silva Suvil¹, Amy R. Lane², Martin Mooses¹. ¹University of Tartu, Tartu, Estonia. ²Moi University, Eldoret, Kenya. ³University of North Carolina, Chapel Hill, NC.
Email: lauri.onnik@ut.ee
(No relevant relationships reported)

Kenyan male and female runners have dominated international running events for decades, however the information about their bone health to date is lacking. High training volumes and low energy availability concurrently could potentially impact greatly on bone health. Previous reports lack comparison with the proper control group.

PURPOSE

To determine the bone health indices of Kenyan high-level male and female distance runners.

METHODS

Participants were 26 female (28.7±6.3 yr; 51.8±5.0 kg; 1.63±0.07 m; 19.5±2.0 kg·m⁻²; IAAF performance score: 1029±132 pt) and 30 male (28.1±3.8 yr; 57.7±6.1 kg; 1.73±0.05 m; 19.6±1.8 kg·m⁻²; IAAF performance score: 1087±66 pt) high level Kenyan distance runners. Control group consisted of 29 female (25.0±5.7 yr; 63.4±9.1 kg; 1.65±0.06 m; 23.3±3.2 kg·m⁻²) and 29 male (24.1±3.8 yr; 62.5±10.1 kg; 1.7±0.08 m; 21.8±5 kg·m⁻²) university students of similar age. DEXA was used to measure BMD at the lumbar spine (LS-BMD), right femur (RF-BMD) and total body (TB-BMD). Low BMD was defined as Z-score between -1.0 and -2.0 and osteoporosis < -2.0.

RESULTS

There were no differences in LS-BMD Z-score, RF-BMD Z-score and TB-BMD Z-score between female-male athletes and their respective controls. LS-BMD Z-score, RF-BMD Z-score and TB-BMD Z-score frequency count in the range of -1 to -2 and below -2 is shown in table 1.

Table 1. Number of participants with Z-scores in the range of -1 to -2 and below -2.

	F Athletes (n=26)	M Athletes (n=30)	F control (n=29)	M control (n=29)
LS-BMD Z -1 to -2	7	5*	6	7
LS-BMD Z < -2	3	1*	2	2
RF-BMD Z -1 to -2	5	2*	3	3
RF-BMD Z < -2	2	0*	3	2
TB-BMD Z -1 to -2	3	1	3	3
TB-BMD Z < -2	0	0	1	0

* - sample size for these values was 20; M = male, F = female

CONCLUSION

There was high prevalence of low BMD (Z-score < -1) in high level male and female Kenyan distance runners and somewhat unexpectedly for control groups too; but, no statistical differences in bone health indices between female-male athletes and corresponding control groups. These findings warrant additional investigation be conducted into the energy balance, eating disorders, disordered eating and hormonal markers to further explain causality, both among Kenyan athletes and controls.

898 Board #24 May 27 1:30 PM - 3:00 PM May The Force Be With You: Acceleration-based Estimates Of Vertical Ground Reaction Forces During Running

Dovin Kiernan, David Hawkins. University of California, Davis, Davis, CA.
(No relevant relationships reported)

Running-related injury (RRI) may be caused by combinations of load magnitudes and numbers exceeding musculoskeletal structure capacity. Few methods exist, however,

to quantify external loads (vertical ground reaction forces; vGRFs) during running in ecologically valid settings. **PURPOSE:** Develop models to accurately estimate vGRF second ("active") peaks during running from iliac crest and sacrum accelerations. **METHODS:** Anthropometric and sex data were collected from 40 runners. Runners wore inertial measurement units (IMUs) ($\pm 100g$, $\pm 2000deg/s$, 1000Hz) secured to their iliac crests and sacra while they ran a 25m track with embedded force plate (1000Hz). Speed, IMU accelerations, and force plate data were synchronously recorded for ten stances per foot at "slow", "typical", and "fast" self-selected speeds. Accelerations were transformed to a segment coordinate system. Force and acceleration signals were 50Hz low-pass filtered and divided into 0-8Hz low frequency (LoF) and ≥ 10 Hz high frequency (HiF) signals. Acceleration and vGRF peaks were extracted from the original, LoF, and HiF signals. Two multiple linear regressions were created to estimate log-transformed vGRF second peak: One used sacrum accelerations to predict bilateral forces, the other used iliac crest accelerations to predict ipsilateral forces. Each model included sex and limb lengths as fixed effects and was validated using an eight-fold cross-over. **RESULTS:** Both models predicted observed vGRF second peaks well ($r^2=0.78$, mean absolute error $<7\%$). Addition of participant as a random effect ($r^2 \geq 0.93$, mean absolute error $<4\%$) or speed as a fixed effect ($r^2 \geq 0.83$, mean absolute error $<6\%$) further improved results. **CONCLUSIONS:** The models developed here demonstrate a single IMU secured over the iliac crest or sacrum can estimate ipsilateral or bilateral vGRF second peak, respectively, with high accuracy. This approach could greatly impact our understanding of RRI by facilitating quantification of the step-by-step external forces experienced by runners over long time periods in ecologically valid settings. Supported by an ACSM Doctoral Student Research Grant, a Sigma Xi Grant-in-Aid of Research, the Maury Hull Endowed Fellowship for Musculoskeletal Biomechanics Research, and an NSERC Post-Graduate Scholarship.

Are All Running Workloads Created Equal?
 Megan R. Ryan¹, Tayler M. Vickery¹, Adriana Miltko¹, Richard T. Beltran¹, Christopher Napier², Max R. Paquette¹. ¹University of Memphis, Memphis, TN. ²University of British Columbia, Vancouver, BC, Canada. (Sponsor: Douglas W. Powell, FACSM) Email: mrbriley@memphis.edu
 (No relevant relationships reported)

Training workload (WL) has become a more common monitoring approach in runners and is defined as the product of external and internal training loads. Although rating of perceived exertion (RPE) is a widely accepted measure of internal load, various types of external load metrics can be used in running. **PURPOSE:** The purpose of this study was to compare week-to-week changes among different training WL measures in high school runners. **METHODS:** 12 male cross-country runners from the same high school team participated in two consecutive weeks of training monitoring. Training minutes were prescribed by the team coach. Session internal load was collected after each run using RPE on a 1-10 visual analog scale. Session external loads included miles, minutes, IMU-based proprietary tibial load (Bone Stimulus, IMeasureU), and estimated cumulative peak vertical force obtained from wireless insole data (Force, loadsol, Novel). Different weekly WL measures were calculated from session RPE and external load measures. Paired t-tests and Cohen's *d* effect sizes were used to compare between-week percent change (%Δ) among different WL measures and weekly minutes ($p \leq 0.05$). **RESULTS:** Different between-week %Δ were observed between RPExMinutes ($p = 0.003$; $d = 1.83$), RPExBone Stimulus ($p < 0.001$; $d = 0.74$), RPExForce ($p = 0.002$; $d = 1.91$), and weekly miles ($p = 0.011$; $d = 0.71$) compared to weekly minutes (Figure 1). We also observed greater individual variability in the between-week differences for all three WL measures compared to the volume only measures (Figure 1) due to high variability in the between-week %Δ in average sRPE (SD = 26%). **CONCLUSION:** These findings suggest that only monitoring a prescribed volume metric can greatly obscure week-to-week individual training responses of runners. The inclusion of an internal training load (i.e., session RPE) allows for the monitoring of the physiological response to training and explains the large variability of the three WL measures.

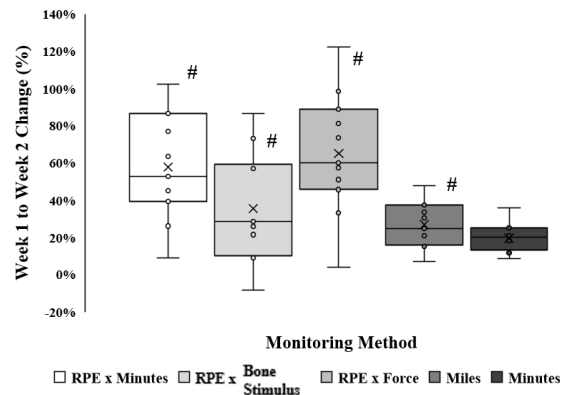

Figure 1. Box plot of week-to-week percent change among different methods of training monitoring. Force (estimated cumulative peak vertical force from combination of wireless force insole peak vertical GRF and cadence), Bone Stimulus (metric from IMeasureU IMU-Step software), and Minutes were used as the external load measures in combination with sRPE to calculate three difference training WLs. #: different than Minutes.

900 Board #26 May 27 1:30 PM - 3:00 PM
Effect Of Cupping Therapy On Respiratory Gas Exchange And Hip Extensor Force Production In Runners
 Maximilian T. Antush, Lorrie R. Brilla, FACSM, David N. Suprak, Carolyn F. Watson, Katie M. Olinger. Western Washington University, Bellingham, WA.
 (No relevant relationships reported)

Literature on the efficacy of cupping therapy (CT) is limited. Potential mechanisms of action of cupping therapy include increased localized blood and restructuring of fascial protein conformations through mechanotransduction, which has implications for improved running economy (RE) and hip extensor force production (HEFP). **PURPOSE:** To elucidate the effects of myofascial decompression through CT on RE and HEFP in well-trained runners. **METHODS:** Five minutes of CT or placebo gel was applied to bilateral gluteus maximus, biceps femoris, semimembranosus, and semitendinosus of 7 female (29.3 ± 2.1 yrs, 1.68 ± 0.06 m, 60.2 ± 3.4 kg) and 8 male (27.5 ± 6.2 yrs, 1.77 ± 0.04 m, 69.1 ± 4.0 kg) well-trained runners (female 10-km time = 41.4 ± 4.4 min, male 10-km time = 33.5 ± 1.2 min) after a 10-minute treadmill warm-up. Maximal HEFP was measured immediately post CT or gel using an isokinetic dynamometer. Then RE was measured using two 6-minute steady-state treadmill runs (fixed velocity and subject 10-km velocity). Maximal oxygen consumption (VO_2 max) test followed the RE tests. All subjects performed both conditions in randomized order separated by at least 1 week, but not more than 3 weeks. Maximal HEFP, RE, respiratory exchange ratio (RER) during steady-state, and VO_2 max after CT and gel were compared independently using paired two-sample t-tests. Effect size for all variables was calculated using Cohen's *d*. **RESULTS:** Maximal HEFP was not significantly different between conditions (CT: 1.63 ± 0.47 Nm kg^{-1} ; 1.51 ± 0.40 Nm kg^{-1} , $p = 0.18$, $d = 0.29$). There was no difference in RE expressed as % VO_2 max between CT and gel (fixed = $76.9 \pm 10.6\%$ of VO_2 max vs. $76.6 \pm 10.5\%$ of VO_2 max, $p = 0.72$, $d = 0.02$; 10-km = $84.2 \pm 7.2\%$ of VO_2 max vs. $83.7 \pm 6.9\%$ of VO_2 max, $p = 0.17$, $d = 0.07$). There was also no difference in VO_2 max between CT and gel (65.1 ± 9.1 ml $kg^{-1}min^{-1}$ vs. 65.0 ± 10.3 ml $kg^{-1}min^{-1}$, $p = 0.96$, $d = 0.004$); however, RER was significantly increased by CT compared to gel (fixed = 0.92 ± 0.06 vs. 0.90 ± 0.04 , $p = 0.04$, $d = 0.32$; 10-km = 0.94 ± 0.04 vs. 0.92 ± 0.03 , $p = 0.02$, $d = 0.52$). **CONCLUSIONS:** Acute cupping therapy increases steady-state carbon dioxide expiration in well-trained runners without changing oxygen consumption. This has implications for enhanced buffering from putative increased localized blood.

901 Board #27 May 27 1:30 PM - 3:00 PM
Acute Physiological And Cognitive Responses During A 100-mile Ultramarathon
 Laura Wheatley, Ellis Jensen, Nathan Jensen, Adam Clawson, Taran Bailey, Andrew Creer. Utah Valley University, Orem, UT. Email: laura.wheatley@uvu.edu
 (No relevant relationships reported)

Participation in ultra-running events, particularly 100-mile races, is rapidly increasing, yet the physiological demands and dynamics during these events are not well-

understood. It is clear is that physical and metabolic costs of these events are quite high; most participants take 20-35 hours to complete the distance and burn upwards of 10,000 calories. As such, many 100-mi. events are reporting 30-50+% "Did Not Finish" (DNF) rates among their participants. Ultra-runners are also challenged by sleep deprivation, which may lead to the decline of cognitive skills and reaction time over the course of these events, potentially leading to exhaustion or injury. **PURPOSE:** To observe and assess physiological and cognitive dynamics during a 100-mile ultramarathon with relatively flat terrain (~7500 ft. vertical gain). **METHODS:** Nine registered participants (age 46 ± 9.5 yrs., weight 74.0 ± 6.1 kg., height 176.4 ± 7.8 cm.) completed the 100-mile distance (Finish time 24.02 ± 3.23 hrs.). Measurements were collected pre-race, at each 20-mile interval (20, 40, 60, 80), and post-race. Measurements included lap time, foot volume, cognition, and reaction time. Foot volume was measured by making a figure-8 with cloth tape around the subjects' bare foot and ankle. Cognitive performance was assessed using mental calculation and reaction time tests via iOS applications. The mental calculation test involved solving as many equations possible in 100 s, while the reaction test required the participant to tap the screen as many times as possible in 30 s. Comparisons were made across the 20-mile intervals using repeated-measures ANOVA. **RESULTS:** While the duration to complete each 20-mi. lap significantly differed throughout the race ($F_{4,20}=7.896$, $p=0.001$), no differences were found in foot volume ($F_{5,15}=2.13$, $p=0.118$), reaction time ($F_{5,10}=0.945$, $p=0.493$), or cognition ($F_{5,20}=0.896$, $p=0.503$). **CONCLUSIONS:** A relatively flat-terrain 100-mile distance does not elicit cognitive exhaustion or significant foot swelling. More research is needed to determine if there are other physiological or metabolic variables correlated with high DNF rates, and to compare these data to those of more "challenging" courses with greater elevation gain/loss.

Is There A Difference In Strength, Flexibility, Range Of Motion Between Postpartum And Nulliparous Runners?

Shefali Christopher, Hannah Janssen, Kimberly Colby, Erin Kane, Susan Chinworth, Srikanth Vallabhajousula. *Elon University, Elon, NC.* (Sponsor: Dr. Stephen Bailey, FACSM)
Email: schristopher3@elon.edu
(No relevant relationships reported)

Research has shown that women are returning to sport as soon as two weeks after birth with most resuming running by two months postpartum. There are significant musculoskeletal and physiologic changes during pregnancy as well as the effects of childbirth that a postpartum runner to recover from to return to running. Research on returning to running guidelines are nonexistent in the postpartum population. **Purpose:** To investigate the differences in strength, range of motion (ROM), and flexibility between postpartum runners (PP) and nulliparous controls (NC). **Methods:** Healthy postpartum (up to 3 years) and nulliparous runners were recruited from local running groups. Three trials of strength, ROM and flexibility of the hip, knee and ankle were collected using a hand held dynamometer, inclinometer or goniometer respectively and then averaged. An independent samples t-test was performed to compare groups. **Results:** 28 runners participated (14 PP, 14 NC) and were matched for BMI (24.2 kg/sq.m). There were no significant differences in strength of the hip, knee and ankle between the groups. Right and left ankle dorsiflexion was significantly greater in PP group (Right Soleus: PP, 10.33 ± 3.9 cm; NC, 6.75 ± 2.68 cm; $p=0.01$; Left soleus: PP, 11.32 ± 3.8 cm; NC, 7.34 ± 2.74 cm; $p=0.004$; Right Gastrocnemius: PP, $7.95 \pm 2.74^\circ$; NC, $4.67 \pm 4.59^\circ$; $p=0.032$; Left Gastrocnemius: PP, $8.48 \pm 3.39^\circ$; NC, $4.5 \pm 5.23^\circ$; $p=0.026$). Knee and Hip ROM were not significantly different between the groups. **Conclusion:** The current study shows that postpartum runners have significantly more dorsiflexion ROM than controls. When breastfeeding, hormones that influence elasticity like prolactin are still present in the body which may be allowing for the postpartum women to have significantly more ROM than nulliparous controls. Future studies should investigate the effect of breastfeeding duration on range of motion in runners as well as if while breastfeeding return to running guidelines should be different than women that cease breastfeeding at different stages.

Effects Of A 4-week Supplemental Breathwork Program On Aerobic Performance Of Recreational Runners

Adrian Bilyk, Sara R. Sherman, Craig Horswill. *University of Illinois at Chicago, Chicago, IL.*
Email: abilyk89@gmail.com
(No relevant relationships reported)

PURPOSE: This study investigated the effects of a novel supplementary functional breathing program (FBP) on the aerobic performance of recreational runners. **METHODS:** Two groups of recreational runners participated in a 4-week aerobic

endurance training program. One group supplemented the aerobic endurance training program with FBP (FBP; $n=8$, 34.8 ± 5.1 yrs, 25.3 ± 2.5 kg/m²), and one completed the same aerobic endurance program, but not the FBP (CON, $n=8$, 28.8 ± 5.4 yrs, 22.7 ± 2.3 kg/m²). The 4-week running program consisted of 3 days of low intensity running (i.e. below aerobic threshold heart rate), and 1 day of high intensity interval running (i.e. above ventilatory threshold heart rate) per week. FBP consisted of daily breathing exercises completed at rest, and nasal breathing completed during low intensity running sessions. Subjects were tested before (PRE) and after (POST) 4-weeks of training. Testing included a breath holding test (BOLT) followed by a treadmill $\dot{V}O_{2max}$ test using a progressive workload. During the $\dot{V}O_{2max}$ test subjects wore a secure piece of tape covering their mouth under a face mask and were instructed to perform the $\dot{V}O_{2max}$ test to the best of their abilities using this induced nasal breathing condition. When they felt that they could no longer run with nasal breathing, the tape was removed, and the test continued under normal breathing conditions until $\dot{V}O_{2max}$ was reached. The maximal running time using nasal breathing only (MNRT) and maximal nasal breathing oxygen uptake (MNB $\dot{V}O_2$) were recorded and data were assessed using a two-way ANOVA ($p < 0.05$). **RESULTS:** No significant groupXtime interactions were found in MNRT, MNB $\dot{V}O_2$, or $\dot{V}O_{2max}$. There was a significant groupXtime interaction in BOLT times [Δ from PRE: +1.9 sec (CON), +11.7 sec (FBP); $p = 0.04$]. There were significant time effects in MNRT (+58.7 sec, $p=0.038$), MNB $\dot{V}O_2$ (+2.34 ml/kg/min, $p=0.007$), and $\dot{V}O_{2max}$ (+1.26 ml/kg/min, $p=0.028$), suggesting the training stimulus was adequate for the relatively short training program. **CONCLUSION:** This study demonstrated that the 4-week supplementary functional breathing protocol was effective in increasing breath hold time at rest, but not MNRT, MNB $\dot{V}O_2$, and $\dot{V}O_{2max}$ in recreational runners.

Should Runners Pay Less Life Insurance

Jingyuan Zhu, Zezhao Chen, Weimo Zhu, FACSM. *University of Illinois at Urbana, Champaign, Urbana, IL.*
Email: jz5@illinois.edu
(No relevant relationships reported)

PURPOSE: An ad "Can You Run An 8 Minute Mile?" (so that you could qualify for lower rates on life insurance) has brought lots of public attention and discussions, and the purpose of this study was to examine the scientific basis for this claim by estimating the impact of physical fitness on modifiable health risk behaviors and related health care expenditures.

METHODS: Using keywords "Physical Fitness," "Cardiorespiratory," "Health Risks," "Health Care Costs," etc., a comprehensive literature search was conducted, and identified publications were reviewed and analyzed.

RESULTS: Over 45 research publications were documented, and 15 articles were included in this review, focusing mostly on 10 modifiable health risks. Over 23 components were found in influencing the future medical costs, e.g., emotional health, stress, blood glucose levels, extreme bodyweight, tobacco user, sedentary lifestyle, per metabolic equivalents (METs) increase, and so on. Amount them, the key components rising the potential health care costs are high blood glucose levels ranging from 12.5% to 111.5%, high stress ranging from 17.45% to 70%, depression ranging from 8.5% to 46%, etc. The most effective measure to reduce potential health care costs is increasing metabolic equivalents (METs) per unit by aerobic exercises ranging from 5.4% to 13.4%.

CONCLUSION: A set of measures has been developed to assess the relationships between health risks and aerobic fitness, and there is a foundation to support the claim that a fit runner will likely have better aerobic fitness, less likely to have health risks, therefore spend less money in health care and medical expense. Yet, significant work is still needed to develop specific and accurate prediction equations so that the cost of life insurance can be determined based on aerobic fitness and other risk factors.

Validity Of A Field-based Critical Velocity Test On Predicting 5,000 M Running Performance

Nicholas R. Voth¹, Charles M. Laurent², Jessica E. Kiss³, Adam M. Fullenkamp³, ¹St. Ambrose University, Davenport, IA. ²Tarleton State University, Stephenville, TX. ³Bowling Green State University, Bowling Green, OH. (Sponsor: Lynn Darby, FACSM)
(No relevant relationships reported)

Measuring and modeling known adaptations to endurance training can be achieved through a variety of physiological parameters. A unique and emerging performance parameter receiving attention is the notion of critical velocity (CV). This concept allows an athlete's performance to be mathematically modeled based on the relationship that exists between distance and time. **PURPOSE:** To assess the validity

of a field-based CV test on predicting 5,000 m running performance. **METHODS:** Five runners ($VO_{2peak} = 60.14 \pm 4.96 \text{ ml}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$) completed a graded exercise test to determine VO_{2peak} , a CV test to predict performance, and a 5,000 m time-trial. The CV assessment protocol included time-trials of 3,600 m, 2,400 m, and 1,200 m at maximal exertion on a standard 200 m indoor track. Running performance was predicted using the distance-time model where CV was given by the slope and the anaerobic work capacity (D') was given by the intercept from linear regression analysis of distance covered against time for each of the three time-trials. Statistical significance was determined *a priori* at $p < 0.05$. **RESULTS:** Predicted 5,000 m performance ($18.28 \pm 4.38 \text{ min}$) and actual 5,000 m performance ($18.17 \pm 4.07 \text{ min}$) were not significantly different, $t(4) = 0.58$, $p = 0.594$, $d = 0.26$. The mean difference in performance was $0.11 \pm 0.42 \text{ min}$ [95% LoA, -0.71 min , 0.93 min]. CV ($4.59 \pm 0.88 \text{ m}\cdot\text{s}^{-1}$) was significantly slower than actual 5,000 m velocity ($4.73 \pm 0.82 \text{ m}\cdot\text{s}^{-1}$), $t(4) = -3.081$, $p < 0.05$, $d = -1.37$. The mean difference in velocity was $-0.14 \text{ m}\cdot\text{s}^{-1} \pm 0.10 \text{ m}\cdot\text{s}^{-1}$ [95% LoA, $-0.34 \text{ m}\cdot\text{s}^{-1}$, $0.06 \text{ m}\cdot\text{s}^{-1}$]. **CONCLUSION:** The linear distance-time model can be used to predict 5,000 m running performance. This field-based approach allows performance predictions to be made in a relatively short period of time without the need for access to expensive laboratory equipment.

908 Board #34 May 27 1:30 PM - 3:00 PM
Attempting To Acutely Manipulate Ground Contact Time Imbalances Impairs Running Economy

Dustin P. Joubert, Broderick L. Dickerson, Eric J. Jones, Dani D. Willis. *Stephen F. Austin State University, Nacogdoches, TX.* (Sponsor: Stephen F. Crouse, FACSM)
 Email: joubertd@sfasu.edu
(No relevant relationships reported)

Running economy (RE) is a key performance determinant. Biomechanical markers have been linked to RE, including ground contact time (GCT), cadence, and vertical oscillation (VO). Recently, we showed a strong relationship between GCT imbalances and RE. Because these markers can be tracked real-time with consumer-wearable devices, runners now have access to instant feedback concerning their mechanics. **Purpose:** Determine if attempting to correct GCT imbalances real-time alters mechanics and RE. **Methods:** 7 recreational runners ($38 \pm 15 \text{ years}$, $24.7 \pm 2.8 \text{ kg/m}^2$, 5 male) completed 2, 10-minute running trials (9.65 km/hr) on separate days. For both trials, subjects ran with a heart rate (HR) monitor/watch that measured GCT, GCT imbalances, cadence, and VO. For the control trial, subjects were not permitted to receive feedback from the watch. During the feedback trial, the watch was set to display GCT imbalances, and subjects were prompted every 20-30 seconds to monitor/attempt to correct any imbalances. Both trials were preceded by a dynamic warmup and 5-minute jog. For the feedback trial warmup, subjects were acclimated to the watch and allowed to experiment with manipulating their GCT imbalances. VO2 was monitored continuously throughout each 10-minute trial, and average values from 6 to 9 minutes were determined for each trial. Average values for all running biomechanical variables were calculated from 0.5 minutes to 9.5 minutes. Comparisons between trials were made with a dependent sample t-test. **Results:** Data are displayed in Table 1. **Conclusions:** Acutely attempting to correct GCT imbalances did not result in improved mechanics and actually impaired RE. Altering mechanics based on real-time feedback from consumer-wearable devices may impair performance in the short term. Given that GCT imbalances have been linked to impaired RE, future research should determine how to better correct these imbalances rather than attempting to acutely manipulate them.

	Control	Feedback	p-value
VO2 (ml/kg/min)	33.4 (1.8)	35.5 (1.6)	0.011*
RER	.91 (.04)	.92 (.05)	0.170
Heart Rate (beats/min)	159 (26)	163 (24)	0.191
GCT Difference (%)	1.69 (.67)	1.70 (1.70)	0.983

Changes In Step Time And Length Between Kilometer Eleven And Thirty-nine Of A Marathon

Dean M. Cordingley, Jeff Leiter, Sheila McRae. *Pan Am Clinic Foundation, Winnipeg, MB, Canada.*
(No relevant relationships reported)

Purpose: Marathon running invokes neuromuscular fatigue which has been shown to result in kinematic changes in a laboratory setting. However, there are limited studies on changes that take place during a race. The purpose of this study was three-fold: 1) to evaluate the step time and step length at an early and late time point in a full marathon and quantify the change between the two points; 2) to identify differences in step time and length associated with sex; and 3) to determine if step time and length are predictors of race finish time.

Methods: This is an observational study in which runners were filmed at two stations, at kilometer 11 (S1) and kilometer 39 (S2) of a full 42.2 kilometer marathon. Each station incorporated two cameras, one in the sagittal plane to assess kinematics and the second to identify the runners' bib numbers. A 5-meter section of roadway was marked with chalk, delineating each meter, to allow for assessment of step length using Dartfish 5.5 Video Analysis software (Dartfish, Fribourg, Switzerland).

Results: Step time was slower at S2 compared to S1 with a mean difference \pm SD of $0.290 \pm 0.403 \text{ m/s}$ (95%CI $0.246 - 0.334$; $p < 0.001$). Step length was shorter at S2 compared to S1 with a difference of $0.098 \pm 0.111 \text{ m}$ (95%CI $0.086 - 0.110$; $p < 0.001$). There was no interaction in step time for males or females between S1 and S2 (S1, Male $0.35 \pm 0.02 \text{ s}$, Female $0.33 \pm 0.02 \text{ s}$; S2, Male $0.35 \pm 0.02 \text{ s}$, Female $0.34 \pm 0.02 \text{ s}$; $p = 0.099$) however, an interaction was detected for step length (S1, Male $1.16 \pm 0.13 \text{ m}$, Female $1.05 \pm 0.11 \text{ m}$; S2, Male $1.05 \pm 0.13 \text{ m}$, Female $0.98 \pm 0.11 \text{ m}$; $p = 0.01$). A regression model to predict finish time found that step length at S1 accounted for 47% of the variability ($F(1,323) = 283.7$; $p < 0.001$), this increased to 68.3% when S1 step time was included ($F(2,322) = 350.4$; $p < 0.001$), S2 step length increased this to 75.2% ($F(3,321) = 328.4$; $p < 0.001$) while including S2 step time increased it to 76.7% ($F(4,320) = 268.4$, $p < 0.001$).

Conclusion: Step time was slower and step length was shorter at the 39-kilometer point of the full-marathon compared to the 11-kilometer point. Step time did not differ at either time point in the race for males or females; however, they both demonstrated a reduction in step length. Step time and step length at both points in the race are able to account for a significant amount of finish-time variability.

CHARACTERIZING PERFORMANCE IN ELITE TRACK AND FIELD SPRINTERS IN RELATION TO THE ACUTE:CHRONIC WORKLOAD RATIO

Brett R. Hanna, H E. Saylor, J G. Schuster, A Shelton, R C. Hickner, FACSM, G Chow, M J. Ormsbee, FACSM. *Florida State University, Tallahassee, FL.*
 Email: brh17b@my.fsu.edu
(No relevant relationships reported)

PURPOSE: The acute:chronic workload ratio is a method of training load quantification that quantifies internal and external responses to training. Chronic training load is a rolling average of the most recent 28 days of training, and the acute workload is the most recent 7 days. The purpose of this study was to explore the relationship between the acute:chronic workload ratio and peak performance in elite track and field sprinters over the course of the 2018 outdoor season. **METHODS:** The acute:chronic workload ratio was determined retrospectively by calculating the sum of the 7 days before a competition session ratings of perceived exertion of training load (acute load) and dividing it by the average weekly session rating of perceived exertion of training load over the 28-days prior to competition (chronic workload). Partial correlations were used to characterize the relationship between race time (covaried for confounding variables of temperature, humidity, and wind) and the acute:chronic workload ratio. Secondly, the adjusted race times were used to create Z-scores for each sprinters' race time. Bins were then created for the acute:chronic workload ratio ranges, and the Z-scores were pooled into the acute:chronic workload ratio bins with which they corresponded. **RESULTS:** Moderate, positive correlations between the acute:chronic workload ratio and race times for the 100m ($r = 0.542$) and 200m ($r = 0.711$) races were observed. 85% of 100m sprinters and 60% of 200m sprinters had their lowest times within the 0.8-1.3 z-score bin: a range cited in previous research as being associated with a lowest risk of injury. **CONCLUSIONS:** Maintaining an acute:chronic workload ratio between 0.8 and 1.3 may be optimal for elite track and field sprinters to reach their peak performance in the 100m and 200m races. An individualized approach to training load using the acute:chronic workload ratio should help coaches and performance staff with individualized training-load prescription for the sprinters to reach peak performance.

Evaluating The Validity Of Heart Rate Measured By The Suunto Spartan Sport Watch During Trail Running
 RW Salatto¹, James W. Navalta, FACSM¹, Jeff Montes², Nathaniel Bodell³, Bryso Carrier¹, Jacquelyn V.L. Sertic¹, Brenna Barrios¹, Peyton Cater¹, Dustin Davis¹, Jacob W. Manning⁴, Mark DeBeliso, FACSM⁴. ¹University of Nevada, Las Vegas, Las Vegas, NV. ²Monmouth College, Monmouth, IL. ³California State University, San Bernardino, San Bernardino, CA. ⁴Southern Utah University, Cedar City, UT. (Sponsor: James Navalta, FACSM)
 Email: robert.salatto@unlv.edu
 (No relevant relationships reported)

Purpose: In the last decade or so, a plethora of fitness tracking devices have come to market. With this, use of these devices has increased exponentially. Among these devices' many functions is the ability to monitor heart rate (HR). The purpose of this investigation was to determine if HR measured by the Suunto Spartan Sport watch was statistically comparable to that of our criterion, the Polar H7 HR monitor.

Methods: Twenty-one participants (male n = 11, female n = 10, age = 31±2 yrs [mean±SE], ht = 173±2 cm, wt = 76±3 kg) completed a two-mile trail run which included elevation changes of 48 m (McCullough Hills Trail, Henderson, NV), 55m (Three Peaks Trail, Cedar City, UT) or 104m (Bristlecone Trail, Mt Charleston, NV). Heart rate was obtained from the Suunto Spartan Sport watch with accompanying heart strap and the Polar H7 chest-worn heart rate monitor as the criterion reference. Validity was determined using the Mean Absolute Percent Error (MAPE), Bland-Altman analysis with accompanying bias and Limits of Agreement (LoA), and single measures Intraclass Correlations (ICC). A Pearson Product Moment Correlation Coefficient was used to determine the relationship between the validity measures with significance accepted at p<0.05. **Results:** During uphill running, the MAPE was 1.46%, and the lower and upper LoA were -11.53 and 12.34, respectively. The single measures ICC was 0.95 with a 95% CI of 0.953 to 0.956 (F(14834, 14834) = 43.15, p < 0.000). During downhill running, the MAPE was 2.18% with the lower and upper LoA at -15.76 and 14.15, respectively. The single measures ICC was .94 with a 95% CI of 0.946 to 0.951 (F(9075, 9075) = 38.45, p < 0.000). **Conclusions:** These results demonstrate a there was a very low percentage of error for the Suunto Spartan Sport watch in recording HR for both uphill and downhill running. This suggests that The Suunto Spartan Sport might be a valid and reliable option for consumers wishing to monitor HR during outdoor trail running activities.

The T10 Treadmill Test Is Reliable And Valid To Determine Critical Speed In Recreational Runners
 Sergio G. da Silva, Lucio Follador, Edilson F. de Borba, Armando L. Bonfim Neto. UFPR, Curitiba, Brazil. (Sponsor: Carlo Baldari, FACSM)
 (No relevant relationships reported)

Current methods to assess critical speed (CS) are limited by the need for subjects to perform a set number of time-to-exhaustion trials at a constant speed on a treadmill or through several maximal runs on separate days on a running track. **Purpose:** To assess the reliability and validity of a 10-minute submaximal treadmill test of critical speed (CS). **Methods:** Twenty-nine recreational road runners (21 men, 8 women; age: 31.8 ± 5.7 years; VO_{2max}: 52.5 ± 6.9 ml.kg⁻¹.min⁻¹) completed a familiarization trial consisted of running 10 minutes (T10) at a vigorous self-selected speed plus two experimental trials (T10-test and T10-retest). Speed from the T10-test and T10-retest were assessed using coefficient of variation (CV), limits of agreement (LoA) and intraclass correlation (ICC). Next the CS assessed from an additional T10-test was compared with the CS assessed through Field tests. The Field tests consisted of 3 runs on separate days on a running track over 1200, 2400 and 3600 m. **Results:** Reliability analysis between the T10-test and T10-retest showed a CV of 3.2% (95% CI: 2.5-4.3%), LoA of ± .32 m.s⁻¹, and an ICC of .94 (95% CI: .87, .97). Validity data showed that speed (m.s⁻¹) (T10-test: 3.79 ± .47; Field-test: 3.80 ± .49) did not differ between trials (p = 1). Also, the T10-test was highly correlated with the Field-test (r = .90, p < .001) and presented a CV of 4% (95% CI: 3.2-5.4%) and LoA of ± .41 m.s⁻¹. **Conclusion:** The submaximal 10-minute treadmill test (T10) yields reliable and valid estimates of CS providing a useful alternative for assessing CS on a treadmill.

Comparison Of Running Economy Between Straight-line Running And Running With Change Of Direction In Collegiate Males
 Xiaotian Li¹, Yezi Li², Yongming Li³. ¹Central South University, Changsha, China. ²Hunan University of Chinese Medicine, Changsha, China. ³Shanghai University of Sport, Shanghai, China.
 Email: xiaotianli@csu.edu.cn
 (No relevant relationships reported)

Running economy (RE) is one of the important indicators for evaluating endurance. However, treadmill running (TR) test, seems not to be specific enough for team sport, considering their running characteristics with change of direction. **PURPOSE:** To investigate the RE of TR and 20m-shuttle running (SR).

METHODS: 18 physically-active collegiate man (22.4 ± 2.4yrs, 177.4 ± 7.5cm, 69.3 ± 8.2kg, VO_{2max}: 48.9 ± 6.2 ml/kg/min, training experience: 4.6 ± 1.6yrs) volunteered to participate in one incremental TR (8, 10, 12 and 14km/h) and one incremental SR (6, 8, 10 and 12km/h), with the duration of 5 min for each step, and the interval of 1 min between each 2 steps. The VO_{2max} was also assessed in combination with the TR test. The portable gas metabolism system (K4b², Cosmed, Italy) was used to measure the breathing gas during running. The RE for each speed was calculated as the averaged VO₂ of the last 1 min during each step.

RESULTS: At the same running speed (8, 10 and 12km/h), the RE of the SR are lower (oxygen consumption is higher) than the TR (34 ± 3.6 vs. 32.5 ± 4.9 ml/kg/min, 47.9 ± 5 vs. 37.9 ± 5.9 ml/kg/min, 54.9 ± 6.2 vs. 42.0 ± 7 ml/kg/min), with the difference significant at the two higher speed (p<0.05). **CONCLUSIONS:** At the same running speed, the RE of SR is lower than that of TR. Assessment of RE with TR might overestimate the RE in running with change of direction. Running test with change of direction (e.g. SR) is recommended for examining the RE in team sport players.

Roller Massage Prior To Running Does Not Affect Gait Mechanics In Well-trained Runners
 Jessica G. Hunter, Ross H. Miller. University of Maryland, College Park, MD. (Sponsor: Irene S. Davis, FACSM)
 Email: jghunter@umd.edu
 (No relevant relationships reported)

Fatigue is often considered an injury risk factor due to gait adjustments that occur during prolonged running, and 41% of physical therapists recommend roller massage (RM) for injury prevention. However, whether RM prior to running affects gait mechanics and fatigue is currently unknown.

PURPOSE: To investigate the effects of an acute bout of RM on gait mechanics and fatigue after a treadmill run.

METHODS: Fourteen well-trained runners (mean VO₂ max: 53 ml/kg/min) completed 3 sessions each on separate days. In a Baseline session, participants sequentially ran overground at their 5k pace, performed 3 maximal countermovement jumps (CMJ), and completed a maximal oxygen consumption test. Force and motion data were measured during running and jumping. In fatigue sessions, run and CMJ protocols identical to the Baseline session were performed before (PRE) and after (POST) a 30-minute fatiguing treadmill run at a pace associated with 84% of ventilatory threshold. Before the fatiguing run, participants rested for 12 minutes (REST) in one visit, and performed a 12-minute RM protocol (ROLL) in the other visit. Two-way analysis of variance (ANOVA) compared end tidal pressure of carbon dioxide (PETCO₂) every 5 minutes of the treadmill runs to assess fatigue. From the run and CMJ data, 2-way multiple analysis of variance (MANOVA) compared vertical average loading rate (VALR), free moment, tibial shock, and jump height between REST and ROLL conditions at times PRE and POST.

RESULTS: PETCO₂ decreased throughout both treadmill runs, indicating general fatigue (p < 0.001). VALR, free moment, tibial shock, and jump height did not differ significantly between PRE and POST treadmill run on both REST and ROLL days (Table 1).

CONCLUSIONS: Well-trained runners exhibited fatigue in respiratory measures but not in neuromuscular performance, or gait mechanics. RM had no effect on any outcomes. We can conclude no benefits of pre-run RM on resistance to fatigue-induced changes in running mechanics.

Table 1. Outcomes by Condition and Time (mean (SD))

Condition	Time	VALR (BW/s)	Free Moment (%BW*Ht)	Shock (g's)	Jump Height (m)
REST	PRE	100.0 (31.0)	16.6 (7.7)	2.37 (1.06)	0.35 (0.08)
	POST	110.0 (32.5)	17.0 (5.3)	2.57 (0.76)	0.34 (0.08)
ROLL	PRE	95.9 (28.9)	16.1 (5.3)	2.35 (0.70)	0.35 (0.07)
	POST	100.7 (28.6)	17.0 (5.8)	2.61 (0.74)	0.30 (0.06)

Musch, FACSM². ¹University of Hawaii, Hilo, HI. ²Kansas State University, Manhattan, KS. ³University of Utah, Salt Lake City, UT. ⁴University of Colorado, Aurora, CO. ⁵US Food and Drug Administration, Silver Spring, MD. ⁶Purdue University, West Lafayette, IN. (Sponsor: Tim Musch, FACSM)
Email: scott.ferguson@hawaii.edu
(No relevant relationships reported)

Hemolysis associated with Sickle Cell Disease (SCD) compromises nitric oxide (NO) bioavailability and results in a plethora of cardiopulmonary and skeletal muscle complications causing severe exercise intolerance. Recent evidence suggests that cell-free Hb reduces NO bioavailability and lowers the skeletal muscle microvascular PO₂ during contractions, likely due to a reduction in blood flow. Despite these observations, the effects of Hb on skeletal muscle vascular control during locomotory exercise remain unknown. **Purpose:** We tested the hypothesis that acute exposure to Hb would increase mean arterial pressure (MAP) and decrease hindlimb muscle blood flow in the exercising rat. **Methods:** MAP and hindlimb skeletal muscle blood flow (fluorescent microspheres) were measured in male Sprague-Dawley rats (3-6 months, n=8) during submaximal treadmill running (20 ml/min, 5% grade) following a vehicle (0.2 ml of saline) and Hb (50 mg/kg) infusion. **Results:** Relative to control, Hb resulted in a significantly greater exercising MAP (control: 137 ± 3, Hb: 150 ± 3 mmHg, p<0.05) and blood [lactate] (control: 2.51 ± 0.25, Hb: 3.13 ± 0.42 mM, p<0.05). Total exercising hindlimb skeletal muscle blood flow (control: 179 ± 14, Hb: 111 ± 7, ml/min/100 g, p<0.05) and vascular conductance (control: 1.34 ± 0.13, Hb: 0.75 ± 0.05 ml/min/100 g/mmHg, p<0.05) were lower following Hb infusion when compared to control. **Conclusion:** These data support the hypothesis that free Hb impairs vascular control and lowers skeletal muscle O₂ delivery during exercise and provides a potential mechanism by which hemolytic diseases like SCD impair exercise tolerance in humans. Peripheral Revascularization Reverses The Decline In Active Muscle Oxygen Saturation In Peripheral Artery Disease**

J. Carter Luck¹, Danielle JK Kim¹, Cheryl A. Blaha¹, Samuel Pai¹, Faisal Aziz¹, John F. Radtka, III¹, Kimberly S. Faszewski², Abigail SL Stickford², Amanda J. Miller¹, Matthew D. Muller³, Lawrence I. Sinoway¹. ¹Penn State College of Medicine, Hershey, PA. ²Appalachian State University, Boone, NC. ³University Hospitals Cleveland Medical Center, Cleveland, OH.
(No relevant relationships reported)

Peripheral artery disease (PAD) is a progressive atherosclerotic disease that limits blood flow to the skeletal muscles in the lower extremity. Reductions in blood flow may be more pronounced during ambulation or exercise and produce leg cramping or pain known as intermittent claudication. Recent studies have shown an exaggerated blood pressure response with lower muscle oxygen saturation (SmO₂) during foot exercise in patients with PAD. However, it is unclear whether surgical and/or

endovascular interventions normalize this response. **PURPOSE:** To examine whether revascularization procedures improve calf muscle SmO₂ and reduce blood pressure responses during dynamic foot exercise in patients with PAD. We hypothesized that revascularization would improve SmO₂ responses (indicating greater tissue perfusion) and that the blood pressure response would be attenuated during exercise. **METHODS:** Patients with symptomatic PAD (n = 6) performed incremental supine plantar flexion exercise, starting at 0.5 kg and increased by 0.5 kg every minute for up to 6 minutes, pre- and one-month post peripheral revascularization procedure. SmO₂ was measured continuously from the gastrocnemius muscle, while heart rate and blood pressure were measured beat-by-beat. **RESULTS:** Reductions in SmO₂ from baseline to end-exercise were attenuated post-revascularization (-6.5 ± 6.2% vs. -39.8 ± 22.5%, P < .05). The change in mean arterial blood pressure was reduced post-revascularization (4 ± 4 mmHg vs. 16 ± 12 mmHg P < .05). PAD patients exercised longer post-revascularization (5.8 ± 0.4 min vs. 4.0 ± 1.5 min P < .05). **CONCLUSIONS:** These data suggest that revascularization lessens the degree and rapidity of decline in SmO₂ during exercise, and lowers the exaggerated blood pressure response in patients with PAD. Endothelial Shear Stress In The Common Carotid Artery During Boxing Training**

Karla F. Carrillo, Francisco Morales-Acuna, Manuel Gomez, Lisa Rodriguez, Paulina Caraveo, Alvaro N. Gurovich, FACSM. The University of Texas at El Paso, El Paso, TX. (Sponsor: Alvaro N. Gurovich, FACSM)
(No relevant relationships reported)

PURPOSE: Endothelial function is highly regulated by the interaction between blood flow and the endothelium. Endothelial shear stress (ESS) is defined as the dragging force generated by this interaction and it has been reported that low ESS affects nitric oxide bioavailability which in turn might increase blood pressure. Exercise programs are one of the best suited approaches to prevent high blood pressure, however, there are no studies describing changes on ESS in the common carotid artery during specific modalities of exercise, such as boxing training. Therefore, the purpose of this study was to quantify ESS in the common carotid artery during maximal and submaximal boxing training in normotensive and pre-hypertensive subjects. **METHODS:** A cohort of 5 healthy normotensive and 5 pre-hypertensive subjects matched by age, gender, height, and weight were recruited for this study. All 10 subjects performed two boxing tests. The first was a graded maximal boxing test to estimate their maximal oxygen uptake (VO₂max). The second one, performed 48 hours after the first evaluation, was a 2-workload steady-state boxing test at 60%VO₂max and at 95%VO₂max for 3 minutes each. A high-definition Doppler ultrasound recorded common carotid artery diameters and blood flow velocities throughout each steady-state condition. ESS was estimated using Womersley's approximation. **RESULTS:** There was a significant increase in antegrade ESS with higher workloads in both groups (p < 0.05 for all). No difference were found in antegrade ESS at baseline (Normotensive: 33.9±13.9 dynes/cm², Pre-HTA: 34.7±5.5 dynes/cm²; p = 0.936), at 60%VO₂max (Normotensive: 51.3±19.1 dynes/cm², Pre-HTA: 49.6±7.6 dynes/cm²; p = 0.894, and at 95%VO₂max (Normotensive: 72.9±30.9 dynes/cm², Pre-HTA: 85.2±12.5 dynes/cm²; p = 0.560) between both groups. Meanwhile, no retrograde blood flow was present at baseline for either groups, but it was identified at 60%VO₂max (Normotensive: 8.1±0.7 dynes/cm², Pre-HTA: 7.8±7.8 dynes/cm²; p = 0.971) and 95%VO₂max (Normotensive: 22.5±18.9 dynes/cm², Pre-HTA: 20.8±5.6 dynes/cm²; p = 0.891). **CONCLUSIONS:** ESS increases in an exercise-intensity manner during boxing training in normotensive and prehypertensive population. Boxing training might be beneficial in high blood pressure prevention due to increments on ESS.

The Effects Of A High Fat Meal On Blood Flow Regulation During Arm Exercise**

Alexander H. Chiu, Lauren Pederson, Jeremy O. Via, Natalie J. Bohmke, Jacob Richardson, Aaron Autler, Hunter Reed, Eric Henderson, Robert L. Franco, Ryan S. Garten. Virginia Commonwealth University, Richmond, VA.
Email: chiu@myemail.vcu.edu
(No relevant relationships reported)

A diet high in saturated fats results in endothelial dysfunction and can lead to atherosclerosis, a precursor to cardiovascular disease. Exercise training is a potent stimulus though to mitigate the negative effects of a high saturated fat diet; however, it is unclear how high-saturated fat meal (HSFM) consumption impacts blood flow regulation during a single exercise session. **PURPOSE:** This study sought to examine the impact of a single HSFM on peripheral vascular function during an acute upper limb exercise bout. **METHODS:** Ten young healthy individuals completed two sessions of progressive handgrip exercise. Subjects either consumed a HSFM (0.84 g of fat/kg of body weight) 4 hours prior or remained fasted before the exercise

bout. Progressive rhythmic handgrip exercise (6kg, 12kg, 18kg) was performed for 3 minutes per stage at rate of 1 Hz. The brachial artery (BA) diameter and blood velocity was obtained using Doppler Ultrasound (GE Logiq e) and BA blood flow was calculated with these values. **RESULTS:** BA blood flow and flow mediated dilation (normalized for shear rate) during the handgrip exercise significant increased from baseline in all workloads, but no differences were revealed in response to the HFSM consumption. **CONCLUSION:** Progressive handgrip exercise augmented BA blood flow and flow mediated dilation in both testing days; however, there was no significant differences following the HFSM consumption. This suggests that upper limb blood flow regulation during exercise is unaltered by a high fat meal in young healthy individuals.

A Physiological Analysis Of Vibrating Orthotics

Katie Hudson, Dallin Johnson, Austin Kropushek, Tyler Standifird, Anthony Ciccone, Shane Draper. *Utah Valley University, Orem, UT.*

(No relevant relationships reported)

INTRODUCTION: Orthotics are commonly used to aid individuals with foot disorders such as foot or arch pain and gait abnormalities. A new development of vibrating orthotics, which sends out safe vibration frequencies, are gaining popularity on the market. Future developments could lead to vibrating insoles being beneficial for individuals with restricted blood flow, nerve damage, or balance issues caused by diseases such as diabetes or multiple sclerosis. However, few studies have been done on the efficacy and potential benefits. **PURPOSE:** The purpose of this study was to determine if vibrating orthotic insoles increased the amount of blood flow to the foot and ankle at rest. **METHODS:** Participants included 5 students ages 22-26 years. An Initial baseline test was administered upon arrival and again after resting for 30 minutes on the examination table. The Logiq 7 ultrasound Doppler transducer (9L probe at 5 Mhz) was used to locate the posterior tibial artery for the baseline measurement and probe placement was marked on the skin for consistent measuring. Following the second baseline measurement, vibrating orthotics were turned on and blood flow measurements were taken in 5 minute increments for 45 minutes. For each measurement, the artery was found and blood flow was measured for 7 seconds. Blood flow was calculated in milliliters per minute based on blood velocity and arterial radius utilizing the following equation: $\text{Blood flow} = \text{Vmean} \pi (\text{vessel diameter}/2)^2 \times 60$. **RESULTS:** Blood flow was analyzed across time using a multi-level model with subject as a random effect and time (categorical) as a fixed effect. There was a significant main effect of time. Tukey post hoc analysis revealed a difference between the first baseline and after 45 minutes of vibration ($p=0.0375$), but no significant difference between any other measurements. After 45 minutes of vibration, blood flow increased 3.46 ml/min (126%). **CONCLUSION:** The results suggest that the use of vibrating insoles may be beneficial for increasing blood flow in the foot and ankle. The use of vibrating insoles may be beneficial for individuals with conditions that restrict blood flow in the foot and ankle such as peripheral artery disease, diabetes, or poor circulation.

Upper Body Exercise And Passive Limb Movement To Increase Limb Blood Flow In Paraplegics

Keith J. Burns¹, Brandon S. Pollock¹, Jon Stavres², John McDaniel³. ¹Walsh University, Canton, OH. ²Penn State University College of Medicine, Hershey, PA. ³Kent State University, Kent, OH.

Email: kburns@walsh.edu

(No relevant relationships reported)

Previous investigations on the ability of upper body exercise (UBE) to increase femoral artery blood flow (FABF) in the paraplegic population have produced a wide range of results. However, this could have been the result of a non-homogenous population with a wide range of injury level and severity. The use of a more homogenous population, controlling for both level and severity of injury may result in more robust data. In addition, previous reports suggest passive limb movement (PLM) could be used as a modality to increase femoral artery blood flow in this population. A combination of UBE and PLM may provide a sufficient stimulus for a robust increase in femoral artery blood flow. **PURPOSE:** To determine the effectiveness of UBE when used alone and in combination with PLM to increase FABF in the paraplegic population. **METHODS:** Nine paraplegics with a clinically confirmed complete lesion between the 3rd and 11th thoracic vertebra participated in the study. The subjects underwent 10 minutes of (UBE), 5 minutes at a low intensity (LI) and 5 minutes at a moderate intensity (MI), during which FABF was measured. After a 30 minute break, the protocol was replicated with the addition of repeated bouts of passive limb movement being conducted every other minute during the upper body exercise (CMB). **RESULTS:** Two-way repeated measures ANOVA showed no statistically significant interactions ($p>0.05$) between the two exercise modalities for changes in FABF. During the UBE condition, while not statistically significant, FABF increased from

113±78 ml/min to 160±130 ml/min ($p=0.06$) and 162±131 ml/min ($p=0.06$) during the LI and MI conditions, respectively. FABF for the CMB protocol was 119±93 ml/min and increased to 150±125 ($p=0.09$) and 155±136 ($p=0.13$) ml/min during LI and MI conditions, respectively. **CONCLUSIONS:** While not statistically significant, these data indicate the upper body exercise when used in combination with passive limb movement can invoke a large increase in femoral artery blood flow. This could have a profound clinical application for this population.

Dietary Nitrate Does Not Increase Exercising Muscle Blood Flow In Rat With Pulmonary Arterial Hypertension

Gary M. Long¹, Andrea Frump², Ashley Troutman², Melissa Mailand², Kaylee Ann Ellis², Amanda Fisher², Keith Avin², Tim Lahm², Andrew R. Coggan, FACSM³, Mary Beth Brown⁴.

(No relevant relationships reported)

PURPOSE: Pulmonary arterial hypertension (PAH) is a disease characterized by pulmonary artery remodeling, right ventricular hypertrophy, and exercise intolerance. We have previously found a significant reduction in skeletal muscle blood flow during exercise in a rat model of PAH, accompanied by an increase in blood lactate. In an attempt to increase flow, we administered beetroot juice (BRJ) to severely afflicted PAH rats, as BRJ has previously been shown to be effective in animal models and patient populations.

METHODS: Male Sprague Dawley rats ($n=18$, 200-250 g) were injected with 60 mg/kg monocrotaline to elicit a severe PAH phenotype. At 3 wk post-injection, rats performed two trials of a $\text{VO}_{2\text{max}}$ treadmill test 2 h after oral gavage of a single dose (1 mmol/kg) of BRJ (BRJ, $n=9$), or placebo (PL, $n=9$), in counterbalanced order. Three days later, rats performed a final treadmill run 2 h after gavage of either BRJ or PL, in which fluorescent microspheres were administered during running (at 50% $\text{VO}_{2\text{max}}$) to determine skeletal muscle blood flow. Nitrate and nitrite concentrations in plasma and skeletal muscle samples were determined via HPLC, whereas muscle cGMP was measured using ELISA.

RESULTS: As expected, MCT induced impaired exercise tolerance with a 26±6% (+/-SE) reduction in $\text{VO}_{2\text{max}}$ at 3 wk post-injection, that was not improved with BRJ ($p=0.15$). BRJ significantly increased plasma nitrate ($p<0.001$) and nitrite ($p=0.002$) compared to PL; however only nitrate was elevated in the soleus ($p=0.006$) and vastus lateralis ($p=0.02$) by BRJ, with no significant differences in nitrite ($p=0.13-0.66$) or cGMP ($p=0.08-0.68$). BRJ did not increase blood flow in any of the 8 muscles sampled when compared to PL ($p=0.23-0.96$), nor did it reduce lactate accumulation during exercise ($p=0.37$).

CONCLUSIONS: A single dose of dietary nitrate does not enhance exercising muscle blood flow or $\text{VO}_{2\text{max}}$ in a PAH rat, despite significantly increasing plasma nitrate and nitrite. This may be explained by a lack of efficacy in BRJ increasing muscle nitrite and cGMP, known mediators of the nitric oxide pathway and tissue perfusion. Future work should examine mechanisms for reduced skeletal muscle blood flow and further exploration of nitric oxide signaling in PAH patients. Racial Differences In Exercising Limb Blood Flow During Elevated Sympathetic Activity

Austin C. Hogwood¹, Kevin Decker², Ashley Darling², Jennifer Weggen², Alex Chiu², Ruhi Maniyar², Ryan Garten². ¹University of Virginia, Charlottesville, VA. ²Virginia Commonwealth University, Richmond, VA.

(No relevant relationships reported)

PURPOSE: Young, healthy African Americans (AA) exhibit lower vascular conductance during an exercise bout compared to Caucasian Americans (CA). This disparity may be due to greater sympathetic vasoconstriction and an impairment in functional sympatholysis during exercise in AA. Thus, the purpose of this study is to examine racial differences in vascular conductance during lower limb exercise in the presence of elevated sympathetic activity administered via cold pressor test (CPT). **METHODS:** A total of 5 African American (AA) and 4 Caucasian (CA) young (24 ± 2 yrs), healthy males were recruited. Subjects then underwent 6 minutes of rhythmic plantar flexion (PF) exercise at 30% of their previously determine maximum voluntary contraction (MVC). Doppler ultrasonography was utilized to measure superficial femoral artery blood flow on the exercising leg while simultaneous measures of mean arterial pressure (MAP) were obtained via finger plethysmography. Subjects underwent the CPT (minutes 4-6) during which the hand was placed in cold water (4 °C) during PF exercise. Measures were obtained during steady state exercise blood flow

(measured at minutes 3-4) and during the CPT (measured at minute 5-6) to determine differences in vascular conductance with and without the presence of elevated sympathetic activity.

RESULTS: The CPT resulted in similar increases in MAP in both AA (+24.8 ± 3 mmHg) and CA (+25.56 ± 13 mmHg) (p = 0.95) when compared to PF exercise alone. Exercising leg blood flow [AA (-38.89 ± 62 mL/min); CA (+137.97 ± 62 mL/min) (p = .09)] or leg vascular conductance [AA (-1.00 ± .6 mL/min/mmHg); CA (-0.28 ± .4 mL/min/mmHg) (p = .35)] was not different between groups when evaluated during the CPT and expressed as change from PF exercise alone.

CONCLUSIONS: This study suggests that during lower limb exercise, young AA males, when compared to CA, are similarly resistant to reductions in lower limb vascular conductance in response to elevated sympathetic activity.

Sex-differences In Exercising Hemodynamics: Role Of Exercising Muscle Mass

Joshua Bovard¹, Daniele A. Cardinale², Filip J. Larsen², Emma Reiter¹, Mads Jensen-Urstad³, Erik Rullman³, David Morales-Alamo⁴, Bjorn Ekblom², Jose A. L. Calbet⁴, Robert Boushel¹.

(No relevant relationships reported)

Sex-differences in O₂ transport include O₂ content (C_aO₂) and quantity of muscle mass. **PURPOSE:** To determine their consequences on exercising hemodynamics with large (e.g., 2-leg cycling (BIKE)) vs. small (e.g., 1-leg knee extension (KE)) muscle mass. **METHODS:** Healthy young subjects (4M, 3W) completed BIKE and KE exercise tests. The femoral artery and vein were catheterized to measure leg blood flow (Q), C_aO₂, and mean arterial pressure (MAP). Vascular conductance (VC), O₂ delivery, and leg O₂ uptake (VO₂) were calculated. Measures were normalized to the right leg (BIKE) or quadriceps (KE) lean mass. Whole body VO₂ was measured with a metabolic cart. Men and women were compared at similar and maximal work rates. **RESULTS:** Body mass was greater in men (M: 80±6 vs. W: 59±12 kg, p=0.03). Although quadriceps mass (3.3±0.2 vs. 2.0±0.3 kg, p<0.001) and C_aO₂ were lower, women had a higher mass-specific Q, VC (p=0.054), O₂ delivery, and leg VO₂ to maintain whole body VO₂ during similar KE (Table 1). These differences were maintained during maximal KE, at which women tended to achieve a higher mass-specific work rate (21±2 vs. 25±3 W·kg⁻¹, p=0.10). They were also apparent during similar BIKE despite a lower leg lean mass in women (8.7±0.3 vs. 5.3±0.7 kg, p<0.001). However, the differences were no longer present during maximal BIKE when mass-specific work rate was similar (21±2 vs. 20±2 W·kg⁻¹, p=0.70) and whole body VO₂ was lower in women. **CONCLUSION:** These findings highlight a greater hemodynamic capacity for women to overcome differences in C_aO₂ and maintain whole body VO₂ at similar work rates during exercise. They also implicate the quantity of exercising muscle in facilitating the greater hemodynamic capacity and mass-specific work rate during maximal exercise with a small but not large muscle mass. Support: The Swedish National Centre for Research in Sports, Ministerio de Educacion y Ciencia of Spain, Dr. Manuel Morales Foundation, NSERC

Effects of Dietary Sodium Intake on Blood Flow Regulation During Exercise in Salt Resistant Individuals

Kevin P. Decker, Morgan T. Kimmel, Hunter L. Reed, Alex H. Chiu, Austin C. Hogwood, Jennifer B. Weggen, Ashley M. Darling, and Ryan S. Garten. Department of Kinesiology and Health Sciences Virginia Commonwealth University, Richmond, VA.

PURPOSE: Dietary guidelines for sodium intake is less than 2,300 mg/day, yet 90% of Americans exceed this value. This study examined individuals resistant to salt-induced changes in blood pressure to determine the impact of a high sodium diet on blood flow regulation during upper and lower limb exercise. **METHODS:** Six young (25 ± 2 years) males followed recommended dietary sodium intake guidelines on two separate weeks, with one week supplemented with salt capsules (HS: 6,900 mg/day of sodium) and the other week supplemented with placebo capsules (LS: 2,300 mg/day of sodium). Resting central hemodynamic measurements [heart rate (HR), heart rate variability (HRV), and mean arterial pressure (MAP)] were evaluated the end of each diet. Peripheral hemodynamic measurements [blood flow (BF), shear rate (SR), and flow mediated dilation (FMD)/SR] of the brachial and superficial femoral artery were taken during rhythmic (1 Hz), progressive handgrip (HG) and plantar flexion (PF) exercise, respectively. Exercise workloads were three minutes in length and increased by increments of 8 kilograms until exhaustion. **RESULTS:** Between each diet (LS and HS) there were no significant differences in resting MAP (82 ± 4 v 80 ± 5 mmHg; p = 0.3), HR (56 ± 6 v 59 ± 10 bpm; p = 0.4), or HRV (2.7 ± 1.9 v 8.3 ± 15.1 LF/HF; p = 0.4). During progressive HG and PF exercise the BF, SR, and FMD/SR were significantly increased by workload (p < 0.03 for all), but not different between diets (p > 0.05 for all). **CONCLUSION:** Despite previous evidence reporting a HS diet can impair resting vascular function, this study revealed that peripheral vascular function and blood flow regulation during exercise is not impacted by a HS diet in salt resistant individuals.

Impact Of 6-month Exercise Training On Neurovascular Function In Persons With Spinal Cord Injury

Erin D. Ozturk¹, Matthew Lapointe¹, Dong-Il Kim², Jason W. Hamner¹, Can Ozan Tan¹. ¹Spaulding Rehabilitation Hospital, Cambridge, MA. ²Gachon University, Gyeonggi-do, Korea, Republic of.

(No relevant relationships reported)

Accumulating evidence shows an exacerbated incidence of cognitive impairment after spinal cord injury (SCI); however, the physiology that underlies this apparent post-SCI cognitive decline is unknown.

PURPOSE: To investigate the impact of injury and 6-month full-body exercise training on neurovascular coupling in individuals with SCI.

METHODS: In 24 participants with SCI and 16 controls, we investigated hemodynamic (heart rate, blood pressure, CO₂) and middle cerebral artery blood flow velocity responses to a working memory task (neurovascular coupling) before and after training. Neurovascular coupling was compared across groups while accounting for injury parameters. Within individuals with SCI, 6-month changes in neurovascular coupling and its relation to changes in aerobic capacity were compared via linear mixed effect model.

RESULTS: Reaction time tended to be higher in individuals with SCI, especially those with high-level ($\geq T4$) injuries, possibly due to upper motor impairments. Neurovascular coupling was graded across task difficulty ($p < 0.01$), while injury did not have a significant impact (group effect $p = 0.99$, interaction $p = 0.70$). Individuals with low-level injuries ($< T4$) had higher aerobic capacity than those with high-level injuries ($p < 0.01$). Aerobic capacity increased significantly with training in both groups ($p < 0.01$). While there was no overall significant improvement in neurovascular coupling with training at the group level, the degree of improvement was closely related to that in aerobic fitness in individuals with high-level ($R^2 = 0.19$, $p = 0.03$) but not low-level ($R^2 = 0.04$, $p = 0.46$) injuries, which translated to an increase in reaction time ($R^2 = 0.16$, $p = 0.05$).

CONCLUSIONS: The apparent cognitive impairment after SCI is primarily due to physical deconditioning, rather than injury itself, and can be mitigated by aerobic exercise training. This has significant implications for long-term care and management for individuals with SCI.

Email: joaquin.gonzales@ttu.edu

(No relevant relationships reported)

Oral supplementation with L-citrulline (CIT) has been reported to improve muscle oxygenation during moderate-intensity exercise in young men; however, examination of the impact of CIT in young women is scarce. **PURPOSE:** To examine the influence of CIT on muscle blood flow responses to exercise in young women. **METHODS:** Women were assessed during the follicular ($n = 13$, 24 ± 2 y) and luteal ($n = 11$, 25 ± 2 y) phases of the menstrual cycle. Supplementation with CIT (6 g/day) or placebo occurred 7 days prior to the testing day in a crossover design across two menstrual cycles. All women performed rhythmic handgrip exercise at 10% maximal grip strength while forearm blood flow (FBF) was measured in the right brachial artery using Doppler ultrasound. FBF was calculated per duty cycle (contract:relax, 1:2s) before being fit with a monoexponential model. Amplitude of the FBF response and the number of duty cycles for FBF to reach 63% of the steady-state amplitude (τ FBF) were derived from the model. **RESULTS:** Menstrual cycle groups were similar in age, body mass index, resting brachial artery diameter, and maximal grip strength (all $p > 0.10$). CIT did not change the amplitude of FBF or τ FBF as compared to placebo in women tested during the follicular (CIT vs. placebo: 166 ± 50 vs. 158 ± 52 ml/min, $p = 0.41$; 7 ± 5 vs. 6 ± 3 duty cycles, $p = 0.28$) or luteal phases (163 ± 41 vs. 173 ± 49 ml/min, $p = 0.34$; 11 ± 5 vs. 9 ± 4 duty cycles, $p = 0.26$). Interestingly, the amplitude of the FBF response was similar between women tested during the follicular (163 ± 44 ml/min) and luteal (170 ± 41 ml/min, $p = 0.68$) phases, but τ FBF was slower for women tested during the luteal as compared to the follicular phase (11 ± 4 vs. 7 ± 3 duty cycles, $p = 0.01$). **CONCLUSION:** Muscle blood flow response to rhythmic handgrip exercise was not changed by short-term supplementation with CIT in young women irrespective of menstrual cycle phase.

Hypertrophic Cardiomyopathy And Heart Failure With Preserved Ejection Fraction: A Common Phenotype Explaining Exercise Intolerance

Katrin A. Dias¹, James P. MacNamara¹, Michinari Hieda¹, Christopher M. Hearon¹, Erin J. Howden², Aslan T. Turer³, Mark S. Link³, Satyam Sarma¹, Benjamin D. Levine, FACSM¹. ¹Institute for Exercise and Environmental Medicine, Texas Health Presbyterian Hospital Dallas & University of Texas Southwestern Medical Center, Dallas, TX. ²Baker Heart and Diabetes Institute, Melbourne, Australia. ³University of Texas Southwestern Medical Center, Dallas, TX.

(No relevant relationships reported)

Hypertrophic cardiomyopathy (HCM) is characterized by diastolic dysfunction which contributes to exercise intolerance despite a preserved ejection fraction. This phenotype is strikingly similar to that reported in HFpEF. While disease etiologies clearly differ and HCM patients may not have heart failure, the degree of exercise intolerance is comparable and may be due to similar impairments in cardiac function. **PURPOSE:** To compare systolic function and early diastolic relaxation during submaximal cycle exercise in HCM and HFpEF patients. **METHODS:** Patients with HCM without heart failure ($n = 12$, 48 ± 7 years) were compared to HFpEF patients ($n = 12$, 67 ± 5 years), and old ($n = 11$, 70 ± 5 years) and young ($n = 11$, 31 ± 3 years) controls. Subjects underwent semi-recumbent echocardiography at rest and during steady state exercise at a heart rate of 100bpm. Tissue Doppler velocities of the septal and lateral mitral annulus were averaged during systole (S') and early diastole (E'), and the difference in resting and exercise velocities were calculated. **RESULTS:** There were no differences in resting S' between groups, and all subjects similarly increased S' from rest to exercise (Figure). HCM patients had significantly lower resting E' velocities compared to HFpEF patients and young controls ($P = 0.032$ and $P < 0.001$, respectively). While all groups augmented E' from rest to exercise ($P < 0.05$), the magnitude of the increase was significantly less in patients with HCM compared to young and old controls but indistinguishable from HFpEF patients. **CONCLUSION:** Patients with HCM are unable to increase E' from rest to exercise to the same extent as healthy young and old individuals. In fact, augmentation of early diastolic relaxation was similar between HCM and HFpEF patients, despite the HCM cohort being almost 20 years younger and without heart failure. Although the disease etiologies differ, these data suggest a common phenotype explaining exercise intolerance in HCM and HFpEF.

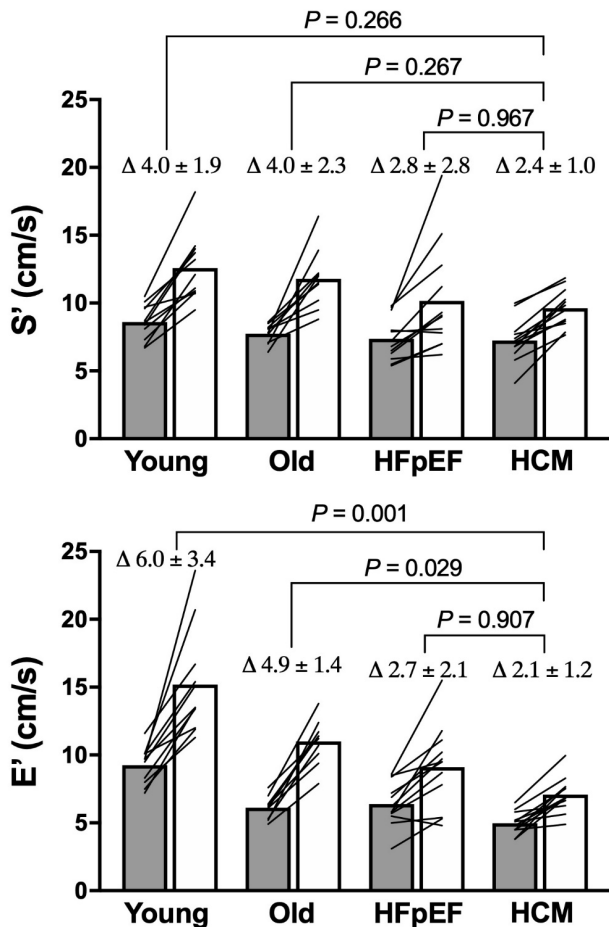

Figure. Systolic (S') and diastolic (E') tissue Doppler velocities at rest (grey bar) and during steady state exercise (white bar) in healthy young and old subjects, and patients with HFpEF and HCM. Δ indicates the mean change and standard deviation from rest to exercise.

and CON (86±12 mmHg; $P=0.17$) and MAP increased similarly during IHG (ARNi: Δ 10±12 vs. CON: 8±10 mmHg) and PEI (ARNi: Δ 6±4 vs. CON: 5±10 mmHg; ANOVA $P>0.90$). Resting MAP was reduced after 12 weeks of ARNi (87±7 mmHg) and was unchanged in CON (91±20 mmHg; ANOVA interaction $P=0.048$). However, the increase in MAP during IHG (ARNi: Δ 11±8 vs. CON: 13±6 mmHg; $P>0.60$) and PEI (ARNi: Δ 8±6 vs. CON: 12±3 mmHg; $P>0.60$) after 12 weeks was not impacted by ARNi (ANOVA time $P=0.24$) or different between groups. Maximal raw force and RPE ratings during IHG were similar between groups and not different following 12 weeks of ARNi (ANOVA $P>0.70$). **CONCLUSION:** These preliminary data suggest that although 12 weeks of ARNi therapy reduces resting MAP in HFREF, there are no significant reductions on MAP response to exercise. Additional data are needed to fully understand the impact of ARNi on cardiovascular responses to exercise in HFREF. Supported by ACSM grant 19-00934 and P20 GM 113125.

The Feasibility And Physiological Responses Of Single Leg Cycling In Individuals With Hemiparesis
 Tyler J. Singer, John McDaniel, Cody Dulaney, Eric Heidorn.
 Kent State University, Kent, OH. (Sponsor: Ellen Glickman, FACSOM)
 Email: tsinger4@kent.edu
 (No relevant relationships reported)

INTRODUCTION: The primary treatment for individuals post stroke is intensive rehabilitation focusing on improving and restoring motor control. Typically, the rehabilitation does not focus on increasing cardiovascular fitness due to the inability of these individuals to coordinate those modalities of aerobic exercise (i.e. walking and cycling). Both cycling and walking can promote increases in cardiovascular fitness in individuals' post-stroke but most of the increases are minimal. Single leg cycling (SLC) is a modality of exercise that has never been attempted by this population. Working around their affected side while utilizing SLC may be what they need as a means to get a quality cardiovascular workout. **PURPOSE:** The purpose of this study aims to examine feasibility and safety of SLC in this population as well as how effective it may be at increasing oxygen consumption, heart rate, blood pressure, cognitive function, cerebral blood flow and proprioception compared to traditional double leg cycling (DLC). **METHODS:** Individuals with completed a bout of DLC and SLC. We continuously collected metabolic data (Oxygen consumption, resting exchange ratio), cardiovascular data (Heart rate, blood pressure, cardiac output, stroke volume) as well as tissue saturation via Near infrared spectroscopy. The subjects were randomized into either SLC or DLC. We started both exercise bouts at a wattage they could handle and increased by 10w every 30 seconds until volitional fatigue or they reached a goal of 55% of their heart rate reserve. They had a 15-minute washout period in between exercise bouts. **RESULTS:** Vo₂ was elevated during the SLC trial compared to the DLC trial ($p=0.05$). HR and BP were also elevated during the SLC trial compared to DLC ($p=0.01$). There was no significant difference in RPE across the two conditions. **CONCLUSION:** The results suggest that single leg cycling may be more beneficial to individuals with hemiparesis. Elevated Vo₂, HR, and BP during SLC suggest that they were able to work around their affected side and coordinate this exercise more effectively than traditional DLC.

 (No relevant relationships reported)

Angiotensin Receptor Neprilysin inhibitors (ARNi) is a new class of drug approved for heart failure patients with reduced ejection fraction (HFREF). ARNi reduces resting blood pressure (BP) in HFREF. However, the effect of ARNi on BP response to exercise in HFREF has not been established. **PURPOSE:** We hypothesized that BP response to isometric handgrip exercise (IHG) would be attenuated in HFREF after 12 weeks of ARNi therapy. **METHODS:** HFREF participants were recruited from local cardiology clinics and completed a baseline experimental visit and follow up visit 12 weeks later: 6 patients were prescribed ARNi by their cardiologist [64±10 years, Men: 5, BMI: 30±6 kg/m², EF: 26±7%; 4 with Non-ischemic cardiomyopathy (NICM)], and 5 participants continued on conventional treatment [CON: 57±6 years, Men: 2, BMI: 27±5 kg/m², EF: 30±4% and NICM: 3; all $P = NS$]. During each experimental visit, BP was measured at rest and during 2-minutes IHG at 30% maximal voluntary contraction followed by post-HG exercise ischemia (PEI) to isolate the metaboreflex. The change in mean arterial pressure (Δ MAP) from baseline to exercise and PEI was assessed; statistical comparisons were performed using 2x2 repeated-measures ANOVA. **RESULTS:** At baseline, resting MAP was similar between ARNi (96±14 mmHg)

Sensory Neuron Sensitization By Pkc-induced Trpv1 Phosphorylation In Type 2 Diabetic Rats
 Rie Ishizawa¹, Han Kyul Kim¹, Norio Hotta², Gary A. Iwamoto¹, Wanpen Vongpatanasin¹, Jere H. Mitchell, FACSOM¹, Scott A. Smith¹, Masaki Mizuno¹. ¹University of Texas Southwestern Medical Center, Dallas, TX. ²Chubu University, Kasugai, Kasugai, Japan.
 (No relevant relationships reported)

Skeletal muscle reflex-induced increases in blood pressure are exaggerated during exercise in type 2 diabetes mellitus (T2DM). We previously demonstrated that skeletal muscle afferent discharge in response to capsaicin, a transient receptor potential cation channel subfamily V member 1 (TRPV1) agonist, is heightened in T2DM likely contributing to the potentiated pressor response. However, the underlying mechanisms remain unclear. Evidence suggests that the high glucose levels in T2DM sensitize sensory neurons through the receptor for advanced glycation end products (RAGE)/ protein kinase C (PKC) pathway in dorsal root ganglia (DRG). Moreover, early-stage diabetes associated with TRPV1 overactivity is mediated through PKC. Therefore, it was hypothesized that the augmentation in muscle afferent discharge in T2DM previously reported is due to the phosphorylation of TRPV1 via an overactive RAGE/PKC pathway. **PURPOSE:** To investigate 1) the impact of T2DM on plasma levels of advanced glycation end products (AGE) and high-mobility group box-protein 1 (HMGB-1), both RAGE ligands, and 2) the impact of T2DM on the RAGE/PKC pathway including the phosphorylation of TRPV1 in DRG subserving skeletal muscle afferents. **METHODS:** For 14-16 weeks, Sprague-Dawley rats were given either a normal diet (control) or a high fat diet in combination with a low dose (35 mg/kg) of

streptozotocin (T2DM). Plasma insulin, HMGB1 and AGE were determined using ELISA. RAGE, phosphorylated PKC and TRPV1 protein levels were quantified in DRG by western blotting. **RESULTS:** After overnight fasting, T2DM rats exhibited hyperglycemia (95 ± 6 vs. 156 ± 18 mg/dL, $P < 0.05$) and hyperinsulinemia (1.6 ± 0.2 vs. 4.1 ± 0.4 ng/mL, $P < 0.05$). HMGB1, AGE and RAGE did not differ between groups. Phosphorylated PKC (1.0 ± 0.1 vs. 1.2 ± 0.2 arb unit, $P = 0.08$) and TRPV1 (1.0 ± 0.3 vs. 1.3 ± 0.4 arb unit, $P = 0.08$) levels in DRG tended to be greater in T2DM than control.

CONCLUSIONS: These findings suggest that phosphorylated TRPV1 may be increased by PKC overactivity in DRG of T2DM but acts independently of RAGE. Importantly, these changes may mediate the sensitization of skeletal muscle afferents facilitating the exaggerated pressor response to exercise characteristic of T2DM.

Acute Effect Of Hyperglycemia On The Mechanoreflex And Metaboreflex

Yu Huo, Ann-Katrin Grotle, Michelle L. Harrison, Audrey J. Stone. *The University of Texas at Austin, Austin, TX.* (Sponsor: Hirofumi Tanaka, FACS) Email: henryhuo@utexas.edu
 (No relevant relationships reported)

Recent studies in both humans and rodents have shown that the mechanoreflex and metaboreflex are exaggerated in type 2 diabetes mellitus (T2DM). Hyperglycemia is a main characteristic of T2DM and is known to cause damage to both cardiovascular and nervous system structures. However, the effects of the presence of hyperglycemia on the mechanoreflex and metaboreflex are not known. **PURPOSE:** To determine the acute effect of hyperglycemia on the mechanoreflex and metaboreflex.

METHODS: Experiments were conducted after an overnight fast in unanesthetized, decerebrated healthy male and female Sprague-Dawley rats. The mechanoreflex was evoked by stretching the Achilles tendon for 30 s and the metaboreflex was evoked by locally injecting lactic acid (0.2ml, 24mM) into the hindlimb. Time and dosage for glucose infusion were selected based on a preliminary study that showed infusing 250 mg/ml of glucose solution for 15 min into the hindlimb circulation, with blood flow to and from the hindlimb restricted, would elevate local blood glucose concentration to the same degree as that seen in T2DM rats with an exaggerated exercise pressor reflex. To elicit an acute hyperglycemia environment while preventing an endogenous insulin response, somatostatin (3.9 ug/100 ul) was infused systemically and simultaneously along with local glucose infusion. Changes in mean arterial pressure (Δ MAP) and heart rate (Δ HR) in response to tendon stretch and lactic acid injection were measured and compared before and after infusion.

RESULTS: We found that the peak pressor and cardioaccelerator responses to tendon stretch were not significantly affected by acute hyperglycemia (Δ MAP before: 12 ± 2 mmHg, after: 12 ± 3 mmHg, $n=6$, $p>0.05$; Δ HR before: 10 ± 3 bpm, after: 10 ± 3 bpm, $n=6$, $p>0.05$). Likewise, the pressor and cardioaccelerator responses to lactic acid were not significantly affected by acute hyperglycemia (Δ MAP before: 13 ± 2 mmHg, after: 16 ± 3 mmHg, $n=10$, $p>0.05$; Δ HR before: 10 ± 2 bpm, after: 12 ± 5 bpm, $n=10$, $p>0.05$).

CONCLUSIONS: The acute presence of hyperglycemia in the local circulation of the hindlimb does not contribute to the exaggerated mechanoreflex or metaboreflex. This project was supported by NIH R01 HL144723.

The Role Of Camk2δ-MEF2 Signaling Pathway In Aerobic Exercise-induced Improvement Of Cardiac Function In Hypertension

WU Ying, Shi Lijun. *Beijing Sport University, Beijing, China.* Email: wuying@bsu.edu.cn
 (No relevant relationships reported)

Objective: The purpose of this study was to investigate the effects of aerobic exercise on the Calcium/calmodulin-dependent protein kinase II δ (CaMKII δ)-Myocyte enhancer factor-2(MEF2) signaling pathway in SHR myocardial cells, and the role of the A-kinase anchoring protein 150(AKAP150).

Methods: 12-week-old male SHR and WKY rats were randomly assigned to sedentary groups (WKY-SED, SHR-SED) and exercise training groups (WKY-EX, SHR-EX). Exercise groups were performed a 12-week moderate intensity treadmill running. After 12 weeks, the myocardial cells were enzymatically isolated. The experimental methods include HE staining, the Langendorff technique of isolated heart perfusion, immunohistochemistry, immune cell fluorescence, Western blot.

Results: 1) After 12 weeks of exercise, SBP in both WKY-EX and SHR-EX were significantly lower than that of their sedentary counterparts. 2) Compared with the WKY-SED group, the SHR-SED group +dp/dtmax, -dp/dtmax significantly decreased, and the SHR-EX group was significantly higher than the SHR-SED group, +dp/dtmax significantly increased, -dp/dtmax decreased ($P < 0.01$), LVSP increased ($P < 0.01$). 3) The fluorescence intensity of CaM and AKAP150 in the SHR-SED group was higher

than WKY-SED group ($P < 0.01$), and the fluorescence intensity of the SHR-EX group AKAP150 was higher than SHR-SED group ($P < 0.01$), and the expression of CaM was lower than the SHR-SED group ($P < 0.01$). 4) The protein expression of p-CaMKII δ , CaMKII δ and AKAP150 in the SHR-SED group was higher than that in the WKY-SED group ($P < 0.01$). The expression of p-CaMKII δ /CaMKII δ , p-HDAC4/HDAC4 and MEF2 of SHR-EX group are lower than the SHR-SED group ($P < 0.01$). The expression of AKAP150 of SHR-EX was higher than SHR-SED group ($P < 0.01$).

Conclusion: Aerobic exercise reduced the activity of the CaMKII δ -MEF2 signaling pathway and increased the expression of AKAP150 in the SHR myocardial, which is one of the molecular mechanisms to improve the function of the heart.

Key words: cardiac function; CaMKII δ -MEF2 signaling pathway; aerobic exercise; AKAP150

Physical Activity Is An Important Prescription For Kidney Transplant Patients And Those Receiving Dialysis

Eli G. Thalos¹, Alexis C. King², Lewis E. Jacobson³, Jonathan M. Saxe³, Cynthia Villalobos¹, Courtney D. Jensen¹. ¹University of the Pacific, Stockton, CA. ²University of Illinois at Urbana-Champaign, Champaign, IL. ³St. Vincent Hospital, Indianapolis, IN.
 Email: e.thalos@gmail.com
 (No relevant relationships reported)

Chronic kidney disease (CKD) affects 13% of U.S. adults. Patients endure a disproportionate amount of cardiovascular complications with nearly 50% of dialysis patients experiencing a premature death related to cardiovascular disease. Although participation in regular physical activity can mitigate CKD complications, more than half of nephrologists fail to recommend it to their patients. **PURPOSE:** To investigate the effects of physical activity on hemoglobin and health outcomes in CKD patients.

METHODS: We analyzed patients admitted to a hospital in the Midwestern United States. A comprehensive metabolic panel and health history, including physical activity (PA) levels, were obtained upon admittance. Patients were assigned a status of either active (N=23) or sedentary (N=45). Independent-samples t-tests and chi-squared tests compared sedentary and active groups. Linear and negative binomial regression models tested the effect of PA on Hb and hospital length of stay (LOS). **RESULTS:** Across the total sample, patients were 64.7 ± 17.4 years old, 40.3% were obese, they remained in the hospital for 6.9 ± 7.5 days, 16.2% received dialysis during treatment, 5.9% had a history of kidney transplant, and 4.4% died. Patients with a history of transplant had a reduction in Hb of 3.7 g/dL ($p < 0.001$) and exhibited a trend for a higher rate of engagement in PA ($p = 0.073$). Patients receiving dialysis had 2.4 g/dL lower Hb ($p = 0.006$) and comparable rates of PA ($p = 0.616$). All cases of mortality occurred in the sedentary group, and the Hb of patients who expired was 2.2 g/dL lower; owing to a small sample, this failed to reach significance ($p = 0.179$). Physically active patients had 1.4 g/dL higher Hb ($p = 0.041$). Holding constant transplant status and whether patients received dialysis, PA predicted an increase in Hb of 1.75 g/dL ($p = 0.007$; 95% CI: 0.489 to 3.011) and a 96.4% shorter LOS ($p = 0.005$; 95% CI of IRR: 0.003 to 0.373). In turn, Hb was a trending predictor of mortality; each additional g/dL predicted a 38.3% reduction in odds ($p = 0.069$; 95% CI of OR: 0.367 to 1.038). **CONCLUSION:** Independent of dialysis and transplant status, engagement in regular physical activity elicited an increase in Hb and shortened hospital stays among CKD patients. Our findings reinforce the importance of physical activity prescription as a standard component of care.

Evaluating Acceptability Domain Of An Intradialytic Exercise Program-Patient Adherence And Nursing Documentation

Iwona Gabrys¹, Stephanie Thompson². ¹Alberta Kidney Care North, Alberta Health Services, Edmonton, AB, Canada. ²University of Alberta, Edmonton, AB, Canada.
 Email: igabrys12@gmail.com
 (No relevant relationships reported)

For patients with end stage renal disease, exercise during hemodialysis (HD), intradialytic exercise (IDE), may mitigate treatment related symptoms including

cramping, restless legs, and fatigue. In Alberta Kidney Care North, IDE is supervised by a clinical exercise physiologist (CEP) and dialysis unit staff assist with program delivery.

PURPOSE: The aim of this study was to examine program responsiveness to the patients' needs (acceptability) by evaluating documentation of patient adherence. **METHODS:** 1,752 exercise sessions were audited at 6 hemodialysis units. Patient reported participation was collected directly from patients within 10 days of the audit. Baseline and subsequent physical reassessments were examined to verify the validity of patient recall, relative to the required exercise dose. Data points were divided into 2 categories: active IDE participants (A-IDE) and non-active IDE (NA-IDE) participants. A-IDE were defined as patients who completed at least 1 IDE session/week for 4 weeks. NA-IDE participants were defined as those previously assessed and programmed but recently discharged, on a medical hold, or participating in a home exercise program at the time of the audit.

RESULTS: Of the 1,332 A-IDE sessions audited, nurses documented patient participation 28.08%, no participation 49.4%, and did not document 22.52%. Patients reported adherence 63.74%. Physical reassessment data showed improved outcome measures thereby, validating patient recall of adherence. Of 420 NA-IDE HD data sheet analyzed, nurses documented patient participation 1.9%, no participation 70.24%, and did not document 27.85%. Patient report and documentation agreed 2.7%. **CONCLUSIONS:** Assessment of IDE participation is an integral component to the evaluation of an IDE program. Discrepancies between patient report and documented adherence exist. We found that patient report is valid, based on improved measures at reassessments; however, we must establish feasible methods for dialysis staff to collect adherence when CEPs are not present. Staff training, including regular surveys to assess staff knowledge of processes, may provide valuable information on units with a high staff turnover. Implementing an IDE prescription confirmation, as a standard practice in HD treatment preparation, may affirm participation.

Resveratrol Ameliorates Exhaustive Exercise-induced Acute Kidney Injury In Rats Via Sirt1/nf-κB Pathway Modulation

Fang Li, Jianmin Cao. *Beijing Sport University, Beijing, China.*
Email: lifang200621@163.com
(No relevant relationships reported)

PURPOSE: Resveratrol is a naturally sirtuin1 activator, its renal protective effects have been validated in a variety of animal models of kidney disease, however, there is still no systematic study on resveratrol to improve rat kidney damage caused by exhaustive training, and whether the regulation of renal inflammatory response is through SIRT1/NF-κB signaling pathway.

METHODS: In this study, 32 SD rats were randomly divided into: control group (Con), resveratrol group (Rsv), exhaustive exercise group (Ex), exhaustive exercise+resveratrol group (Ex+Rsv). Rsv and Ex+Rsv group were given resveratrol(50mg/kg body weight)by gavage, Ex and Ex+Rsv group performed four weeks of exhaustive training. Anesthesia treatment was taken 24 hours after the last training. **RESULTS:** The results showed that Scr in the Ex group (175.66 ± 16.08 vs. 153.34 ± 8.67 , $P < 0.01$), BUN (6.67 ± 0.53 vs. 5.37 ± 0.19 , $P < 0.01$) and urinary NGAL (9.01 ± 0.18 vs. 7.48 ± 0.31 , $P < 0.01$) were increased significantly compared with the Con group. The expression of NF-κB P65 in Ex group was significantly increased (0.77 ± 0.10 vs. 0.27 ± 0.03 , $P < 0.01$). The expression of SIRT1 in Rsv and Ex+Rsv group were significantly higher than that in the Con (0.90 ± 0.14 vs. 0.43 ± 0.15 , $P < 0.05$) and Ex (1.0 ± 0.28 vs. 0.38 ± 0.12 , $P < 0.01$) respectively; Compared with the Ex group, the NF-κB P65 (0.77 ± 0.11 vs. 0.27 ± 0.03 , $P < 0.05$) and Ac-NF-κB P65 (0.52 ± 0.13 vs. 0.78 ± 0.11 , $P < 0.05$) in Ex+Rsv showed a significant decrease in protein level expression. **CONCLUSIONS:** The above results indicate that high-intensity exhaustive exercise leads to renal injury in rats and activates the expression of NF-κB in rat kidney. Resveratrol can significantly increase the expression of SIRT1 at the protein level and increase the deacetylation to reduce the level of acetylation of NF-κB P65 protein, further reducing the expression of NF-κB. The mechanism by which resveratrol reduces the inflammatory response induced by exhaustive training in rats may be related to the SIRT1/NF-κB pathway.

Role And Determinants Of Chronotropic Incompetence In A Kidney Transplant Recipients Population

Sara Ortolan, Daniel Neunhaeuserer, Francesca Battista, Alessandro Patti, Martina Rossetto, Caterina Di Bella, Andrea Gasperetti, Lucrezia Furian, Andrea Ermolao. *Padova University Hospital, Padova, Italy.*
Email: sara.ortolan88@gmail.com
(No relevant relationships reported)

Hemodialysis patients reveal a significantly reduced exercise capacity, often associated with the presence of Chronotropic Incompetence (CI). Both these conditions are well known cardiovascular risk factors. Very limited data exists on CI in Kidney Transplant Recipients (KTRs).

PURPOSE: To describe the prevalence of CI in a KTRs population and to analyze its potential determinants and its effects on functional capacity. **METHODS:** Consecutively recruited KTRs 3 months after transplantation underwent a Cardiopulmonary Exercise Test with an incremental protocol. 175 KTRs were included and the test was repeated in 60 subjects after a mean period of 22 months. Laboratory and drug therapy data were collected. CI was defined by the formula: $MCI = (HR_{peak} - HR_{rest}) / (HR_{predicted} - HR_{rest}) / (\dot{V}O_{2,peak} - \dot{V}O_{2,rest}) / (\dot{V}O_{2,predicted} - \dot{V}O_{2,rest})$ (MCI: metabolic chronotropic index, HR: heart rate, $\dot{V}O_2$: oxygen consumption). The prevalence of CI was calculated on 175 KTRs, while the multivariate regression analysis was conducted on 60 KTRs that repeated the test.

RESULTS: In the whole population the CI prevalence was 30.9%. The 60 reassessed KTRs (age 51.6 ± 1.3 years, 77% men) showed significant differences between 3 and 22 months after transplantation in the hemoglobin level (123.4 ± 16.6 vs 136.4 ± 17.8 g/L, $p < 0.001$) and in the proportion of beta-blocker therapy (50 vs 23.3%, $p < 0.001$), but no differences in $\dot{V}O_2/kg$ peak (26.5 ± 7.0 vs 26.8 ± 8.2 ml/kg/min, $p = 0.85$) nor in CI prevalence (31.7 vs 36.7 , $p = 0.41$). KTRs with CI demonstrated no significant differences of $\dot{V}O_2,peak$ nor at 3 or at 22 months after transplantation, compared to KTRs without CI. The only determinant of CI at the two visits was the presence of arterial hypertension. Gender, age, BMI, the presence of diabetes, the type of immunosuppressive therapy, the duration of follow-up and beta-blocker therapy did not appear to be determinants of CI. **CONCLUSIONS:** KTRs are characterized by reduced functional capacity but the CI does not seem to significantly limit their functional level. In contrast to what it would be expected, beta-blocker therapy does not appear to be a CI determinant, while its only significant determinant was arterial hypertension.

(No relevant relationships reported)

PURPOSE: Athletes put themselves on a regular physical load to stay competitive. Steroids play a significant role in the regulation of cardiovascular, metabolic and many other functions in stress situations. Our aim was to monitor the response of steroid hormones to physical stress.

METHODS: We investigated the plasma levels of 14 different endogenous steroid molecules in a model of extreme acute physical stress (vita maxima treadmill test) in male athletes (n=45; median age=21). Steroid levels were measured using liquid chromatography-tandem mass spectrometry. Cardiovascular-, metabolic-, and gas-exchange parameters were also evaluated. All values were measured at baseline, at maximum stress and 30 minutes into the rest period.

RESULTS: The plasma concentrations of 9 steroids elevated significantly ($p < 0.05$) at the peak compared to baseline, and 11 metabolites elevated significantly ($p < 0.05$) in the rest period compared to baseline. After load 9 steroid showed an increase of at least 50% compared to baseline. Aldosterone showed the highest increase at peak, with 75.83%, and in the rest phase corticosterone elevated with 123.36%. Blood pressure, heart rate and lactate parameters increased significantly at the peak of the load ($p < 0.01$). Cardiac and metabolic values did not correlate with the steroid concentrations. We calculated 11 enzyme activities from the product and substrate ratios, and we found significant differences. There were 4 enzymatic pathway which showed significant increase. 11β-HSD ($p < 0.01$) and aldosterone-synthase ($p < 0.01$) elevated at the peak. In the restitution 17,20-lyase and 11β-HSD in another pathway increased significantly ($p < 0.01$).

CONCLUSIONS: All three lines of the adrenal cortex are affected by extreme physical stress. Cardiovascular, metabolic and gas-exchange parameters increase early,

followed by changes in the levels of endogenous steroids, as a later response. We showed for the first time in this model the elevation of some steroids, like aldosterone, corticosterone and others, and identified the enzymatic pathways involved. Literature results were partially reproduced, with further changes in steroid levels revealed by our model. This research was supported by: GINOP-2.3.2-15-2016-00047, Széchenyi 2020., 20765/3/2018 FEKUTSRAT projects.

Renal And Segmental Artery Hemodynamic Response To Mild Hypercapnia

Christopher L. Chapman¹, Paul J. Kueck¹, Wenjie Ji¹, Emma L. Reed¹, Morgan L. Worley¹, Hannah Zazulak¹, Zachary J. Schlader, FACSM², Blair D. Johnson, FACSM¹. ¹University at Buffalo, Buffalo, NY. ²Indiana University, Bloomington, IN. (Sponsor: Blair Johnson, FACSM)
 Email: cc338@buffalo.edu
 (No relevant relationships reported)

The risk of kidney disease is elevated in conditions associated with sustained or transient elevations in the partial pressure of carbon dioxide, such as chronic obstructive pulmonary disease or sleep apnea. Indirect evidence indicates that hypercapnia induces renal vasoconstriction, a response that differs from the vasodilatory response that occurs in most other vascular beds. Thus, one mechanism underlying an increased risk of kidney disease is that repeated hypercapnia-induced episodes of renal vasoconstriction reduce oxygen delivery and compromise renal oxygenation. However, it is unknown if hypercapnia elevates vascular resistance in vessels going to or within the kidneys. **PURPOSE:** To test the hypothesis that breathing a hypercapnic gas mixture increases vascular resistance in the renal and segmental arteries. **METHODS:** After 45 min of supine rest, renal hemodynamics were assessed in eleven healthy adults (27 ± 4 years, 5 females) immediately prior to (AIR) and while breathing a 3% CO₂, 21% O₂, 76% N₂ gas mixture for 5 min (CO₂). The partial pressure of end-tidal CO₂ (PETCO₂, capnography) and mean arterial pressure (MAP, finger photoplethysmography) were measured continually. Blood velocity (BV) in the distal segment of the right renal artery (Renal) and the middle portion of the same segmental artery within a given subject (Segmental) were assessed using the coronal approach via Doppler ultrasound. Vascular resistance (VR) was calculated as MAP/BV. **RESULTS:** CO₂ increased PETCO₂ (45 ± 3 vs. 48 ± 3 mmHg, P<0.01). CO₂ did not change MAP (AIR: 90 ± 4, CO₂: 90 ± 5 mmHg, P=0.83). In the renal artery, CO₂ reduced BV (33.7 ± 8.0 vs. 31.3 ± 7.7 cm/s, P=0.02), and elevated VR (2.8 ± 0.9 vs. 3.1 ± 1.0 mmHg/cm/s, P=0.03). Similarly, in the segmental artery, CO₂ reduced BV (24.5 ± 5.9 vs. 22.0 ± 4.6 cm/s, P<0.01) and increased VR (4.0 ± 1.1 vs. 4.3 ± 1.1 mmHg/cm/s, P<0.05). **CONCLUSION:** These findings suggest that mild hypercapnia elevates vascular resistance in the renal and segmental arteries.

Heart Rate Variability Responses To Exercise In Mid-spectrum Chronic Kidney Disease

Matthew N. Peterson¹, Jeffrey S. Forsse¹, Zacharias Papadakis², Peter W. Grandjean, FACSM³. ¹Baylor University, Waco, TX. ²Barry University, Miami Shores, FL. ³University of Mississippi, Oxford, MS. (Sponsor: Dr. Peter Grandjean, FACSM)
 (No relevant relationships reported)

BACKGROUND: Heart rate variability (HRV) is a measure of autonomic nervous system (ANS) activity, and decreased HRV is associated with many cardiovascular conditions. Chronic kidney disease (CKD) is characterized by a decrease in renal function and may be associated with ANS imbalances in the renal vasculature. Low HRV is associated with CKD incidence. Exercise is able to alter HRV by modulating the ANS. The effect of exercise on HRV in mid-spectrum CKD patients remains understudied. **PURPOSE:** To determine the effect of steady-state exercise (SSE) and high-intensity interval exercise (HIIE) on post-exercise HRV in patients with stage 3 or 4 CKD. **METHODS:** Twenty participants with stage 3 or 4 CKD (n = 6 men; n = 14 women; age 62.0 ± 9.9 yr; weight 80.9 ± 16.2 kg; body fat 37.3 ± 8.5% of weight; VO_{2max} 19.4 ± 4.7 ml/kg/min, eGFR 51.5 ± 6.82). On separate days, each participant completed 30 minutes of aerobic exercise on the treadmill with exercise intensities set at 65% VO₂ reserve for SSE and 90% and 20% of VO₂ reserve in 3:2 min ratio for HIIE in a randomized crossover design. Both conditions averaged ~ 65% VO₂ reserve. HRV was measured at baseline, immediately post-exercise (IPE), 1-hr post-exercise, and 24-hr post-exercise. HRV was measured for 5 mins in the supine position using an elastic belt and Bluetooth monitor (Polar H7). CardioMood software was used to process HRV variables high frequency (HF), low frequency (LF), and standard deviation of all NN intervals (SDNN). Data were analyzed using 2 (condition) by 4 (time) repeated-measures ANOVAs. Data violated normality and were natural log (ln) transformed prior to analysis. Significant main effects were followed up using pairwise comparisons using a Bonferroni adjustment for multiple comparisons. All analyses were performed using SPSS (v.26). **RESULTS:** For ln LF/HF there were no significant main effects for exercise condition, time, or their interaction (p > 0.05). For ln HF (F

= 3.507, p < 0.05, η_p² = 0.156). In LF (F = 3.093, p < 0.05, η_p² = 0.140), and ln SDNN (F = 3.761, p < 0.05, η_p² = 0.165) there was a significant main effect for time. Post-hoc comparisons revealed that HF, LF, and SDNN were lower IPE than for all other time points. **CONCLUSION:** Thirty minutes of aerobic exercise transiently decreases HRV in mid-spectrum CKD patients. This response was not modified by exercise condition.

INCREASES IN PHYSICAL CAPACITY (VO2 PEAK) IMPROVES RENAL PROTECTIVE EFFECTS IN CKD AND MITOCHONDRIAL FUNCTION

Wesley H. Silva, Rafael S. Luiz, Alexandre Saud, Natália Reinecke, Luciana Jorge, Samuel Trindade, Rodolfo Rampaso, Waldemar S. Almeida, Mirian Boim. University Federal of São Paulo, São Paulo, Brazil.
 (No relevant relationships reported)

PURPOSE: Physical exercise improves mitochondrial function and biogenesis. It is common for CKD patients to be physically inactive having less physical and functional capacity when compared to the general population. The aim of this study was to evaluate physical capacity, renal function and mitochondrial function in rats with CKD by nephrectomy 5/6 (Nx5/6)

METHODS: Adult Wistar rats were divided into groups (n=8): SHAM; Sedentary+Nx5/6+Sedentary (Sed), Sedentary+Nx5/6+Exercise (SE), Exercise+Nx5/6+Sedentary (ES) and Exercise+Nx5/6+Exercise (Exe). The physical capacity was performed with ergospirometry test (Vo2 peak) and maximal exercise test (Mtest). EXE periods were as follows: 40-60min/day, 5 days a week, during 8 weeks, 40 to 60% of Mtest. We evaluated proteinuria (uProt), blood urea nitrogen (BUN) and blood pressure (BP). By Western Blotting evaluated renal AMPK Pathway (AMPK and PGC1- alpha) was

RESULTS: The Physical Capacity (VO2 peak) was increased in SE and Exe vs Sed (31.8±0.7; 35.2±0.9 vs 23.1±1.8. p<0.05, respectively), and Mtest was improved in SE and Exe vs Sed (34.2±2.1; 37.9±1.7 vs 24.8±0.6. p<0.05, respectively). The Exe group presented a significant reduction in proteinuria when compared to the SE and ES (61.1±20.9 vs 173±39.2 vs 124.4±14.1. p <0.05, respectively). BUN was higher in SE and ES vs Exe (57.2±7.4 vs 65.6±7.8 vs 51.1±7.4. p <0.05, respectively). There was a decrease in BP in the SE and Exe groups when compared with the Sed group (215±1 and 219±2 vs 251±2, p <0.05, respectively), but the blood pressure values still remained high. The Renal AMPK Pathway was reduced in all group vs Sed in terms of protein levels (AMPK and PGC1- alpha)

CONCLUSIONS: The Increased physical capacity Vo2 peak and Mtest minimized the impact of Nx5/6 in the CKD, attenuating proteinuria, an important index of progressive loss of renal function and to improve mitochondrial function. Finally, previous exercise induced protection for CKD, especially under this experimental protocol. Thus, it is reasonable to suggest that exercise may be an additional strategy to be employed in CKD

942 Board #68 May 27 2:30 PM - 4:00 PM
Overshoot Of The Respiratory Exchange Ratio During Recovery From Maximal Exercise In Kidney Transplant Recipients

Alessandro Patti, Daniel Neunhaeuserer, Sara Ortolan, Francesca Battista, Lucrezia Furian, Andrea Gasperetti, Andrea Ermolao. Padua University-Hospital, Italy, Padua, Italy.
 (No relevant relationships reported)

PURPOSE: The overshoot of the respiratory exchange ratio (RER) during recovery from maximal cardiopulmonary exercise testing (CPET) has been found reduced in magnitude among patients with heart failure, possibly due to the slow recovery kinetics of VO₂. To investigate whether this phenomenon could be present also in patients with peripheral limitations to exercise, a population of kidney transplant recipients (KTRs) was specifically studied, since these patients may present peripheral alterations at the muscular and microvascular level. **METHODS:** RER was retrospectively evaluated during recovery after maximal exercise (peak RER > 1.1) in KTRs without history of systolic dysfunction that underwent CPET for clinical purposes. Variables assessed were the maximum RER during recovery (RER-max), the RER overshoot magnitude (RER-OM: (RER-max - peak RER) / peak RER %) and the time from peak RER to RER-max. Patients signed informed consent. **RESULTS:** 57 KTRs were included in the study (28% females). The median value of peak RER was 1.2 (IQR 0.1). Mean RER-max and RER-OM were 1.6 ± 0.2 and 28.4 ± 12.7%, respectively. The time to reach RER-max was on average 131.4 ± 42.8 s. RER-OM showed significant correlations with peak VO₂ (ρ=0.57; P<0.01), VO₂ at the anaerobic threshold (r=0.44; P<0.01), VE/VCO₂ slope (r=-0.32; P<0.05) and oxygen uptake efficiency slope (r=0.48; P<0.01). RER-max showed comparable correlations with these parameters, however, conversely to RER-OM, it was conditioned by peak RER (ρ=0.50; P<0.01). Finally, RER-OM was found significantly different among sub-populations of KTRs when stratified by patients' aerobic capacity (Weber class A vs. B+C: 31.1 ± 12.1% vs. 18.6 ± 9.9%; P<0.01) or ventilatory efficiency (Ventilatory class I vs. II: 30.9 ± 13.3% vs.

23.2 ± 9.6%; P=0.03). CONCLUSIONS: This is the first study in KTRs investigating the recovery of RER, which seems to be affected by patients' cardiorespiratory fitness. The present data showed that the RER-OM values of this population are similar to normal subjects' values reported in literature. Moreover, RER-OM appears as a valuable parameter to assess the recovery of RER, being independent from peak RER and directly correlated to other prognostic CPET parameters.

A Practical Measure Of Endothelial Function Applicable To The Routine Clinical Setting?

Melanie A. Heath¹, Drew D. Gourley¹, Stanley J. Kleis², Morteza Naghavi³, Hirofumi Tanaka, FACSM¹. ¹The University of Texas at Austin, Austin, TX. ²University of Houston, Houston, TX. ³Endothelix, Houston, TX. (Sponsor: Hirofumi Tanaka, FACSM)
(No relevant relationships reported)

Background: The VENDYS-II is an alternative, fully automated and noninvasive methodology to evaluate endothelial function using temperature change on finger as a surrogate measure of the magnitude of vascular reactivity index (VRI). Due to the simplicity, it could provide more feasible technique to assess vascular endothelial function in the clinical setting. A most recent modification to the technique includes the application of occlusion cuff at the base of a finger. **Purpose:** To assess the validity of the VENDYS-II device compared with the standard flow-mediated dilation (FMD) protocol. **Methods:** Twelve participants (7 males; 37±16 years) varying widely in age, health, ethnic, and socioeconomic status were studied. Occlusion cuff was placed over the right antecubital fossa or at the base of the right index finger. Temperature monitors were placed on bilateral index fingers to assess change in temperature throughout 5-minute occlusion and recovery phases. FMD was obtained simultaneously using high-resolution ultrasound. **Results:** Mean brachial artery FMD was 7.2±2.6%. Measures of VRI obtained with the upper arm occlusion were significantly associated with simultaneously obtained brachial artery FMD (r=0.73). VRI values obtained with the finger occlusion (1.6±0.4AU) were not significantly different from VRI measured with the brachial artery occlusion (1.7±0.3AU), and both VRI values were moderately correlated with each other (r=0.50). **Conclusion:** Finger-based VRI may be a valid and novel alternative measure of endothelial function that is more suitable than the standard FMD for the assessment of endothelial function in the routine clinical setting.

Chronic And Acute Benefits Of Reduced Sitting In Individuals With Increased Cardiovascular Risk

Yvonne Hartman, Laura Tillmans, David Benschop, Astrid Hermans, Kevin Nijssen, Peter Willems, Cees Tack, Maria Hopman, FACSM, Jurgen Claassen, Dick Thijssen. *Radboudumc, Nijmegen, Netherlands.*
Email: yvonne.hartman@radboudumc.nl
(No relevant relationships reported)

Sedentary behavior increases the risk for cardiovascular and cerebrovascular disease. However, little work examined the causal link between a decline in sedentary behavior and cardio- and cerebrovascular function, and the potential underlying mechanisms for this relation. **PURPOSE** to examine the chronic (16-week) and acute (3-hour) impact of reducing sedentary behavior on vascular and cerebrovascular function in subjects with increased cardiovascular risk. **METHODS** This prospective study included 24 individuals with increased cardiovascular risk (65±5 years, 29.8±3.9 kg/m²). Before and after 16-week reduced sitting, using a mobile-Health device with vibrotactile feedback, we examined: *i.* vascular function (flow-mediated dilation (FMD)), *ii.* cerebral blood flow (CBFv, transcranial Doppler), and *iii.* cerebrovascular function (cerebral autoregulation (CA) and cerebral vasomotor reactivity (CVMR)). To better understand potential underlying mechanisms, before and after intervention, we evaluated the effects of 3-hour sitting with and without light-intensity physical activity breaks (every 30-minutes). **RESULTS** The first wave of participants showed no change in sedentary time (n=9, 10.3±0.5 to 10.2±0.5 hours/day, P=0.87). Upon intervention optimization, the subsequent participants (n=15) decreased sedentary time (10.2±0.4 to 9.2±0.3 hours/day, P<0.01). This resulted in significant increases in FMD (3.1±0.3 to 3.8±0.4%, P=0.02) and CBFv (48.4±2.6 to 51.4±2.6 cm/s, P=0.02), without altering CA or CVMR. Before and after the 16-week intervention, 3-hour exposure to uninterrupted sitting decreased FMD and CBFv, whereas physical activity breaks prevented a decrease (both P<0.05). CA and CVMR did not change (P>0.20).

CONCLUSION Long-term reduction in sedentary behavior in older subjects with increased cardiovascular risk improves peripheral vascular function and cerebral blood flow, and acutely prevents impaired vascular function and decreased cerebral blood flow. These results highlight the potential benefits of reducing sedentary behavior to acutely and chronically improve cardio/cerebrovascular risk. Study is registered at the Netherlands Trial Register (NTR6387) (<https://www.trialregister.nl/trial/6215>).

EXPLORING SEX DIFFERENCES ON ARTERIAL STIFFNESS IN RESPONSE TO HEAVY ROPE EXERCISE

Sarah G. Kearney, Jason C. Parks, Erica M. Marshall, Stacie M. Humm, Meredith C. Paskert, J Derek Kingsley, FACSM. *Kent State University, Kent, OH.*
(No relevant relationships reported)

PURPOSE: To evaluate sex differences on aortic and carotid arterial stiffness, and carotid artery compliance (CAC), following heavy rope exercise (HRE). **METHODS:** Twenty-seven resistance-trained individuals (Men: n=14, Mean±SD: Age: 23 ± 3 yrs; Women: n=13, Age: 22 ± 2 yrs) participated. All measurements were collected at Rest, and 15 (Rec1), 30 (Rec2), and 60 (Rec3) minutes following HRE. Aortic arterial stiffness was assessed by pulse wave velocity (PWV), while carotid arterial stiffness, via beta stiffness index (BSI), and CAC, were collected via Doppler ultrasound. HRE utilized six 15-second exercise bouts using a double wave pattern (180bpm), with 30-second seated recovery. Two-way repeated measures ANOVAs were used to determine differences in PWV, BSI, and CAC, between the sexes across time. **RESULTS:** Men had significantly greater height ($p \leq 0.001$) and weight ($p \leq 0.001$). There were no significant sex by time interactions for PWV ($p = 0.96$) or BSI ($p = 0.09$). A significant main effect of time ($p \leq 0.001$) showed that PWV significantly increased during Rec1, however, returned to below resting value at Rec3 (Men= Rest: 5.9 ± 0.7 m/s, Rec1: 6.2 ± 0.7 m/s, Rec2: 6.0 ± 0.7 m/s, Rec3: 5.7 ± 0.7 m/s; Women= Rest: 5.3 ± 0.8 m/s, Rec1: 5.7 ± 0.9 m/s, Rec2: 5.3 ± 0.7 m/s, Rec3: 5.1 ± 0.5 m/s). A main effect of time for BSI ($p = 0.002$) showed a significant increase during Rec1 and Rec2 from Rest, while Rec3 returned to Rest (Men= Rest: 3.2 ± 1.1 units, Rec1: 4.0 ± 1.5 units, Rec2: 3.5 ± 1.6 units, Rec3: 3.3 ± 1.5 units; Women= Rest: 2.6 ± 1.0 units, Rec1: 3.6 ± 1.6 units, Rec2: 4.3 ± 1.7 units, Rec3: 2.4 ± 0.8 units). There was a significant sex by time interaction for CAC ($p = 0.05$). Men did not significantly change across time, however, from Rest women significantly decreased during Rec2, then significantly increased from Rec2 to Rec3 (Men= Rest: 0.2 ± 0.1 mm²/mmHg, Rec1: 0.2 ± 0.1 mm²/mmHg, Rec2: 0.2 ± 0.1 mm²/mmHg, Rec3: 0.2 ± 0.1 mm²/mmHg; Women= Rest: 0.3 ± 0.1 mm²/mmHg, Rec1: 0.2 ± 0.1 mm²/mmHg, Rec2: 0.2 ± 0.1 mm²/mmHg, Rec3: 0.3 ± 0.1 mm²/mmHg). **CONCLUSIONS:** These data suggest that HRE does not produce differences in aortic or carotid arterial stiffness between sexes. The initial decrease in women's CAC is likely due to greater relative intensity, while the increase in CAC back to resting values is potentially due to the cardioprotective effects of estrogen.

L-citrulline Supplementation Attenuates Aortic Pressure And Wave Reflection Responses To Cold Stress In Older Adults

Salvador J. Jaime¹, Jessica Nagel¹, Elizabeth Schwab¹, Christopher Martinson¹, Kim Radtke¹, Richard P. Mikat¹, Arturo Figueroa, FACSM². ¹University of Wisconsin-La Crosse, La Crosse, WI. ²Texas Tech University, Lubbock, TX. (Sponsor: Arturo Figueroa, FACSM)
Email: sjaime@uwlax.edu
(No relevant relationships reported)

PURPOSE: Aging is a major risk factor for cardiovascular events due to increased pressure wave reflection. Cold exposure augments central blood pressure and wave reflection due to sympathetic-mediated vasoconstriction, which elevates the risk for adverse cardiovascular events in older adults. L-citrulline (L-CIT) supplementation improves endogenous synthesis of nitric oxide and contributes to reduce aortic systolic blood pressure (SBP) and pulse pressure (PP) responses to cold pressor test (CPT) in young men; however, the impact on wave reflection in older adults is unknown. The purpose of this study was to elucidate the efficacy of L-CIT to attenuate aortic hemodynamic responses to CPT in older adults. **METHODS:** Sixteen adults (n=16, 60-85 yrs) were randomly assigned to placebo or L-CIT (6g/day) for 14 days in a crossover, double-blind design. Brachial and aortic SBP, PP, augmented pressure (AP), augmentation index standardized at 75 bpm (AIx@75), and pressure of the forward (Pf) and reflected (Pb) waves were evaluated at

rest and during CPT before and after the assigned intervention. An analysis of variance with repeated measures was used to determine if there were differences within and between interventions at rest and during CPT.

RESULTS: No significant changes with either intervention were observed at rest. Responses in aortic PP (-9.1 vs. 2.9; $P=.008$), AP (-4.1 vs. 2.1; $P=.004$), AIx (-3.7 vs. 2.1; $P=.015$), AIx@75 (-3.4 vs. 2.4; $P=.024$), Pf (-5.1 vs. 2.9; $P=.034$), and Pb (-3.4 vs. 1.7; $P=.027$) were significantly attenuated following L-CIT supplementation compared with placebo.

CONCLUSIONS: Although L-CIT had no effect on resting aortic hemodynamics, L-CIT attenuated aortic pressure and wave reflection responses during CPT in older adults. Therefore, short-term L-CIT supplementation may elicit cardioprotection during cold exposure in older adults.

Single Dry Cupping Treatment On Vascular Function In Healthy Young Individuals

Arturo A. Arce-Esquivel, S. Andrew Cage, Ashley N. Tulloch, Joyce E. Ballard, FACSM. *The University of Texas at Tyler, Tyler, TX.* (Sponsor: Joyce E. Ballard, FACSM)

(No relevant relationships reported)

Cupping, part of traditional Chinese medicine, is regularly observed to bring about pain relief and to increase a patient's general feeling of well-being. It has been suggested that cupping promotes hyperemia (i.e., increased blood flow). Flow-mediated dilatation (FMD) is a widely used method of assessment of vascular function that provides a surrogate index for arterial health. **PURPOSE:** To examine the effect of a single dry cupping treatment on vascular function among healthy young individuals. **METHODS:** Five apparently healthy young individuals (3 women and 2 men, average age: 22 ± 1.48 years) participated in this study. Dry cupping treatment was performed applying two plastic cups on the non-dominant arm of each participant. Before and after a 10-minute cupping treatment, brachial FMD was evaluated using a high-resolution ultrasound with a 7.5-MHz linear array transducer. **RESULTS:** Following the 10-minute cupping treatment, brachial FMD increased significantly after the treatment from 7.40 ± 0.65 to $8.98 \pm 1.4\%$, $p < 0.05$. Participants did not experience complications as a result of the intervention. **CONCLUSIONS:** These findings demonstrated that in healthy individuals, dry cupping treatment, was capable of increasing vascular function. This study underlies the role of cupping treatment in promoting vascular function improvements. Finally, cupping is an inexpensive and low-risk alternative therapeutic modality.

Dietary Nitrate Counteracts The Elevated Blood Pressure Response To Nitric Oxide Synthase Inhibition In Humans

Anni Vanhatalo, FACSM¹, Jamie Blackwell¹, Stephen J. Bailey¹, Lee J. Wylie¹, Bert Bond¹, Michael Nyberg², Andrew M. Jones, FACSM¹. ¹University of Exeter, Exeter, United Kingdom.

²University of Copenhagen, Copenhagen, Denmark.

(No relevant relationships reported)

Decreased production of nitric oxide (NO) via the endogenous NO-synthase (NOS) pathway is a hallmark of impaired endothelial function and is associated with elevated blood pressure. Potentiation of the alternative nitrate-nitrite-NO pathway via the diet has been suggested as a possible therapeutic strategy to counteract NOS dysfunction, but proof-of-concept that exogenous nitrate treatment compensates in situations of NOS inhibition in humans is lacking. **Purpose:** To determine whether dietary supplementation with nitrate-rich beetroot juice attenuates the detrimental effects of acute NOS inhibition achieved by intravenous infusion of N^o-monomethyl-L-arginine (L-NMMA) on vascular function. **Methods:** Seven male volunteers (age 23 ± 3 years, body mass 77.9 ± 6.8 kg) completed four conditions in a double-blind, randomised cross-over design: 1) 5-d dietary placebo supplementation with acute saline infusion (PL-CON), 2) 5-d placebo supplementation with acute L-NMMA infusion (3 mg/kgBM over 5 min followed by 55 μ g/kgBM/min; PL-LNMMA), 3) 5-d dietary nitrate supplementation (12 mmol/d) with acute saline infusion (BR-CON), and 4) 5-d nitrate supplementation with acute L-NMMA infusion (BR-LNMMA). Heart rate (HR), brachial mean arterial pressure (MAP), and femoral artery blood flow (FBF) were measured every 5 min during 20 min of infusion and compared between conditions using repeated measures ANOVA. **Results:** L-NMMA infusion resulted in decreases from baseline in HR (PL-LNMMA -5 ± 3 , BR-LNMMA -6 ± 5 bpm) and FBF (PL-LNMMA -114 ± 85 , BR-LNMMA -95 ± 71 mL/min) that were greater than after saline infusion (HR: PL-CON -2 ± 5 , BR-CON -1 ± 4 bpm, $P < 0.05$; FBF: 20 ± 40 and 18 ± 36 mL/min, $P < 0.05$), with no effects of dietary supplementation. MAP was elevated by L-NMMA (PL-LNMMA 9 ± 2 , BR-LNMMA 4 ± 2 mmHg) compared to saline infusion (PL-CON -2 ± 2 , BR-CON 0 ± 2 mmHg, $P < 0.05$), and this response was attenuated by ~56% following BR ingestion ($P < 0.05$). **Conclusions:** Acute NOS blockade through systemic infusion of L-NMMA resulted in reduced HR and FBF, and elevated MAP, in healthy humans, resembling cardiovascular impairments

observed in conditions of chronic NOS-dysfunction. BR attenuated the elevation in MAP, highlighting the potential for exogenous nitrate to improve vascular control in situations where NOS function is impaired.

Association Between Arterial Stiffness, Body Mass Index And Cardiorespiratory Fitness In 7-to-17 Years Old Children

Marco Meucci, Hwan Kim, Nicholas D. Tocci, Austin T. Lassiter, Kaitlin T. McShea. *Appalachian State University, Boone, NC.* (Sponsor: Scott Robert Collier, FACSM)

Email: meuccim@appstate.edu
 (No relevant relationships reported)

Excess adiposity is a risk factor for cardiovascular disease, however, the obesity paradox suggests the existence of a subpopulation of obese individuals that do not suffer from those cardiovascular risks. Cardiorespiratory fitness (CRF) is a strong indicator of cardiovascular health in children and adults. Both obesity and low CRF have shown to independently increase the risk of cardiovascular diseases. **PURPOSE:** The aim of this study was to investigate how central arterial stiffness is associated with aerobic capacity and body fat percentage and body mass index (BMI) in children aged 7-to-17-years. **METHODS:** Seventy healthy children, 34 boys and 36 girls (age 7-17 years; BMI 21.5 ± 5.4 kg/m²; fat mass $23.4 \pm 11.5\%$), participated in this study. Percentage of fat mass (FM%) and fat free mass (FFM) were assessed using air displacement plethysmography (Bod Pod COSMED). Arterial stiffness was assessed measuring carotid-femoral PWV (cfPWV) with the SphygmoCor XCEL (AtCor Medical, Inc.). CRF was assessed through breath-by-breath gas analysis (K5, COSMED) using a 15 watts per minute graded exercise test on a cycle ergometer. The VO₂ at the first ventilatory threshold (VT1) was identified using the V-slope technique and as the lowest respiratory equivalent for oxygen. Differences in cfPWV between quartiles of VO₂ at VT1, %BF, and BMI were assessed using a multivariate general linear model. **RESULTS:** cfPWV was higher in the first VO₂ at VT1 quartile compared to the fourth when VO₂ is normalized by FFM (4.99 ± 0.73 vs 4.24 ± 0.69 m/s, $p < 0.05$). No differences in cfPWV were observed between first and fourth VO₂ at VT1 quartiles when VO₂ is normalized by body mass (5.05 ± 0.92 vs 4.34 ± 0.71 m/s). cfPWV was higher in the fourth and third BMI quartile compared to the first (4.26 ± 0.53 and 4.90 ± 0.66 vs 5.09 ± 0.89 , $p < 0.05$) but no differences in cfPWV were observed between fourth, third and first BF% quartiles (5.06 ± 1.04 , 4.57 ± 0.54 , 4.61 ± 0.64). **CONCLUSION:** Low central arterial stiffness in children is associated with high CRF expressed as VO₂ at VT1, and with low BMI.

Brachial And Aortic Blood Pressure Soon After Delivery In Women With Versus Without A Past Adverse Pregnancy Outcome

Catherine A. O'Byrne¹, Abby J. Heinichen¹, Chloe W. Caudell¹, Paige K. Wilbanks¹, William C. Tucker¹, Bo Fernhall, FACSM², Abbi D. Lane-Cordova¹. ¹University of South Carolina, Columbia, SC. ²University of Illinois at Chicago, Chicago, IL.

Email: kobyrne17@gmail.com
 (No relevant relationships reported)

PURPOSE: Adverse pregnancy outcomes (APOs), such as preterm birth, gestational diabetes, and hypertensive disorders of pregnancy, are associated with excess maternal risk of hypertension and cardiovascular disease years later. Little is known about the effect of an APO on aortic blood pressure (BP) in the first few years after delivery. Our purpose was to test the hypothesis that women with a history of APO would have higher peripheral and aortic BP in the 6 months- 3 years after delivery. **METHODS:** We recruited 37 women aged 18-45 years (26 white/9 black /2 other), from the greater Columbia, SC area who delivered a singleton infant 6 months - 3 years ago to participate in our study. Women were excluded if they were smokers, had diabetes, HIV/AIDS, or were receiving cancer therapy. Participants completed a single visit following an overnight fast during which brachial and aortic BP were measured using an oscillometric cuff and applanation tonometry, respectively. History of APO and sociodemographic information were determined via self-report. After assessing the distribution of the data with Shapiro-Wilk tests, we tested for differences in brachial and aortic systolic, diastolic, and mean BP between groups using t-tests or Kruskal-Wallis tests, as appropriate. **RESULTS:** Mean age was 33 ± 1 yrs and mean BMI was 26.6 ± 1.0 kg/m² with no difference between groups. Of the 37 women in the study, 12 had a history of APO with no difference in race distribution by group. Mean brachial and aortic systolic BP tended to be higher in women with a history of APO: 116 ± 4 versus 108 ± 3 mmHg, $p = 0.07$ (brachial) and 105 ± 4 versus 97 ± 1 mmHg, $p = 0.08$ (aortic). There was no difference in brachial or aortic diastolic or mean BP between groups.

CONCLUSIONS: Women with a history of APO tended to have higher peripheral and aortic systolic BP 6 months- 3years after delivery. The effects of an APO on BP may be detectable soon after the pregnancy ends and might represent a target for prevention of overt cardiovascular disease in affected women.

952 Board #78 May 27 2:30 PM - 4:00 PM
The Effect Of A High-fat Meal On Sympathetic Vasoconstrictor Responsiveness In Men And Women

Justin J. Duong, Breanne S. Collison, S.M. Majedul Karim, Darren S. DeLorey, FACSM. *University of Alberta, Edmonton, AB, Canada.*

(No relevant relationships reported)

Consumption of a high-fat (HF) meal has been shown to reduce flow-mediated dilation (FMD) in men, but not women. This decline in FMD may be a result of decreased nitric oxide (NO) bioavailability. NO inhibits sympathetic vasoconstriction and a HF meal may, therefore, heighten sympathetic vasoconstrictor responsiveness. However, the effect of a HF meal on sympathetic vasoconstriction in men and women has not been investigated. **PURPOSE:** The purpose of this study was to investigate the hypothesis that consumption of a HF meal would heighten sympathetic vasoconstrictor responsiveness in men, but have no effect in women. **METHODS:** In a randomized cross-over design, young males (n=15) and females (n=15) consumed a HF or an isocaloric low-fat (LF) meal on separate days. Two hours post-meal, subjects underwent a cold pressor test (CPT) and measurement of brachial artery FMD to determine sympathetic vasoconstrictor responsiveness and endothelial function, respectively. Beat-by-beat blood pressure was measured by Finometer and mean arterial pressure (MAP) was calculated. Forearm blood flow (FBF) was measured by Doppler ultrasound at the brachial artery and forearm vascular conductance (FVC) was calculated as FBF/MAP. Sympathetic vasoconstrictor responsiveness was calculated as the percentage decrease in FVC (%ΔFVC) in response to CPT. FMD was calculated as the percentage increase in brachial artery diameter from baseline and normalized for cumulative shear rate. **RESULTS:** Sympathetic vasoconstrictor responsiveness was not different (p>0.05) between meal conditions or between females (LF: -27±14%; HF: -30±15%) and males (LF: -29±23%; HF: -24±16%) in either meal condition. FMD was higher (main effect of sex; p<0.05) in females (LF: 8.1±2.1%; HF: 7.4±1.4%) compared to males (LF: 6.2±1.5%; HF: 5.1±1.1%) and FMD was lower (main effect of meal; p<0.05) in the HF compared to the LF meal condition. No interaction (p>0.05) was observed between meal condition and sex for FMD. FMD normalized for shear rate was not different (p>0.05) between meal conditions or between females and males in either meal condition. **CONCLUSION:** These data suggest that, despite evidence of a post-prandial decrease in endothelial function, a HF meal does not alter sympathetic vasoconstrictor responsiveness in men or women.

The Relationship Between Estimated Pulse Wave Velocity With Cardiorespiratory Fitness In Young Adults

Kashaun J. Curry¹, Brock Jensen², Kevin Heffernan¹, Michael Holmstrup, FACSM. ¹*Syracuse University, Syracuse, NY.* ²*Slippery Rock University, Slippery Rock, PA.* (Sponsor: Michael E. Holmstrup, FACSM)

(No relevant relationships reported)

Introduction: Carotid-femoral pulse wave velocity (cfPWV) is used to measure aortic stiffness and offers insight into cardiovascular disease (CVD) risk. The measurement requires specialized equipment and technical expertise to perform accurately. Estimated carotid-femoral pulse wave velocity (ePWV) is an easily calculated alternative to objectively measured cfPWV that offers comparable CVD risk prediction. Whether ePWV also offers similar insight into CVD resiliency has not been explored. Cardiorespiratory fitness (CRF) is associated with lower CVD risk and individuals with greater CRF have lower cfPWV. **Purpose:** To investigate the relationship between ePWV and CRF in young adults. **Methods:** Sixty young, healthy adults (mean age 25±7 years; mean body mass index 24.7±4.0 kg/m²; female n=30) volunteered for this study. cfPWV was assessed using applanation tonometry via simultaneous measurements of carotid and femoral pressure waves. ePWV was calculated from a regression equation using age and mean arterial pressure. A treadmill protocol with metabolic gas analysis was used to measure VO₂ peak. Pearson correlation coefficients were used to analyze the association between PWV measures and VO₂ peak. **Results:** cfPWV and ePWV were moderately associated (r=-0.34, p=0.007) with a mean difference between measures of 0.6 m/s and a coefficient of variation of 13%. There was a significant, inverse correlation between measured cfPWV and VO₂ peak (r=-0.26, p=0.045). There was also a significant, inverse correlation between ePWV and VO₂ peak (r=-0.30, p=0.021). **Conclusions:** Individuals with higher CRF have lower aortic stiffness. ePWV and measured cfPWV were similarly associated with CRF. As such, ePWV may offer comparable insight into CVD resiliency as measured cfPWV.

Effects Of Methionine Restriction And Exercise On Cardiac Fibrosis Of Spontaneously Hypertensive Rats.

Chien-Hui Chan¹, Hsin-Wei Tsai¹, Yi-Hung Liao², Shioh-Chwen Tsai¹. ¹*Institute of Sports Sciences, University of Taipei, Taipei City, Taiwan, Taipei, Taiwan.* ²*Department of Exercise and Health Science, National Taipei University of Nursing and Health Sciences, Taipei City, Taiwan, Taipei, Taiwan.* (Sponsor: Chia-Hua Kuo, FACSM)

Email: sctsaib@gmail.com

(No relevant relationships reported)

PURPOSE: To investigate the effect of low methionine diet and endurance exercise training on cardiac function of spontaneously hypertensive rats. **METHOD:** A total 80 male spontaneously hypertensive rat (SHR) (six-week-old) were randomly divided into four groups: (1) 0.86% methionine diet and sedentary lifestyle (C), (2) 0.17% methionine diet and sedentary lifestyle (MR), (3) 0.86% methionine diet and endurance exercise (EX), (4) 0.17% methionine diet and endurance exercise (MR+EX). The body weight, water intake, and food consumption were recorded once per week. In the exercise group, the rats were adapted to exercise on treadmill (10 m/min, 10 min/day) for three days. The endurance exercise protocol on the treadmill started from 15 m/min, and progressively enhanced to 27 m/min during eight weeks, and then maintain to 12 months. The rats were trained on treadmill 5 days/week, 60 min/day for 2 or 12 months. We measured the rats' diameter of left ventricle (LVD), and left ventricular posterior wall (LVPW) during diastole and systole period by using echocardiography at beginning and after 2 and 12 month intervention. All data were presented as mean±SEM. One-way ANOVA was used to evaluate differences between the changes, while Dunnett T3 post-hoc analysis was used to compare significant differences between test conditions. Statistical significance was accepted at p<0.05. **RESULTS:** Compared with C group, MR restriction and endurance training significantly reduced the gain of body weight during 12-months intervention (p<0.05), but there is no difference between Ex and EX+MR. Age, Ex, and MR reduce the LVD during diastole (p<0.05). The LVPW of diastole and systole were thickened as growth, endurance training, and restricted with methionine of individual (p<0.05). Cardiomyocytes were enlarged as growth (p<0.05), but endurance training and methionine restriction decelerate the effect. Cardiac fibrosis also increased as growth, endurance training and methionine restriction limited the development of fibrosis. **CONCLUSIONS:** The MR diet might be used as a strategy to ameliorate the pathological effect of hypertension evidenced by reducing the cardiac fibrosis.

955 Board #81 May 27 2:30 PM - 4:00 PM
Sleep Variability Is A Predictor Of Peripheral Vascular Function In Apparently Healthy Undergraduate College Students

Eliisa K. Katulka, Felicia R. Berube, Michele N. D'Agata, Freda Patterson, David G. Edwards, William B. Farquhar, FACSM, Melissa A.H. Witman. *University of Delaware, Newark, DE.* Email: ekatulka@udel.edu

(No relevant relationships reported)

Experimental studies suggest that highly variable sleep-wake patterns may impair vascular function, suggesting a potential mechanism for the increased risk of cardiovascular (CV) diseases seen in shift workers and those with sleep disorders. However, it is unclear if naturalistic, day-to-day variability in sleep-wake patterns of generally healthy individuals poses a risk to vascular function. **PURPOSE:** To examine the association between sleep variability (SLV) and vascular function in undergraduate college students. **METHODS:** SLV metrics were estimated in 39 healthy undergraduate students (20 ±0.2 years) using wrist actigraphy for 14 days and nights. Sleep timing was defined by sleep midpoint (halfway point between sleep onset and wake onset). Sleep timing variability (STV) was then quantified as the standard deviation (SD) of sleep midpoint, and sleep duration variability (SDV) as the SD of sleep duration across 14 days. Sleep quality was assessed using the Pittsburgh Sleep Quality Index (PSQI). Peripheral vascular function was indexed as the magnitude of hyperemia in response to passive leg movement (PLM) and was performed immediately following the end of sleep monitoring. Blood velocity and femoral artery diameter were measured via Doppler ultrasound. **RESULTS:** In a linear regression model adjusting for sex and body mass, SDV predicted peak leg blood flow (LBF) (β=-0.49, p<0.01), change in LBF from baseline to peak (β=-0.50, p<0.01), and LBF area under the curve (AUC) (β=-0.57, p<0.01) during PLM. Associations remained significant when the model included PSQI score (all p<0.01). Similarly, models adjusting for sex and mass found that STV predicted LBF AUC (β=-0.30, p=0.05). **CONCLUSION:** In adjusted models, greater SLV is associated with less optimal peripheral vascular function in healthy college students. These data support the growing body of literature suggesting that regular sleep schedules may be important for CV health, even in otherwise healthy young adults. Supported, in part, by NIH P20GM113125.

INFLUENCE OF TYPE 2 DIABETES AND CARDIOVASCULAR DISEASE FAMILY HISTORY ON METABOLIC SYNDROME SEVERITY

N.R. Stewart, E.M. Heiston, S.L. Miller, A.L. Weltman (FACSM), J.T. Patrie, S.K. Malin (FACSM) University of Virginia, Charlottesville, VA 22904
Background: Family history of cardiovascular disease (CVD) is considered a strong predictor of developing metabolic syndrome (MetS), in part through promoting endothelial dysfunction. In addition, a family history of type 2 diabetes (T2D) relates to lower metabolic insulin sensitivity and may compound their MetS risk severity. We examined in people with MetS if a family history of CVD and T2D (CVD+T2D) increases MetS risk severity compared to individuals with a family history of CVD only (CVD). **Methods:** Twenty, middle-aged obese individuals with MetS (55.9 ± 6.5 yrs; 32.5 ± 3.6 kg/m²) were divided into CVD (n=9; 6F) or CVD+T2D (n=11; 9F). MetS was defined using the NCEP ATP III criteria. MetS severity Z-score was calculated from waist circumference, blood pressure, fasting blood glucose, triglycerides, and high-density lipoproteins. Metabolic insulin sensitivity (i.e. glucose infusion rate, GIR) was measured using a 2-hr hyperinsulinemic-euglycemic (40 mU/m²/min, 90 mg/dl) clamp. Insulin-stimulated brachial artery flow-mediated dilation (FMD) was also measured as the change from fasting to 2-hr during the clamp to assess endothelial function and gain tissue-specific insight into the origin of insulin action. **Results:** There was no difference in anthropometrics between groups. There was also no statistical difference between CVD and CVD+T2D in MetS severity (2.62 ± 1.12 vs. 1.65 ± 0.56 , $P=0.42$), GIR (2.35 ± 0.55 mg/kg/min vs. 2.63 ± 1.56 mg/kg/min, $P=0.86$), or insulin-stimulated FMD ($0.33 \pm 1.57\%$ vs. $1.68 \pm 1.19\%$, $P=0.52$). However, waist circumference was inversely correlated to GIR ($r=-0.63$, $P=0.01$). **Conclusion:** In adults with MetS, T2D family history does not exacerbate MetS severity in adults with CVD family history. However, waist circumference appears to be important for lowering metabolic insulin sensitivity. Thus, targeting abdominal fat may contribute to improved metabolic health independent of T2D and/or CVD family history.

High Fat Relative To Low Fat Ground Beef Consumption Lowers Blood Pressure And Does Not Negatively Alter Arterial Stiffness

Jason R. Lytle, Karina L. Wilson, Sean T. Stanelle, Matthew B. Wofford, Rebecca M. Bonta, Steven E. Martin, John S. Green, FACSM, Stephen F. Crouse, FACSM. *Texas A&M University, College Station, TX.* (Sponsor: Stephen F. Crouse, Ph.D., FACSM)
(No relevant relationships reported)

Beef consumption has been stigmatized as an unhealthy dietary choice. However, randomized control trials to support this claim are lacking. **PURPOSE:** To examine the effect of low-fat (5%) and high-fat (25%) ground beef consumption on blood pressure (BP) and carotid-femoral pulse wave velocity (PWV). **METHODS:** Twenty-three male subjects (age 40 ± 11 yrs, height 177.4 ± 6.7 cm, weight 97.3 ± 25.0 kg, lean mass 64.5 ± 9.5 kg, fat mass 30.6 ± 19.1 kg) volunteered to participate in this cross-over design study. Each participant completed two, 5-week ground beef interventions in a randomized order with a 4-week washout period in-between. All participants visited the lab four times after an overnight fast. Each visit to the lab consisted of supine BP, dual energy x-ray absorptiometry (DXA) scan to assess body composition, and PWV analysis. The PWV recording was assessed on the right carotid and femoral arteries. The distance used for the PWV calculation was 80% of the actual distance between carotid and femoral sites. All PWV measures were completed according to previously published procedures (Van Bortel, 2011). BP and PWV results were analyzed separately via 2x2 repeated measures ANOVA. **RESULTS:** Our results indicate there was a significant decrease in systolic BP ($p=0.01$) following the high-fat ground beef intervention compared to the low-fat. The BP values for low-fat beef and high-fat beef are 120/74 and 116/73 mmHg, respectively. Further, there were no significant differences between the PWV measures. **CONCLUSION:** Based on our results, high fat ground beef favorably alters systolic BP and does not negatively affect PWV measures.

Association Of Physical Activity With Depression And Estimated Pulse Wave Velocity In Older Male Veterans

Andrew R. Heckel¹, John Garcia², Kevin S. Heffernan¹, Tiago V. Barreira¹. ¹Syracuse University, Syracuse, NY. ²University of South Florida, Tampa, FL. (Sponsor: Bo Fernhall, FACSM)
(No relevant relationships reported)

Physical inactivity is associated with an increased risk for cardiovascular disease (CVD) and depression. Veterans are a physically inactive population with a higher risk of developing CVD and depression than the general population. Whether objectively measured physical activity is associated with CVD risk and depressive symptoms in veterans has not been widely studied. **PURPOSE:** To examine the relationship between accelerometer measured moderate-vigorous physical activity (MVPA) and novel measures of CVD risk (estimated aortic stiffness and systemic inflammation) and depression in older veterans. **METHODS:** 152 older male veterans (mean age 71.9 ± 9.2 years) from the 2005-2006 NHANES were used in this analysis. Valid accelerometer data and MVPA were determined using standard NHANES procedures. Cardiovascular disease risk was determined by calculating estimated pulse wave velocity (ePWV) from a regression equation using age and mean blood pressure. Systemic inflammation was determined as C-reactive protein (logCRP). Depression score was determined through the Depression Screener Questionnaire (DPQ). One-tailed Spearman correlations were conducted to determine associations between variables. **RESULTS:** Physical activity guidelines were met by 17% of the veterans in this analysis. There was a significant, inverse relationship between MVPA and ePWV ($r=-0.34$, $p<0.01$), MVPA and logCRP ($r=-0.24$, $p<0.01$), and MVPA and depression score ($r=-0.16$, $p<0.05$). In addition, a significant positive association between ePWV and depression score ($r=0.17$, $p<0.05$) was noted. **CONCLUSION:** Decreased moderate-vigorous physical activity levels in older male veterans are associated with elevated aortic stiffness, systemic low-grade inflammation, and depressive symptomatology. This suggests that veterans who do not meet recommended physical activity guidelines may be at higher risk for CVD and depression.

Sex Differences In Microvascular Function In Pre-pubertal Children

Raffaele J. Massarotto, Gary J. Hodges, Alexandra Woloschuk, Deborah D. O'Leary, Bareket Falk, FACSM. *Brock University, St. Catharines, ON, Canada.*
Email: rm17ui@brocku.ca
(No relevant relationships reported)

There is little research examining the effect of sex on skin blood flow (SkBF) in adults, and less in children. Sex-related differences in SkBF may help explain known thermoregulatory differences between males and females. **Purpose:** To determine whether there are sex-related differences in the SkBF response to exercise, local heating, and acetylcholine (ACh). Additionally, the role of nitric oxide (NO) was examined. **Methods:** Laser-Doppler flowmetry was used to assess forearm SkBF. Responses to exercise (30 min cycling, 60%V_{O₂}max), local heating (44°C), and ACh iontophoresis were assessed in 15 pre-pubertal boys (age=10±1y, V_{O₂}max=1.66±0.25 l/min) and 10 girls (age=10±1y, V_{O₂}max=1.58±0.35 l/min), with and without NO synthase inhibition, using L-NAME iontophoresis. Three-way (group, time, treatment) repeated measures ANOVA was used to examine sex-related differences in the SkBF response during exercise and in the SkBF-ACh dose response. A two-way (group, treatment) repeated measures ANOVA was used to examine local heating-induced increase in SkBF. **Results:** Exercise-induced SkBF was greater in boys compared with girls (654 ± 355 and $316 \pm 182\%$ of baseline, respectively, $p<.0001$). L-NAME blunted the SkBF response more in boys than in girls (group-by-treatment interaction, $p=.004$). Local heating-induced SkBF was not significantly different between boys and girls ($1705 \pm 739\%$ and $1488 \pm 600\%$, respectively, $p=.35$), with no effect of L-NAME. The maximal ACh-induced SkBF was similar in boys and girls ($650 \pm 420\%$ and $612 \pm 411\%$, respectively). L-NAME similarly blunted the SkBF response in boys and girls (group-by-treatment interaction, $p=.52$). **Conclusion:** These findings demonstrate that while maximal SkBF and the vasodilatory response to ACh stimulation are similar in boys and girls, boys display a greater increase in SkBF during exercise of similar intensity. Further, the role of NO in the SkBF response appears greater in boys than girls only during exercise. Since absolute and relative exercise intensity was similar in the two groups, it is suggested that sex-related factors (e.g., hormones) may interact with the exercise response or with other vasodilators, resulting in different SkBF response.

Improved Endothelial Function Following Eight Weeks Of Low-intensity Resistance Training In Young Adults

José M. Briceño-Torres¹, Elizabeth Carpio-Rivera¹, Andrea Solera-Herrera¹, Jeffrey Forse², Peter W. Grandjean, FACSM³, José Moncada-Jiménez¹. ¹University of Costa Rica, San José, Costa Rica. ²Baylor University, Waco, TX. ³University of Mississippi, Oxford, MS. (Sponsor: Peter W Grandjean, Ph.D., FACSM)
 Email: josemiguel5692@gmail.com
 (No relevant relationships reported)

Cardiovascular diseases (CVD) are the leading cause of death worldwide, and compelling evidence indicates that exercise prevents and attenuates CVD. Resistance training (RT) exerts positive health effects; however, there is a lack of evidence regarding the RT intensities that could be prescribed to improve vascular endothelial function. **PURPOSE:** To compare the effects of two RT intensities during eight weeks on vascular endothelial function in sedentary young males. **METHODS:** Thirty-four sedentary men were recruited (age = 20.6 ± 1.8 yr., height = 171.3 ± 5.2 cm, weight = 65.2 ± 10.6 kg, DXA fat mass = 22.3 ± 7.4 %), and randomly assigned to a control group (CTRL, no exercise), RT at 50% of a maximum repetition [1-RM] and RT at 80% 1-RM. The RT program was performed twice a week for eight weeks, and except for the CTRL group, participants performed the same RT exercises at similar total workloads (1920 arbitrary units [AU] for the 80%RM and 1950 AU for the 50%RM). Vascular endothelial function was measured before (pre) and after (post) eight weeks by ultrasound and determined by the percentage of flow-mediated dilatation (%FMD). Mixed factorial ANOVA (3 groups x 2 measurements x 2 occlusions), effect size (ES) and 95% confidence interval (CI_{95%}) were computed for %FMD. **RESULTS:** A significant triple interaction was found on %FMD (p = 0.021). The eight-week post-intervention follow-up analyses showed a significant increase (p = 0.010) in %FMD in the 50%RM (Mean = 9.93 ± 3.73%, ES = 3.70, CI_{95%} = 1.59 to 5.79) compared to the control group (Mean = 5.72 ± 1.71%, ES = 1.67, CI_{95%} = -0.21 to 3.55), and no significant differences between 50%RM and 80%RM (Mean = 7.90 ± 2.51%, ES = 2.18, CI_{95%} = 0.27 to 4.10), and between 80%RM and control groups. **CONCLUSION:** A 50%RM intensity RT program elicited a positive vascular endothelial function adaptation following eight-weeks of training. It seems unnecessary to perform high-intensity RT to obtain arterial health benefits.

Sacubitril-Valsartan Treatment Improves Vascular Function And Functional Capacity In Heart Failure With Reduced Ejection Fraction

Kanokwan Bunsawat, Stephen M. Ratchford, Jeremy K. Alpenglow, Soung Hun Park, Catherine L. Jarrett, Josef Stehlik, Adam Smith, Russell S. Richardson, D. Walter Wray. *University of Utah, Salt Lake City, UT.* (Sponsor: Dr. Tracy Baynard, FACSM)
 Email: kanokwan.bunsawat@hsc.utah.edu
 (No relevant relationships reported)

The PARADIGM-HF (Prospective Comparison of ARNI with an ACE-Inhibitor to Determine Impact on Global Mortality and Morbidity in Heart Failure) trial identified a marked reduction in the risk of death from cardiovascular causes or hospitalization for heart failure (HF) in patients with HF with reduced ejection fraction (HFrEF) treated with sacubitril-valsartan. The mechanisms responsible for this improvement have not been fully identified, but may be related, in part, to improvements in vascular function and functional capacity, two important predictors of mortality and morbidity in this patient group. **PURPOSE:** We sought to test the hypothesis that short-term treatment with sacubitril-valsartan would improve vascular function and functional capacity in patients with HFrEF. **METHODS:** Eleven stable, class II/III patients with HFrEF (10M/1F, age: 69±3 yrs; BMI: 29.0±1.0 kg/m²; ejection fraction: 27±3%) were studied prior to initiation of treatment and at months 1, 2 and 3 of sacubitril-valsartan therapy. Vascular function was evaluated by brachial artery flow-mediated dilatation (FMD) and reactive hyperemia (RH), while functional capacity was determined using the six-minute walk test (6MWT). **RESULTS:** Treatment with sacubitril-valsartan improved brachial artery %FMD after 1 month of treatment, and this favorable response persisted during months 2 and 3 (baseline: 3.25±0.53%; 1-month: 5.23±0.71%; 2-month: 5.81±0.54%; 3-month: 6.35±0.84%, p<0.05). Likewise, %FMD normalized for the shear stimulus improved significantly at months 2 and 3 (baseline: 0.08±0.01%; 1-month: 0.13±0.01%; 2-month: 0.17±0.02%; 3-month: 0.20±0.03%). There was no change in RH, an index of microvascular function, at any time point (p>0.05). The 6MWT distance also increased significantly at months 2 and 3 (baseline: 420±28m; 1-month: 436±30m; 2-month: 465±35m; 3-month: 460±33m), but the changes in 6MWT distance were not correlated to the changes in %FMD or %FMD normalized for the shear stimulus (r=0.13, p=0.39 and r=0.01, p=0.97, respectively). **CONCLUSIONS:** These preliminary findings provide new evidence for the efficacy

of short-term treatment with sacubitril-valsartan to improve vascular function and functional capacity, two possible mechanisms underlying this treatment's benefits, in patients with HFrEF.

Insulin Stimulation Reduces Arterial Stiffness In Adults With Metabolic Syndrome

Brielle L. Dotson, Emily Heiston, Stephanie Miller, James Patrie, Arthur Weltman, FACSM, Steven Malin, FACSM. *University of Virginia, Charlottesville, VA.* (Sponsor: Steven K. Malin, FACSM)
 (No relevant relationships reported)

Purpose: Adults with metabolic syndrome (MetS) have increased fasting arterial stiffness compared with healthy counterparts, and this, in turn, increases risk for cardiovascular disease (CVD) and cardiac events. Although insulin acts to reduce arterial stiffness in healthy adults, the effects in obese individuals with MetS are unclear. We hypothesized that insulin stimulation would reduce measures of arterial stiffness in relation to aerobic fitness and body fat. **Methods:** Thirty-one obese adults (24F; 53.7±6.0yrs; 37.4±4.8kg/m²) were screened for MetS (NCEP ATP III criteria) following an overnight fast. Augmentation index (AIx), augmentation pressure (AP) and brachial systolic (bSBP) and diastolic blood pressure (bDBP) were assessed using SphygmoCor before and after a 2hr euglycemic-hyperinsulinemic clamp (90 mg/dl, 40 mU/m²/min). Aerobic fitness (VO_{2peak}; ml/kg/min) was measured through a treadmill protocol while body fat (BF; %) was determined using DEXA. **Results:** Compared to fasting, insulin significantly reduced AIx (28.5 ± 9.9 vs. 23.2 ± 9.9%, P<0.01) and AP (15.1 ± 6.7 vs. 21.1 ± 5.8 mmHg, P<0.01). However, there was no effect of insulin on bSBP (P=0.19) or bDBP (P=0.21). Fasting AIx and AP correlated with VO_{2peak} (r=-0.42, P=0.02 and r=-0.37, P=0.04) and BF (r=0.64, P<0.01 and r=0.68, P<0.01). Interestingly, neither the change in AIx nor AP from fasting to insulin stimulation correlated with VO_{2peak} (r=-0.18, P=0.33 and r=-0.12, P=0.95) or BF (r=-0.29, P=0.24 and r=-0.17, P=0.58). **Conclusion:** Insulin stimulation reduces indices of arterial stiffness in adults with MetS. While high aerobic fitness and lower BF may contribute to less arterial stiffness in the fasted state, they were not associated with insulin action. This suggests that insulin impacts arterial stiffness through another mechanism. Future research is warranted to determine the role of insulin on arterial health in order to optimize CVD prevention/treatment. Funding was supported by the National Institutes of Health RO1-HL130296.

The Protective Mechanism Of Exercise Training For Coronary Vascular Dysfunction In Atherosclerosis: Er Stress And Ucp-2

Yoonjung Park¹, Junyoung Hong¹, Eunkyung Park¹, Jonghae Lee¹, Yang Lee². ¹University of Houston, Houston, TX. ²Texas A&M University, College Station, TX. (Sponsor: Minsoo Kang, FACSM)
 Email: ypark10@uh.edu
 (No relevant relationships reported)

PURPOSE: Endoplasmic reticulum (ER) stress and uncoupling protein-2 (UCP-2) are a key modulator for endothelial dysfunction in atherosclerosis. We determined the effects of exercise on ER stress and UCP-2 in endothelial dysfunction in atherosclerosis. **METHODS:** We used 4 groups of mice; wild type (WT), WT with exercise training, running on the treadmill for 12 weeks (WT-EX), apolipoprotein E knockout (ApoE KO) and ApoE KO with exercise training (ApoE KO-EX). We measured endothelium-dependent acetylcholine (ACh)-induced vasodilation of isolated and pressurized coronary arterioles in a concentration-dependent manner. Also, ACh-induced vasodilation was elicited in the presence of an inhibitor of eNOS and UCP-2 (L-NAME and Genipin) and the ER stress inducer (Tunicamycin). Immunoblotting was performed to measure the protein expression of ER stress markers (GRP78, IRE1, eIF2α, and CHOP), NLRP3 inflammasome signaling (NLRP3, caspase-1, IL-1β), Bax, TXNIP, and UCP-2 in the heart. The expression of p67^{nox} and superoxide were visualized using immunofluorescence and DHE staining in coronary arterioles. NO production was measured by nitrate/nitrite assay. **RESULTS:** ACh-induced endothelium-dependent vasodilation was attenuated in coronary arterioles of ApoE KO, but it was improved in ApoE KO-EX. L-NAME, tunicamycin, and Genipin attenuated vasodilation in WT, WT-EX and ApoE KO-EX, but not in ApoE KO. Exercise training reduced the expressions of ER stress (GRP78, p/t-IRE1, p-eIF2α, and CHOP), NLRP3 inflammasome (TXNIP, caspase-1 p20, and IL-1β), Bax, superoxide production, and NADPH oxidase p67^{nox}, but it increased NO production in ApoE KO-EX mice. **CONCLUSION:** Our findings suggest that exercise training alleviates endothelial dysfunction in atherosclerotic coronary arterioles through the NOS, UCP-2, and ER stress signaling pathways including TXNIP/NLRP3 inflammasome and oxidative stress.

Isometric Exercise Training, Regardless Of Muscle Mass, Reduces Resting Blood Pressure In Normotensive Healthy Males

Ebony Gaillard¹, Benjamin D. H. Gordon², Maria G. Alessi¹, Joseph S. Marino¹, Jeanette M. Bennett¹, Vanna Sombatsaphay¹, Brittany C. Price¹, Christopher D. Stewart¹, Spencer Green¹, Michael T. Roberts¹, Jenna E. Kachmarik¹, Michael J. Persin¹, Reuben Howden¹. ¹University of North Carolina at Charlotte, Charlotte, NC. ²Slippery Rock University, Slippery Rock, PA.
(No relevant relationships reported)

PURPOSE: Isometric exercise training (IET) is an effective adjunct for the management of resting blood pressure (RBP) but responsible mechanisms have not yet fully been identified. Isometric contractions reduce blood flow as a result of vascular compression altering intramuscular metabolism. In response, active muscle could increase the production and circulation of vasoactive molecules (e.g., VEGF) and alter inflammatory biomarkers (e.g., IL-6 and TNF- α), which may lead to adaptations in resistance vessels. We studied the influence of bilateral arm or leg IET on blood pressure and plasma VEGF, IL-6, and TNF- α over the course of 6-weeks.

METHODS: The study was approved by the UNC Charlotte IRB. Twenty-eight healthy and recreationally active normotensive males (19-25 years) gave written informed consent and were randomized to one of three conditions; double bicep curl IET (IBC), double leg extension IET (ILE), or control (CON). IET groups completed exercise sessions at 15% maximal voluntary contraction (6 x 2-minute contractions) 3 days per week for 6-weeks with RBP assessed at each visit. For a subsample (n=17), 3 blood samples (pre-, 1 hour post-, 24 hours post-training) were collected at the first and last training visits. The CON group performed all study procedures except IET.

RESULTS: Using a repeated-measures ANCOVA (controlling for acclimation RBP and cohort), a significant time by treatment effect was observed from Week 1 to Week 6, $F(2, 23) = 4.10$, $p=.03$, $\eta^2 = .263$. Specifically, IET resulted in a lower systolic RBP, but did not differ by IET group: IBC -4.4 ± 4.0 mmHg; ILE -4.3 ± 7.6 mmHg; CON 2.3 ± 4.0 mmHg. Diastolic RBP did not significantly change for any group. Currently, there are no acute or chronic IET effects on the systemic biomarker levels.

CONCLUSIONS: 6-weeks of bilateral arm or leg IET resulted in significant reductions in systolic RBP. Due to the small sample size (n=17), power may have limited the ability to detect significant effects on circulating VEGF, TNF- α and IL-6. Research should continue to examine how IET alters RBP. The research was funded by Faculty Research Grant (JMB & HR) and the Thomas L. Reynolds Graduate Student Research Award (B.D.H.G)

965 Board #91 May 27 2:30 PM - 4:00 PM

Oscillometric Ambulatory Blood Pressure Monitors Are Prone To Errors In A Controlled Laboratory Setting

V. Patteson Lombardi, Patrick C. Reichhold, Jennifer L. Cramer, Hannah P. Harkness, Natalie J. DeBell, Nicholas R. Dietz, Tova J. Kruss, Savannah S. Lutz, Donald L. Pate. University of Oregon, Eugene, OR.
Email: lombardi@uoregon.edu
(No relevant relationships reported)

We developed a dual monitor protocol for testing the accuracy and reliability of 24-hr ambulatory blood pressure monitors (ABPMs) and determined in normotensives (n=15), hypertensives (n=14) and alcohol-dependents (n=11) that a popular auscultatory ABPM was highly variable, misclassifying up to 70% of patients.

Purpose: To determine the accuracy and reliability of two widely used oscillometric ABPMs, the Oscar 2 (Suntech Medical, Morrisville, NC) and the Spacelabs 90207 (Spacelabs Healthcare, Snoqualmie, WA) under controlled lab conditions. **Hypothesis:** Oscillometric proprietary algorithms were developed from auscultatory reference BPs, thus ABPMs would differ from each other and from observers (O1, O2) using a Hg column and Thinklabs digital stethoscope. **Methods:** BPs were measured in triplicate on both arms in 17 seated subjects (10 ♂, 7 ♀) with simultaneous same arm BPs by O1 & O2 alternating with simultaneous opposite arm BPs by ABPMs. **Results:** The average (x \pm SE) systolic (SBP) and diastolic (DBP) BPs for O1, O2, Oscar & Spacelabs ABPMs were 114.2/67.3 \pm 2.0/1.8 mm Hg, 114.1/67.1 \pm 2.0/1.8 mm Hg, 124.0/67.7 \pm 2.1/1.4 mm Hg, and 119.3/67.9 \pm 1.9/1.3 mm Hg, respectively. Compared to O1O2, the Oscar overestimated SBP by 9.8 \pm 0.9 mm Hg ($P < 0.001$), while the Spacelabs overestimated SBP by 5.2 \pm 0.8 mm Hg ($P < 0.001$). SBP also differed significantly between ABPMs ($P < 0.001$). Though the DBP difference was small between observers and ABPMs, (O1O2 - Oscar = -0.6 mm Hg; O1O2 - Spacelabs = -0.7 mm Hg), there was a high degree of variability with the Oscar ranging from 23 mm Hg above to 20 mm Hg below and the Spacelabs 23 mm Hg above to 26 mm Hg below the observers. Compared to O1O2, Oscar SBP and DBP differed by > 5 mm Hg in 15/17 (88%) and 7/17 (41%), while the Spacelabs SBP and DBP differed by > 5 mm Hg in 11/17 (65%) and 8/17 (47%) of subjects, respectively. **Conclusions:** Controlled lab testing revealed significant measurement errors in widely used oscillometric ABPMs. Given light exercise during 24-hr ambulatory monitoring, the outlook for

accuracy and reliability appears worse. Oscillometric nomogram-like equations are population-specific and indirect 2nd generation estimations and cannot account for individual variations making them highly susceptible to errors, though more testing is required in a greater number of hypertensives.

Associations Of Objectively Measured Sedentary Time With Endothelial Function Biomarkers In Young Male Adults

Chen Zheng, Sinead Sheridan, Stephen H.S Wong, FACSM. The Chinese University of Hong Kong, Hong Kong, Hong Kong.
Email: zhengchen@link.cuhk.edu.hk
(No relevant relationships reported)

PURPOSE: Sedentary behavior (SB) is recognized as a serious global health issue. SB-induced down regulation of shear rate and blood flow play a key role in the pathogenesis of endothelial dysfunction, an important prognostic marker for cardiovascular disease. The purpose of this study was to assess the association between objectively measured sedentary time and endothelial function biomarkers in young male adults.

METHODS: A total of 93 participants (age, 21.8 \pm 3.8 yr; body height, 171.6 \pm 6.4 cm; body weight, 62.1 \pm 6.4 kg; % body fat, 15.6 \pm 4.6%; body mass index (BMI) 21.1 \pm 1.7 kg/m²; waist circumference 74.5 \pm 5.1 cm; heart rate (HR) 67.6 \pm 9.5 bpm; systolic blood pressure (SBP) 108.4 \pm 9.1 mmHg; diastolic blood pressure (DBP) 71.6 \pm 8.1 mmHg) wore the activPALTM continuously for 7 days without removal. Total sedentary time was assessed using PALanalysis v8.0. Bedtime and wake-up time were recorded by participants. Sleep duration was determined as the time between bed time and wake-up time. Sedentary time during waking hours was calculated as the total sitting/lying time minus sleep duration. A fasting venous blood sample was drawn from each of the participants from which serum endothelial cell adhesion molecules E-selectin, P-selectin, Intercellular Adhesion Molecule 1 (ICAM-1) and Vascular Cellular Adhesion Molecule 1 (VCAM-1) were measured using flow cytometry. Multiple linear regression models examined the associations of sedentary time with endothelial function biomarkers using SPSS version 23.0.

RESULTS: E-selectin ($\beta = 0.226$, 95% confidence interval [CI]: 0.021, 0.431) and P-selectin ($\beta = 0.216$, 95% CI: 0.017, 0.415) were positively associated with sedentary time after controlling for age and BMI. After moderate-to-vigorous physical activity (MVPA) was added to the model, there were no significant association between E-selectin and sedentary time. No significant associations were found between ICAM-1 or VCAM-1 with sedentary time or between ICAM-1 or VCAM-1 with sedentary time after controlling age, BMI, and MVPA.

CONCLUSIONS: Objectively measured sedentary time was positively associated with E-selectin and P-selectin in young male adults independent of age and BMI. MVPA may alleviate the adverse effects of sedentary time on biomarkers of endothelial function.

967 Board #93 May 27 2:30 PM - 4:00 PM

Regular Resistance Training Enhances Fibrinolytic Potential

Paul R. Nagelkirk, Kayla Soave, Cody Altherr, Andrew T. Del Pozzi. Ball State University, Muncie, IN.
Email: prnagelkirk@bsu.edu
(No relevant relationships reported)

Blood clots cause most cardiovascular events, such as heart attack and stroke. Blood markers of fibrinolysis, the capacity to dissolve blood clots, are independently associated with cardiovascular morbidity and mortality. Regular resistance training (RT) produces various muscular and vascular adaptations that are theorized to influence thrombotic potential, but there are no published longitudinal studies that examine fibrinolytic adaptations to RT. **PURPOSE:** The purpose of this study was to identify effects of an 8-week RT program on fibrinolytic potential. **METHODS:** Sixteen healthy adults (n = 12 women, 4 men; age = 23 \pm 5 years) completed a RT program that targeted all major muscle groups, 3 times per week for 8 weeks. Exercises included 2-3 sets of 8-12 repetitions performed at approximately 60-80% of 1 RM. Body composition, circumferences, and 1 RM leg and chest press strength measures were obtained via standard methods. Resting blood samples were obtained by clean venipuncture at baseline and after 8 weeks of RT. Enzyme-linked immunosorbency assays were used to assess plasma concentrations of the following fibrinolytic variables: active tissue plasminogen activator (tPA:c), tissue plasminogen activator antigen (tPA:g), active plasminogen activator inhibitor-1 (PAI-1:c), and plasminogen activator inhibitor-1 antigen (PAI-1:g). Statistical analyses were conducted using paired t-tests. **RESULTS:** Significant increases in lean mass (PRE = 52.18 \pm 10.03, POST = 53.64 \pm 10.42 kg), arm circumference (PRE = 29.89 \pm 5.12, POST = 30.97 \pm 4.92 cm), and mid-thigh circumference (PRE = 49.96 \pm 5.43, POST = 51.08 \pm 5.83 cm) were observed (all $p < 0.05$). Maximal chest press (PRE = 57.8 \pm 37.5, POST = 73.3 \pm 43.2 kg) and leg press strength (PRE = 189.5 \pm 95.8, POST = 256.7 \pm 97.9 kg) significantly increased ($p < 0.01$). PAI-1:c (PRE = 20.3 \pm 32.5, POST

= 9.5 ± 20.9 U/ml, p=0.05) and PAI-1:g decreased (PRE = 10.18 ± 8.98, POST = 7.20 ± 5.74 ng/dl, p<0.05). No change in tPA:c or tPA:g occurred. **CONCLUSION:** The decrease in plasma concentrations of total and active PAI-1 indicate reduced inhibition of fibrinolytic activation, suggesting that the risk of a cardiovascular event is reduced after resistance training. The mechanisms underlying this specific adaptation may relate to increased skeletal muscle mass, but additional research is warranted.

Evaluation Of Inter-rater And Test-retest Reliability For Near-infrared Spectroscopy Reactive Hyperemia Measures
 Melissa J. McGranahan, Samuel W. Kibildis, Kevin K. McCully, FACSM, Nathan T. Jenkins. *University of Georgia, Athens, GA.* (Sponsor: Kevin McCully, FACSM)
 Email: mmcg91@uga.edu
(No relevant relationships reported)

Near-Infrared spectroscopy (NIRS) is a non-invasive tool used to measure blood flow in peripheral tissues. More information on test-retest reliability and inter-rater agreement of NIRS-based reperfusion assessments is needed. **PURPOSE:** To assess inter-rater agreement for NIRS based data analysis, and evaluate the measurement's reliability across days. **METHODS:** On three separate days, participants' (N=15 males, 22± 2 yr.) reactive hyperemia was measured in the left gastrocnemius muscle using Continuous-Wave NIRS. A blood pressure cuff was placed proximal to the knee and inflated to occlude lower leg blood flow for 5 minutes. The cuff was rapidly deflated, and the blood flow responses were measured until values returned to baseline. Raw NIRS data were exported and analyzed in a custom-written routine in MATLAB by two individuals. The following NIRS parameters were selected:(1) the time for the O₂Hb signal to reach 50% peak post-occlusion hyperemia (T_{1/2}), (2) The O₂Hb range used to normalize the NIRS signal; (3) the post peak-hyperemic O₂Hb recovery slope, taken as an index of sustained microvascular dilation. Inter-rater agreement was assessed using Intraclass Correlation Coefficients (ICC), calculated using an absolute agreement two-way mixed effects model. 95% confidence intervals (CI) of ICCs are reported. Cronbach's alpha was used to assess day to day reliability for each of the measures. **RESULTS:** The ICC data indicate that there is "good" to "excellent" agreement between NIRS analyzers as shown in table 1.

	Visit 1 Rater 1 (SD)	Visit 1 Rater 2 (SD)	Visit 1 ICC (CI)	Visit 2 ICC (CI)	Visit 3 ICC (CI)
T _{1/2}	9.03 (2.43)	9.71 (3.07)	.63 (.22-.86)	.99 (.98-1.0)	.97 (.91-.99)
O ₂ Hb Range	31.72 (8.57)	33.06 (6.47)	.71 (.33-.89)	.98 (.94-.99)	.97 (.92-.99)
Post peak-hyperemic O ₂ Hb recovery slope	-.17 (.05)	-.18 (.06)	.77 (.45-.92)	.91 (.71-.97)	.86 (.65-.95)

The Cronbach's alpha for raters 1 and 2 were: T_{1/2} (α =.89, α = .91), O₂Hb (α =.95, α = .89), and post peak-hyperemic O₂Hb recovery slope (α =.74, α = .83). **CONCLUSION:** Our data indicate multiple raters can be used to analyze NIRS based reperfusion measures with good agreement and that the method has sufficient test-retest reliability to use in experimental designs involving multiple laboratory visits.

The Influence Of Sleep On Blood Pressure In Healthy Children
 Felicia R. Berube¹, Elissa K. Katulka¹, Michele N. D'Agata¹, Stephen J. Ives², William B. Farquhar, FACSM¹, Melissa A.H. Witman¹. ¹University of Delaware, Newark, DE. ²Skidmore College, Saratoga Springs, NY.
 Email: frberube@udel.edu
(No relevant relationships reported)

Loss of ideal cardiovascular health can begin in childhood with the development of cardiovascular disease (CVD) risk factors occurring on a continuum. Central blood pressure (BP) values may be more reflective of CVD risk than peripheral BP but are rarely measured in children. Additionally, in adults, poor sleep quality is associated with higher BP and incidence of CVD, however these relations are not as well elucidated in children. **PURPOSE:** To evaluate the role of sleep duration, sleep quality, and sleep variability (SLV) on resting central and peripheral BP in apparently healthy 7-12 yr old children. **METHODS:** Sleep duration, total time in bed (TTIB), sleep quality (assessed by sleep efficiency (SE) and wake after sleep onset (WASO)),

and SLV (assessed by sleep midpoint standard deviation (SMSD)) were recorded in 20 healthy children (10 ± 0.5 yrs, 10 boys, 10 girls) for 7 consecutive nights outside of the laboratory via wrist accelerometry. Following sleep monitoring, peripheral BP was measured and using pulse wave analysis (PWA) central BP was estimated. Central and peripheral BP were measured and averaged over 3 trials. Pearson's r correlations were used to assess relations between sleep metrics and BP values. Independent samples t-tests were used to determine group (low vs. high SE) differences. **RESULTS:** Sleep duration averaged 7.9 ± 0.2 hrs/night, while TTIB averaged 9.6 ± 0.1 hrs/night. SE was 82 ± 2%, WASO was 89 ± 9 mins, and SMSD was 48 ± 6 mins. Sleep duration, TTIB, SE, WASO, and SMSD were not significantly associated with central or peripheral BP values. When using an 85% cutoff for SE, central and peripheral BP were not significantly different between groups. Additionally, using the same cutoff for SE, TTIB was not significantly different between groups, however sleep duration was significantly different (7.4 hrs <85% vs 8.4 hrs >85%, p < 0.001). **CONCLUSION:** Preliminary data suggest that children age 7-12 are not getting the recommended amount of sleep (9-11 hrs/night) despite adequate time in bed. Thus far, there seems to be no effect of shortened, poor-quality, and more variable sleep on BP in healthy children age 7-12, but further research is needed. Supported by NIH grant P20GM113125

THE IMPACT OF REPEATED, EXERCISE-INDEPENDENT INCREASES IN BLOOD FLOW ON LOWER LIMB ENDOTHELIAL FUNCTION
 Ellen McGarity-Shipley, Sarah M. Schmitter, Kyra E. Pyke. *Queen's University, Kingston, ON, Canada.*
(No relevant relationships reported)

Exercise training improves endothelial function partially through increases in blood flow-associated shear stress. Local heat training can be used to isolate the exercise-independent effect of increased shear stress on endothelial function. Forearm heat training has been found to improve brachial artery endothelial function, however, this has never been investigated in the lower limb. **PURPOSE:** To examine the effect of heat training on superficial femoral artery (SFA) endothelial function in young, healthy females utilizing reactive hyperemia flow-mediated dilation (RH-FMD) and sustained stimulus FMD (SS-FMD). **METHODS:** Female participants (n=13, 23±2 yrs) had one leg randomized to the heat training intervention (EXP; other leg: control (CON)). The EXP leg underwent 8 weeks of heat training via immersion in 42.5°C water for five 35-minute sessions per week. At week 0, 2, 4, 6, and 8, SFA RH-FMD and SS-FMD were measured in each leg via duplex ultrasound. RH-FMD was characterized as the peak % change in diameter following release of 5 min of thigh occlusion. SS-FMD was characterized as the peak % change in diameter during 6 min of plantar flexion exercise at a target shear stress of 13 dynes/cm². **RESULTS:** Week zero RH and SS-FMD were as follows: RH-FMD: CON 7.3±3.1, EXP 5.1±4.2; SS-FMD: CON 8.1±4.3, EXP 9.2±6.4. RH-FMD and SS-FMD did not change over the training period (RH: p=0.128; SS: p=0.063) or differ between EXP and CON legs (RH: p=0.685; SS: p=0.337; interaction RH: p=0.076; SS: p=0.958). Covariation for the shear stress stimulus did not alter the results. **CONCLUSION:** 8-weeks of leg heat training in young, healthy females did improve SFA endothelial function. These results are in contrast with previous findings that heat training improves upper limb endothelial function. The increased blood flow-associated shear stress elicited by the heating protocol may have been inadequate to elicit adaptation in the SFA. Future studies are needed to determine whether other lower limb conduit arteries or the microvasculature benefit from local, lower limb heat training.

High Intensity But Not Moderate Intensity Exercise Attenuates Carotid Shear-mediated Dilation
 Rintaro Sakamoto, Erika Iwamoto, Yutaka Yamada, Tatsuki Kamoda, Katsuyuki Tamai, Kotomi Yamazaki, Toru Neki, Masaki Katayose. *Sapporo medical university, Sapporo, Japan.*
(No relevant relationships reported)

PURPOSE: Exercise training improves cerebrovascular function. It has been recently speculated that shear-mediated dilation of the internal carotid artery (ICA) is a useful marker of cerebrovascular function. Although exercise intensity is a major factor of exercise prescription, the effects of exercise intensity on shear-mediated dilation of the ICA remain unknown. This study investigated the shear-mediated dilation of the ICA following acute, moderate-, and high-intensity exercise in healthy males. **METHODS:** Twelve healthy males (22 ± 2 years) completed a 30 min leg cycling exercise at moderate [(55-65% of age-predicted maximal heart rate (HR_{max}))] and high (75-85% HR_{max}) intensities. Shear-mediated dilation of the ICA was assessed at pre-exercise (Pre), 5 min (Post5), and 60 min (Post60) after the cessation of exercise. Shear-mediated dilation was induced by 3 min of hypercapnia (target end tidal partial pressure of carbon dioxide +10 mmHg from an individual's baseline) and calculated

as the percent rise of the peak diameter from baseline diameter. Doppler ultrasound was employed to measure the carotid diameter, and blood velocity during exercise, and hypercapnia. Conductance and shear rate (SR) of the ICA at 25 min of exercise was calculated based on the Doppler variables and mean blood pressure.

RESULTS: Neither type of exercise altered the SR of the ICA (Interaction effect; $P = 0.93$, main effect of time; $P = 0.14$). Conductance decreased during high-intensity exercise (Pre to 25 min; 5.1 ± 1.3 to 3.2 ± 1.0 ml/min/mmHg, $P < 0.01$) but not during moderate-intensity exercise (5.0 ± 1.3 to 4.0 ± 0.8 ml/min/mmHg, $P = 0.11$). Shear-mediated dilation immediately declined after high-intensity exercise (Pre to Post5; 6.9 ± 1.7 to $4.0 \pm 1.4\%$, $P < 0.01$), but not after moderate-intensity exercise (7.2 ± 2.1 to $7.3 \pm 1.8\%$, $P = 1.00$). Shear-mediated dilation did not show significant changes at Post60 in either exercise intensity (Post 60; Moderate; 8.0 ± 3.1 , High; $6.4 \pm 2.9\%$). **CONCLUSIONS:** The acute decline of shear-mediated dilation in the ICA following high-intensity exercise may have been due to changes in the sympathetic activity and hemodynamics rather than in the SR. Current findings suggest that moderate-intensity exercise is more suitable for promoting cerebrovascular health than high-intensity exercise.

Concurrent Vibration During Muscle Contractions Acutely Reduces Following Central Arterial Stiffness

Li-Chen Lee¹, Chun-Yi Wang², Hsin-Fu Lin³. ¹Shih Hsin University, Taipei, Taiwan. ²National Taichung University of Science and Technology, Taichung, Taiwan. ³National Taiwan University, Taipei, Taiwan.

(No relevant relationships reported)

Whole body vibration has been shown to elicit vasodilation after intervention. **PURPOSE:** To test the hypothesis that concurrent local vibration while muscle contraction would reduce the vasoconstrictive response induced by exhaustive resistance exercise. **METHODS:** A total of 18 apparently young healthy males (age=22±1 yrs; BMI=23 ± 1kg/m²) were recruited. Following the maximal isometric voluntary contraction determination (MVC), participants were randomly assigned to perform 2 trials of isotonic knee extensor exercise (40%MVC×3 sets, 8 reps for the first 2 sets, exercise to exhaustion in the 3rd set, 1 min rest interval) with (KE+V) and without (KE) concurrent vibration (26Hz, 2-4mm in magnitude) on the customized motor-driven knee extensor device. Brachial blood pressure measured by sphygmomanometer, central and peripheral pulse wave velocity determined by photoplethysmography, and heart rate variability (HRV) were measured before and 5 mins after exercise. **RESULTS:** Heart rate, brachial blood pressure parameters significantly increased from baseline during exercise, and there was no difference between treatments. KE+V trial significantly reduced central pulse wave velocity after exercise, whereas KE did not elicit any changes on pulse wave velocity measures compared with the baseline. HRV analysis showed KE significantly increase low to high frequency ratio (LF/HF) and reduced RMSSD after exercise, whereas no significant changes were observed in KE+V trial. **CONCLUSIONS:** Local concurrent vibration with muscle contraction also exerts vasodilatory responses after exercise, which may be associated with relatively higher parasympathetic dominance induced by vibration.

Distribution Of Passive Leg Movement-induced Hyperemia In Old And Impact Of Occluding The Lower Leg

Katherine L. Shields, Catherine L. Jarrett, Angela V. Bisconti, Soung Hun Park, Jesse C. Craig, Ryan M. Broxterman, Russell S. Richardson. University of Utah, Salt Lake City, UT.

Email: Katherine.Shields@hsc.utah.edu
 (No relevant relationships reported)

PURPOSE: With passive leg movement (PLM), a vascular function assessment, in the young, of the total blood flow (BF) that passes through the common femoral artery (CFA), ~70% is directed to the deep femoral artery (DFA), while only ~30% passes through the superficial femoral artery (SFA). With lower leg cuff-induced BF occlusion, a common practice with drug infusions during PLM, there is an attenuated response in the SFA, which is reflected by a fall in BF in the CFA, but not in the DFA. Interestingly, the proportion of blood passing through the DFA and SFA is unchanged. However, BF distribution during PLM, and the impact of cuffing the lower leg, with aging is unknown. **METHODS:** Therefore, PLM was performed with and without cuff-induced lower leg BF occlusion in 6 healthy old subjects, with BF assessed by Doppler ultrasound. **RESULTS:** In terms of BF distribution during PLM, like the young, of the 80±27 ml of blood that passed through the CFA, 69±22% was directed to the DFA, while only 31±22% passed through the SFA. However, unlike the young, the cuff resulted in the complete ablation of SFA BF and the fall in CFA BF did not achieve statistical significance. As with the young, DFA BF was unaltered by the cuff. **CONCLUSIONS:** Thus, in the old, as with young, the PLM-induced hyperemia

predominantly passes through the DFA. Cuffing appears to impact the SFA BF in the old to a greater extent than the young, but, again, in this population there is no effect on PLM-induced DFA BF.

Decreased Pulse Wave Reflections Associated With Isometric Handgrip Training Improves Cognitive Function In Older Adults

Takanobu Okamoto, Yuto Hashimoto. Nippon Sport Science University, Tokyo, Japan.

Email: tokamoto@nittai.ac.jp

(No relevant relationships reported)

PURPOSE: The purpose of this study was to investigate whether the decrease in pulse wave reflection and central systolic blood pressure (SBP) as a result of isometric handgrip (IHG) training improves cognitive function in older adults.

METHODS: Twenty-two men and women (age 75±7 years, mean±standard deviation) who were not actively involved in regular resistance or endurance training were randomly assigned to either the group that performed IHG training (IHG group, n=11) or the sedentary control group (CON group, n=11). The IHG exercise comprised four unilateral 2-min isometric contractions at 30% of maximal voluntary contraction using a programmed handgrip dynamometer with 1-min rest periods for 5 days per week for 8 weeks. Carotid augmentation index (AIx), an index of the magnitude of pulse wave reflections, and carotid SBP were non-invasively measured after resting in the supine position for at least 5 min in both groups before (baseline) and after 8 weeks of training using an arterial applanation tonometry system. Trail making test (TMT) Part A, which measures processing speed, and Part B, which assesses task shifting, were used to determine processing speed and flexibility in task switching and cognition.

RESULTS: Carotid AIx and carotid SBP in the IHG group after training were significantly lower than baseline values, decreasing from 52±4 to 39±3 mmHg and from 148±5 to 137±5 mmHg, respectively ($p < 0.05$ for both). TMT-A and TMT-B in the IHG group after training were significantly lower than baseline values, decreasing from 34.73±3.04 to 26.41±2.33 and from 60.52±5.25 to 49.39±4.51 s, respectively ($p < 0.05$ for both). The carotid AIx, carotid SBP, TMT-A and TMT-B did not significantly change before and after training in the CON group. A significant positive correlation was observed between the amount of change in carotid AIx and the amount of change in TMT-A ($r = 0.603$, $p < 0.05$) and TMT-B ($r = 0.591$, $p < 0.05$). In addition, a significant positive correlation was observed between the amount of change in carotid SBP and the amount of change in TMT-A ($r = 0.736$, $p < 0.01$) and TMT-B ($r = 0.582$, $p < 0.05$).

CONCLUSIONS: These results demonstrate that isometric handgrip exercises reduce carotid AIx and carotid SBP, which is associated with improving cognitive function.

A Cross-sectional Comparison Of Vascular Health Between Physically Active Pre- And Post- Menopausal Women.

Amélie Debray¹, Nicholas Ravanelli¹, Louis Bherer¹, Laurent Bosquet², Carina Enéa², Daniel Gagnon¹. ¹Montreal Heart Institute, Montreal, QC, Canada. ²University of Poitiers, Poitiers, France.

Email: amelie.debray@umontreal.ca

(No relevant relationships reported)

Following menopause, the risk of developing cardiovascular diseases increases significantly in women. The hormonal changes observed during the menopause transition, including the cessation of estrogen production by the ovaries, seems to accelerate arterial aging by decreasing vasoreactivity and increasing arterial stiffness. Physical activity is considered the most effective strategy to maintain optimal vascular health. For older men, research has demonstrated a positive influence of physical activity on markers of vascular health. However, in older women, the benefits of physical activity on vascular health are still unclear. **PURPOSE:** To determine if physically active post-menopausal women demonstrate preserved vascular health compared to physically active pre-menopausal women. **METHODS:** Five pre- (49 ± 3 years) and five post- (54 ± 2 years) menopausal healthy and active women were recruited. Blood pressure (24-hour ambulatory blood pressure monitoring), physical activity levels (7-day accelerometry), vasoreactivity (brachial artery flow-mediated dilation) and central arterial stiffness (carotid-femoral pulse wave velocity) were compared between groups. **RESULTS:** Despite both groups being physically active

(post: 708 ± 235 vs. pre: 445 ± 302 min/week, P=0.16), post-menopausal women tend to have greater 24-hour systolic blood pressure (125 ± 9 vs. 115 ± 8 mmHg, P=0.14). In contrast, vasoreactivity (post: 3.35 ± 3.68 vs. pre: 4.58 ± 1.40 %, P=0.62) and central arterial stiffness appear similar between groups (post: 7.19 ± 2.11 vs. pre: 6.84 ± 1.40 m/s, P=0.78). **CONCLUSION:** Physically active post-menopausal women tend to have greater systolic blood pressure compared to physically active pre-menopausal women, despite similar values of endothelial function and arterial stiffness.

Sitting-induced Endothelial Dysfunction Is Prevented In Endurance-trained Individuals

Takuma Morishima¹, Yosuke Tsuchiya², Hisashi Ueda², Katsunori Tsuji³, Eisuke Ochi¹. ¹Hosei University, Tokyo, Japan. ²Teikyo Heisei University, Tokyo, Japan. ³National Cancer Center, Tokyo, Japan.

(No relevant relationships reported)

PURPOSE: Prolonged sitting impairs leg endothelial function, which seems to be mediated by a sustained reduction in blood flow-induced shear stress. However, whether regular endurance training is effective in preventing sitting-induced leg endothelial dysfunction remains largely unknown. Herein, we tested the hypothesis that sitting-induced leg endothelial dysfunction is prevented in high endurance-trained individuals.

METHODS: The endurance-trained group comprised 11 male collegiate cyclists (age, 19.7 ± 0.6 years; height, 168.4 ± 6.2 cm; weight, 62.7 ± 7.0 kg; body mass index, 22.1 ± 2.4 kg/m²), and the untrained group comprised 9 male with no regular endurance training (age, 21.1 ± 1.8 years; height, 170.1 ± 6.6 cm; weight, 72.2 ± 8.1 kg; body mass index, 24.8 ± 1.5 kg/m²). Peak oxygen uptake (VO_{2peak}) was initially determined in all participants using incremental exercise test (37.9 ± 4.7 mL/min/kg in the untrained group vs. 60.5 ± 3.6 mL/min/kg in the endurance-trained group). At second visit, the popliteal artery flow-mediated dilation (%FMD) was assessed before and after a 3-h sitting period. During the sitting period, the popliteal artery diameter and blood velocity were measured every hour.

RESULTS: The popliteal artery shear rate was significantly and similarly reduced during the sitting period in both groups (the untrained group and the endurance-trained group: 51.9 ± 19.2 sec⁻¹ vs. 58.3 ± 23.5 sec⁻¹ at pre-sit, 25.5 ± 10.9 sec⁻¹ vs. 25.5 ± 15.2 sec⁻¹ at 1h during sitting period, 19.4 ± 7.4 sec⁻¹ vs. 27.5 ± 12.3 sec⁻¹ at 2h during sitting period, 21.4 ± 8.1 sec⁻¹ vs. 20.8 ± 8.3 sec⁻¹ at 3h during sitting period, 29.4 ± 13.9 sec⁻¹ vs. 29.7 ± 15.8 sec⁻¹ at post-sit, P < 0.001). In a 3-h sitting, a significant impairment in popliteal artery %FMD was observed in the untrained group (4.5 ± 0.6 % vs. 1.6 ± 0.2 % P = 0.003), but it was prevented in the endurance-trained group (6.9 ± 0.7 % vs. 6.2 ± 1.3 %, P < 0.431).

CONCLUSIONS: In conclusion, the present study revealed that sitting-induced leg endothelial dysfunction is preventable in endurance-trained individuals.

B-69 Free Communication/Poster - ACL Injury

The Functional Movement Screen Is Not Associated With Self-reported Disability, Gait, Or Drop Vertical Jump In Individuals With ACL Reconstruction

Eric J. Shumski¹, Caitlyn Heredia², Skylar C. Holmes³, Derek N. Pamukoff¹. ¹California State University, Fullerton, Fullerton, CA. ²Northern Arizona University, Flagstaff, AZ. ³University of Massachusetts, Amherst, MA.

Email: ericshumski@csu.fullerton.edu

(No relevant relationships reported)

Purpose: To determine the associations between Functional Movement Screen (FMS) scores and the International Knee Documentation Committee (IKDC) questionnaire score, Knee Injury and Osteoarthritis Outcome Score (KOOS) subscales scores, gait biomechanics, and drop vertical jump (DVJ) biomechanics in individuals with ACL reconstruction (ACLR).

Methods: 30 individuals with ACLR (53% female; 71.0±46.4 months post-ACLR; 22.6±1.8 years old; 11 patellar tendon graft, 12 hamstring tendon graft, 7 allograft) completed the IKDC and KOOS. Bilateral gait biomechanics were obtained from 5 trials on a 10m runway over 2 force plates. DVJ biomechanics were obtained using a 30cm box placed half their height from the force plates. FMS tasks were scored from 0-3 and summed for analysis. Bilateral gait biomechanics included the knee flexion

angle (KFA) at heel contact, peak KFA, and vertical ground reaction force (vGRF) in the first 50% of stance. Bilateral DVJ biomechanics included the peak knee abduction angle, KFA at heel contact, peak KFA, and peak vGRF. A limb symmetry index (LSI) was calculated for peak KFA and peak vGRF during gait and DVJ. Involved limb values and LSI from gait and DVJ were used for analysis. Separate stepwise linear regression examined the association between the FMS and the IKDC, KOOS subscales, and gait and DVJ biomechanics after accounting for sex and time since ACLR.

Results: No associations were found between FMS score (Mean: 15.0±1.8) and the IKDC (Mean: 84.3±10.6) and KOOS (Mean: 72.0 - 95.6±1.8 - 21.3) after accounting for sex and time since ACLR (ΔR²=0.01 - 0.05, Δp=0.23 - 0.95). No associations were found between FMS score and involved limb biomechanical variables or their LSI's for gait (ΔR²=0.01 - 0.07, Δp=0.17 - 0.79) and DVJ (ΔR²=0.01 - 0.11, Δp=0.08 - 0.99) after accounting for sex and time since ACLR.

Conclusion: The IKDC and KOOS indicated that participants reported some knee-related disability. Conversely, the average FMS score was above the clinical threshold for dysfunctional movement patterns. Therefore, the FMS may not identify knee-related disability in individuals with ACLR. Moreover, FMS score was not associated with gait or DVJ biomechanics, and thus the FMS may not identify hazardous knee movement patterns in individuals with ACLR.

The Relationship Between Hip And Thigh Muscle Strength After Acl-reconstruction

Amelia S. Bruce, Stephan Bodkin, Joe Hart, FACSM. University of Virginia, Charlottesville, VA. (Sponsor: Joseph Hart, FACSM)
 Email: asb5aa@virginia.edu

(No relevant relationships reported)

Purpose: Weakness post ACL reconstruction (ACLR) of hip and thigh muscles are evaluated to track rehabilitation progress and/or inform decisions about return to sports. Lower extremity muscle adaptations are common mechanisms by patients coping with muscle weakness. Relationships among hip and thigh strength measures after reconstruction in ACLR patients may help identify potential coping mechanisms and targets for therapeutic intervention.

Methods: Thirty-four patients with primary unilateral ACLR (21.09±6.70yr, 18M, 170.82±11.95cm, 76.82±21.36kg, 7.97±5.22 mo post ACLR) performed maximum isometric contractions for hip abduction (AB) and adduction (AD) in a supine hook-lying position with the hips flexed to 45-degrees and knee flexed to 90-degrees and knee extension (EX) and flexion (FL) while seated with the hip and knee flexed to 90-degrees; average peak torque was recorded and normalized to body mass. We used Pearson correlation coefficients to determine associations among hip and knee muscle strength.

Results: There were statistically significant positive relationships between all hip and thigh strength values of both limbs (Table 1). Correlations between knee EX and hip AB of the ACLR limb were between 0.640 and 0; the contralateral limb was between 0.583 and 0.769. Correlations between knee FL and hip AB of the ACLR limb were between 0.600 and 0.615; the contralateral limb was between 0.583 and 0.606. Correlations between knee EX and hip AD of the ACLR limb were between 0.579 and 0.726; the contralateral limb was between 0.574 and 0.754. Correlations between knee FL and hip AD of the ACLR limb were between 0.681 and 0.702; the contralateral limb was between 0.642 and 0.700.

Conclusion: Statistically significant, moderate to strong, positive relationships among hip and thigh strength measures were found of both limbs about 7 months post ACLR. Relationships among hip and quadricep strength are all moderate to strong, appearing slightly weaker in the ACLR limb.

Table 1. Pearson Correlation Strength Values for Hip Abductor, Adductor, Quadriceps, and Hamstring of ACLR and Contralateral limbs (*P<0.05)

		Knee EXtension		Knee FLexion	
		ACLR Limb	Contralateral Limb	ACLR Limb	Contralateral Limb
Hip ABduction	ACLR Limb	0.640*	0.793*	0.600*	0.615*
	Contralateral Limb	0.583*	0.769*	0.585*	0.606*

Greater Matrix Metalloproteinase-3 Concentrations Following ACL Injury Associate With Worse Gait Biomechanics 6-months Post-ACL Reconstruction

Alyssa Evans-Pickett, Hope C. Davis-Wilson, Lara Longobardi, Steven J. Pfeiffer, Jeffrey Spang, Alexander R. Creighton, Ganesh Kamath, Richard Loeser, Troy Blackburn, Brian Pietrosimone, FACSM. *University of North Carolina at Chapel Hill, Chapel Hill, NC.* (Sponsor: Brian Pietrosimone, FACSM) Email: alyssae@ad.unc.edu

(No relevant relationships reported)

Matrix metalloproteinase-3 (MMP-3) is a degenerative enzyme associated with joint tissue breakdown and has been shown to be a potential biomarker of osteoarthritis. It remains unknown if synovial fluid (SF) MMP-3 concentrations following ACL injury influence gait mechanics. **PURPOSE:** To compare knee flexion angle (KFA) and internal knee extension moment (KEM) during gait 6 months post-ACL in individuals with the highest concentrations of SF MMP-3 compared to those with the lowest concentrations of SF MMP-3 collected within the first 14 days of injury. **METHODS:** Thirty-seven individuals with ACL injury scheduled for primary patellar tendon autograft ACLR (57% females, 21±4 yrs, 23.7±2.8 BMI) participated. Individuals were grouped into highest (HQ; n=9) and lowest (LQ; n=10) quartiles based on MMP-3 knee joint SF concentrations sampled 6±4 days after ACL injury. At 6 months post-ACLR, biomechanics were collected using 3-dimensional motion capture during gait performed at a self-selected speed. Functional analyses of variance were conducted to compare KFA and KEM between HQ and LQ groups throughout stance. Groups were considered different at any percentage of stance where the 95% confidence intervals of the mean differences did not cross zero. Peak differences (PD) and corresponding effect sizes (Cohen's d) within portions of stance demonstrating differences were also calculated. **RESULTS:** HQ exhibited lesser knee flexion excursion; KFA was lower during 17-24% of stance (PD: 2.1°, d=0.44) and greater during 48-100% of stance (PD: 4.5°, d=0.93). HQ also exhibited lower KEM during 14-30% and 91-100% of stance (PD: 0.72 BW, d=0.67; PD: 0.33 BW, d=1.42) and greater KEM during 45-72% of stance (PD: 0.44, d=0.76) **CONCLUSION:** Compared to individuals in the lowest quartile of SF MMP-3, those in the highest exhibited a stiffened knee gait strategy. Pre-surgery levels of MMP-3 following ACL injury may serve as a biomarker predicting worse gait mechanics 6 months post-ACLR.

Knee Extensor Torque Complexity During A Maximal Voluntary Isometric Contraction Differs Between ACL-reconstructed And Healthy Individuals

Stephan G. Bodkin, Emily A. Dooley, Shawn D. Russel, Joseph M. Hart, FACSM. *University of Virginia, Charlottesville, VA.* (Sponsor: Joseph Hart, FACSM) Email: sgb3d@virginia.edu

(No relevant relationships reported)

PURPOSE: Rehabilitation goals following anterior cruciate ligament reconstruction (ACLR) are structured around maximal force generating capabilities of the quadriceps. ACL injuries may occur through the inability to adapt motor output rapidly and accurately to external demands. Approximate Entropy (ApEn) can be used to describe the complexity of torque production to reflect the functional capacity of the neuromuscular system. The purpose of this study was to compare torque complexity of a maximal voluntary isometric contraction (MVIC) in ACLR limbs compared to the uninvolved limb and healthy controls. **METHODS:** A total of 215 individuals (120 ACLR [65 Female, 21.0±8.3 years, 5.96±48-mo. post-ACLR] 95 Healthy [50 Female, 21.5±2.9 years]) participated in the study. Participants completed a 30-second knee extensor MVIC which was stratified into three 10-second bins. The 3-seconds of lowest variation were used to calculate ApEn for the Early (ApEn₁), Middle (ApEn₂), and Late (ApEn₃) time bins. Torque complexity was compared across the trial, between limbs, and between groups using a repeated measures design. The dependent variable was torque complexity (ApEn) and the independent variables were group (ACLR, Healthy) and time bins (Early, Middle, Late). An *a priori* alpha was set at 0.05. **RESULTS:** There was a significant time main effect for torque complexity ($P < .001$). For all participants, ApEn₁ and ApEn₂ were significantly higher than ApEn₃ ($P < .001$, Figure 1). There was also a significant group by limb interaction ($P < .001$). The ACLR limb (.46±.12) demonstrated greater torque complexity than the uninvolved limb (.38±.12, $P < .001$) and of healthy individuals (.38±.10, $P < .001$, Figure 1). **CONCLUSIONS:** The ACLR limb demonstrated a greater torque complexity at the end of a 30-second MVIC compared to healthy controls and the contralateral limb. Force fluctuations during a sustained maximal task may draw clinical insight into the recovery of motor function following ACLR.

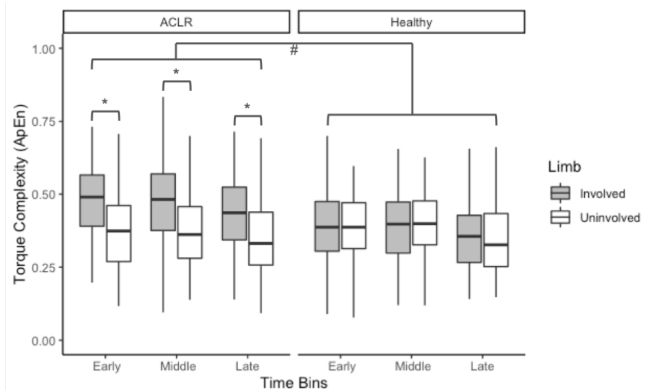

Figure 1: Torque complexity of knee extensor maximal contraction compared between limbs and groups. The involved limb of the ACLR individuals demonstrated significantly higher torque complexity compared to the uninvolved limb (denoted by *) and the healthy individual trials (denoted by #).

Influence Of Resistance Training On Strength And Gait Kinetics In Individuals With Acl Reconstruction

Kevin H. Choe, Julia Freedman Silvernail. *University of Nevada, Las Vegas, Las Vegas, NV.* (Sponsor: James W. Navalta, FACSM) (No relevant relationships reported)

Purpose: Individuals with anterior cruciate ligament reconstruction (ACLR) demonstrate reduced hip and knee extensor strength in their injured limb. Previous research suggests strength imbalances reduce an individuals' ability to propel themselves forward during gait as indicated by the impulse of the anterior ground reaction force (propulsive force; pGRF). As resistance training increases muscular strength, it may improve any propulsion deficits. Therefore, the purpose of this study was to compare hip and knee extensor strength as well as pGRF characteristics between individuals with ACLR who resistance train (RT) and ones who do not (NRT). **Methods:** Hip and knee extensor strength and gait were measured in 16 individuals (22.4±4.2 yr, 1.7±0.1 m, 73.8±15.1kg) with unilateral ACLR via isokinetic dynamometry and force platforms, respectively. The RT group had individuals who

WEDNESDAY, MAY 27, 2020

resistance trained according to the American College of Sports Medicine guidelines consistently after completion of physical therapy. The NRT group included individuals who did not resistance train at all. Independent samples T-tests were used to compare peak hip and knee extensor strength (Nm/kg⁻¹), peak pGRF (N/kg⁻¹), and pGRF impulse (N*s/kg⁻¹) between the RT and NRT groups. Bivariate correlations were used to identify if hip and knee extensor strength were related to pGRF and pGRF impulse. **Results:** The RT group had greater peak knee extensor torque at 60°/sec⁻¹ (KE60) and 180°/sec⁻¹ (KE180) compared to the NRT group. No differences were observed between groups in peak hip torque, pGRF, or pGRF impulse. There was a negative correlation between KE60 and pGRF during walking ($r = -0.531$, $p = 0.034$). No correlations were found between pGRF impulse and hip or knee torque. **Conclusion:** Results confirm our hypothesis that in ACLR, individuals in the RT group exhibited greater knee extensor torque than the NRT group. Additionally, greater KE60 was related to less pGRF during walking. An exploratory analysis found no differences in walking or running velocities, indicating the RT group accomplishes the same goal with less force. This may demonstrate greater movement efficiency resulting from resistance training above the improvements in strength alone.

Effects Of ACL Reconstruction On In Vivo Quadriceps Contractile Behavior During Weight Acceptance In Walking

Amanda E. Munsch¹, Alyssa Evans-Pickett², Hope C. Davis-Wilson², Brian Pietrosimone², Jason R. Franz¹. ¹The University of North Carolina Chapel Hill and North Carolina State University, Chapel Hill, NC. ²The University of North Carolina Chapel Hill, Chapel Hill, NC.

Email: aemunsch@live.unc.edu

(No relevant relationships reported)

Appropriate knee loading during walking is essential for optimal health of mechanosensitive joint tissues and is largely governed by quadriceps muscle forces. However, individuals with anterior cruciate ligament reconstruction (ACLR) often exhibit quadriceps muscle dysfunction conventionally measured via reduced peak knee extensor moments (pKEM). Recent advances in ultrasound imaging provide a unique opportunity to determine if quadriceps dysfunction also manifests as altered contractile behavior between those with ACLR and uninjured controls. **PURPOSE:** Determine differences in quadriceps contractile behavior during weight acceptance in walking between ACLR, contralateral, and control limbs. **METHODS:** Six individuals to date with unilateral ACLR (4 females, 20±2 yrs, BMI: 25.3±1.8, months post-surgery: 7.1±0.7) and 11 uninjured controls (6 females; 24±3 yrs, BMI: 22.0±2.0) walked for 2 min on an instrumented treadmill. We collected motion capture and ground reaction force data and recorded cine B-mode ultrasound images of the vastus lateralis (VL). We quantified pKEM, knee flexion excursion (KFE), and VL fascicle length change during weight acceptance (i.e., heel-strike to the instant of pKEM). We report effect sizes (ES) for all comparisons. **RESULTS:** pKEM was 25% lower in the ACLR limb (0.18±0.18 Nm/kg) than the contralateral limb (0.24±0.11 Nm/kg, ES=0.40) and 75% lower than for uninjured controls (0.74±0.19 Nm/kg, ES=3.03). Similarly, the ACLR limb exhibited 21% less KFE (11.4±3.4°) than the contralateral limb (14.5±2.2°, ES=1.08) and 32% less KFE than in uninjured controls (16.8±3.5°, ES=1.57). In uninjured controls, VL fascicles shortened by 0.13±0.23 cm during weight acceptance despite 1.21±0.26 cm of muscle-tendon-unit lengthening, alluding to a predominant role of tendon elongation. VL fascicles in the contralateral limb of ACLR subjects also exhibited shortening during weight acceptance (0.07±0.33 cm). Conversely, we observed fundamentally different behavior in the ACLR limb, for which VL fascicles lengthened by 0.10±0.14 cm (vs controls, ES=1.21). **CONCLUSION:** ACLR alters quadriceps contractile behavior during weight acceptance in walking. Fascicle lengthening unique to the ACLR limb may be a functional consequence of quadriceps dysfunction relevant to altered knee loading.

Knee Extensor Torque Variability Correlates With Impaired Functional Knee Kinetics After ACLR In Collegiate Athletes

Tyler J. Roehl, Daniel G. Coban, Mikel R. Stiffler-Joachim, Jennifer L. Sanfilippo, Bryan C. Heiderscheidt. *University of Wisconsin-Madison, Madison, WI.*

(No relevant relationships reported)

Quadriceps neuromuscular dysfunction is universal following anterior cruciate ligament reconstruction (ACLR). Quadriceps performance is often characterized by peak strength, but the ability to generate consistent knee extensor (KE) torque is not captured by maximal strength assessments and may be functionally significant. Torque steadiness (TS) quantifies the capacity to produce smooth and consistent contractile forces, but is not well-defined post-ACLR.

PURPOSE: To evaluate KE TS in collegiate athletes 4, 6, and 12 months post-ACLR, and determine the associations between TS, strength, and knee joint kinetics during athletic tasks.

METHODS: 13 Division I athletes (age 20.5 ± 1.0, BMI 26.3 ± 4.7, 6 male) completed maximal voluntary isometric KE contractions (MVIC), countermovement jumps (CMJ), and treadmill running (2.68 m/s) while 3D kinematics and ground reaction forces were recorded 4.1 ± 0.6 (4), 6.3 ± 0.6 (6) and 11.9 ± 1.1 (12) months post-surgery. TS was defined as the mean difference between raw KE torque and a lowpass filtered signal (4th order butterworth filter, 2 Hz cutoff) within a 4 second torque plateau window. Sagittal plane KE impulses were computed from the stance phase of running (RUN) and the concentric (CON) and landing (LAND) CMJ phases. Wilcoxon Signed-Ranks tests assessed between-limb comparisons at each interval, and Spearman's correlation evaluated the associations between TS, MVIC, and KE impulses.

RESULTS: Involved limb TS was significantly reduced at 4 (limb symmetry index (LSI): 36.8%, $p = .002$), 6 (LSI: 75.3%, $p = .001$), and 12 months post-surgery (LSI: 84.7%, $p = .033$). TS was significantly associated with RUN at 4 and 6 months post-surgery ($r_s = .881$ and $.865$), CON at 4, 6, and 12 months ($r_s = .720$, $.587$, and $.708$), and LAND at 6 and 12 months ($r_s = .678$ and $.564$). MVIC was significantly correlated with RUN at 4 months ($r_s = .762$) and CON at 4, 6, and 12 months ($r_s = .787$, $.587$, and $.689$). TS and MVIC were not correlated at any interval ($r_s = -.335$, $-.346$, and $-.225$). **CONCLUSIONS:** KE TS is reduced 4-12 months post-ACLR in collegiate athletes, and asymmetrical TS is generally strongly associated with asymmetrical KE kinetics. KE TS and strength appear to be unique characterizations of quadriceps performance post-ACLR. Interventions to improve KE TS post-ACLR are recommended to restore knee function.

Similar Biomechanics During Change Of Direction In Adolescents With Contact Versus Non-contact Acl Injury

Mia Katzel, Curtis VandenBerg, Adriana Conrad-Forrest, Tishya Wren. *Children's Hospital Los Angeles, Los Angeles, CA.*

(No relevant relationships reported)

Purpose: Patients who sustain non-contact (N-CON) anterior cruciate ligament (ACL) injuries may be predisposed to injury due to deficient biomechanics. In contrast, patients who sustain contact (CON) ACL injuries may be injured due to unlucky trauma rather than poor biomechanics. This study compared biomechanics during change of direction movements between patients with CON vs. N-CON ACL injury mechanisms. We hypothesized that patients with CON ACL injury would have better biomechanics (greater shock absorption and less dynamic limb valgus) than patients with N-CON ACL injury.

Methods: 15 patients age 10-18 years with CON ACL injury (4 female; mean age 15.5, SD 2.1) and 94 with N-CON ACL injury (11 female; mean age 15.6, SD 1.9) underwent motion analysis 6-12 months (mean 7.5, SD 1.3) after ACL reconstruction (ACLR). Subjects performed forward-backwards and lateral change of direction tasks. 3D kinematic and kinetic variables reflecting dynamic limb valgus (frontal and transverse plane) and shock absorption (sagittal plane) were compared between patients who had CON and N-CON injury mechanisms using 2-tailed t-tests.

Results: No significant differences were observed between the CON and N-CON groups (Table).

Conclusion: The CON injury group did not have better biomechanics than the N-CON group. This may be due to both groups engaging in similar rehabilitation programs. Alternatively, the CON injury group may have had similar pre-injury biomechanics to the N-CON group but happened to suffer a contact injury. These results suggest that all patients post-ACLR have potentially modifiable risk factors for re-injury and should have their biomechanics evaluated so any deficiencies can be rectified prior to return to sport regardless of injury mechanism.

Table: Comparison of kinematics and kinetics between contact and non-contact ACL injury groups

	Deceleration			Lateral Shuffle		
	Non-Contact	Contact	P-value	Non-Contact	Contact	P-value
SHOCK ABSORPTION						
Max hip flexion	75.3 (15.2)	76.9 (16.4)	0.72	68.4 (14.6)	71.9 (13.6)	0.39
Max knee flexion	65.2 (14.1)	68.8 (20.9)	0.39	61.4 (13.1)	65.2 (13.5)	0.31

Revisiting Central And Peripheral Contributions To Muscle Weakness After ACL-Reconstruction

Steven A. Garcia, Kazandra M. Rodriguez, Chandramouli Krishnan, Riann M. Palmieri-Smith. *University of Michigan, Ann Arbor, MI.*

Email: stevenag@umich.edu

(No relevant relationships reported)

Purpose: Alterations in quadriceps muscle morphology (i.e. cross-sectional area [CSA]) and volitional activation (VA) contribute to muscle weakness following anterior cruciate ligament reconstruction (ACLR). Research on the relative contributions between each factor and quadriceps weakness remain inconclusive as few studies have concurrently evaluated VA and muscle morphology in the same cohort of ACLR patients. Further, the magnitude of contribution of morphology and activation may vary depending on whether data are considered for the ACLR limb alone or if data are reported as a limb symmetry index (LSI), taking into account the uninvolved leg. Thus, aims of this study were to determine the contributions of VA and CSA on quadriceps strength in ACLR patients and to determine if the contributions were similar when using the involved limb or the LSI. **Methods:** Sixteen individuals 6-12 months post-ACLR (time post ACLR: 40.3±8.2 wks, Age: 22.3±6.0yr, Height: 1.7±0.1m, Mass: 68.7±11.5 kg, Sex: 9F) were recruited for this study. Quadriceps isometric peak torque (PT) and VA, via the interpolated triplet technique, were assessed bilaterally at 90° of knee flexion on a dynamometer. Ultrasound images were acquired to assess vastus lateralis CSA in both legs. LSI's were calculated for all outcome variables by expressing values of the involved leg as a percent of the uninvolved leg. Paired t-tests were used to compare outcomes between legs (Bonferroni-adjusted $\alpha = 0.017$). Two separate stepwise linear regressions were performed to examine the contribution of VA and CSA on quadriceps PT where model 1 used LSI for all variables, and model 2 used variables from the involved leg (Bonferroni-adjusted α 's = 0.025). **Results:** Regression model 1 indicated PT LSI was significantly predicted by VA LSI ($R^2=0.45$, $P<0.01$), but not by VL CSA LSI ($R^2=0.01$, $P=0.87$). Model 2 indicated that involved leg PT was significantly predicted by VL CSA ($R^2=0.50$, $P<0.01$) but not quadriceps VA ($R^2=0.08$, $P=0.11$) of the involved leg. All dependent variables were smaller in the involved compared to uninvolved leg ($P<0.017$). **Conclusions:** The contributions of VA and CSA on

quadriceps PT differed greatly if LSI or involved leg outcomes were used. Evaluation of VA and CSA in unison may provide a more holistic understanding of the sources of muscle weakness after ACLR.

Preventing Acl Injuries With Martial Arts Break Falling Training

Karen M. Myrick¹, Conor Kasabo², Richard Feinn², Juan Garbalosa². ¹University of Saint Joseph, Connecticut, West Hartford, CT. ²Quinnipiac University, Hamden, CT.

Email: kmrick@usj.edu

(No relevant relationships reported)

PURPOSE: ACL injuries have remained prevalent despite numerous prevention attempts. Most prevention has focused on traditional approaches. We propose a novel approach to injury prevention by implementing martial arts falling techniques. This training uses proprioceptive and kinesthetic conditioning to reinforce the athlete's ability to mitigate at-risk postures. This study aims to evaluate the proprioceptive function and risk factors in soccer athletes that undergo fall training. **METHODS:** Members of a premier soccer club, ages 9 to 16, were recruited to. All subjects continued usual training. Subjects partook in the interventional training of martial arts fall training, taught by a 3rd degree black belt master in karate and aikido, twice weekly for ten weeks. Baseline and post-intervention, proprioceptive testing was performed using the Neurocom Balance Master. A linear mixed model was used to determine the effect of the intervention on variables of interest. The fixed effect was time point, used to compare pre to post intervention measures, and random effects included intercepts for subjects and trials within subjects. The level of significance was 0.05.

RESULTS: A significant increase in movement time from pre to post (Premean=1.14, Postmean=1.94, $p=0.032$), no significant change in turn time, turn sway, or sway energy. There was a non-significant decrease in impact index (Premean=46.3, Postmean=36.9, $p=0.206$). A significant decrease in the mean impact index for the right lower extremity. While not statistically significant, downward trends were observed in right lower extremity for mean turn time, mean turn sway, and mean sway energy. Additionally, increases noted for mean equilibrium and mean strategy.

CONCLUSIONS: Results of the mean impact index test highlight the efficacy of martial arts fall training in the dominant lower extremity. Furthermore, the trend of improvement in the dominant leg in a variety of proprioceptive metrics is noteworthy, suggesting the intervention reinforced the more honed neural pathways of the dominant side quicker than the non-dominant. Future research is needed to elucidate whether the non-dominant side can demonstrate the plasticity seen in the dominant side. Finally, the overall increase seen in mean equilibrium and mean strategy is promising.

Decreased Loading During Gait Alters Intralimb Coordination In Anterior Cruciate Ligament Reconstructed Individuals

Cortney N. Armitano-Lago, Brian Pietrosimone, FACSM, Alyssa Evans-Pickett, Hope Davis-Wilson, Jason Franz, Troy Blackburn, Adam W. Kiefer. *University of North Carolina at Chapel Hill, Chapel Hill, NC.*

Email: carmitan@email.unc.edu

(No relevant relationships reported)

Aberrant lower extremity loading following anterior cruciate ligament reconstruction (ACLR) is theorized to play a role in posttraumatic osteoarthritis (PTOA) development. Cueing an increase or decrease in loading could potentially optimize gait biomechanics and slow progression to PTOA. Stable coordination is fundamental for functional gait as a mediating process for the distribution of joint loads. Accordingly, examining how joint loading impacts coordination during gait may elucidate compensatory movement strategies following ACLR. **PURPOSE:** Determine the effect of cueing an increase or decrease in lower extremity loading on intralimb coordination between the knee-hip joints in ACLR participants. **METHODS:** Coordination was assessed in 10 individuals (age: 21±4 years; 9±1 months post-surgery; 4F) with unilateral ACLR during three separate loading conditions. Loading was manipulated via real-time feedback using a force measuring treadmill that cued a change in peak vertical ground reaction force (vGRF). Three conditions were conducted on separate days in a random order: 1) preferred (no feedback), 2) overload (cue 5% body weight [BW] increase in vGRF), and 3) underload (cue 5% BW decrease in vGRF). The intralimb coordination between sagittal plane knee-hip angles was assessed via measures of coordination dynamics (mean [M] and standard deviation [SD] of relative phase [RP] and percent determinism [%DET] from cross-recurrence quantification analysis) for each condition. One-way repeated-measures analyses of variance were used to determine differences among conditions. **RESULTS:** A main effect of loading was observed for M RP ($F_{2,26}=6.9$, $p<0.05$) and SD RP ($F_{2,26}=9.5$, $p<0.05$). The underloaded condition exhibited significantly different coordination stability (lower M and higher SD of RP) compared to the preferred and overloaded conditions ($p<0.05$).

A significant effect of loading on %DET ($F_{2,26}=2.7$ $p<.05$) was also observed; the underloaded condition led to tighter coupling than the preferred condition. ($p<.05$).
CONCLUSIONS: Overall, underloading changed the pattern and multi-scale stability of knee-hip coordination. These findings indicate manipulations in joint loading result in altered movement strategies that concern the development of PTOA.

990 Board #116 May 27 1:30 PM - 3:00 PM
Changes In Gait Biomechanics Between Level And Downhill Walking Do Not Differ Between Those With Anterior Cruciate Ligament Reconstruction And Controls

Derek Dewig, Chris Johnston, Brian Pietrosimone, FACSM, Troy Blackburn. *The University of North Carolina at Chapel Hill, Chapel Hill, NC.*
 Email: ddewig@live.unc.edu
 (No relevant relationships reported)

Conflicting evidence exists regarding the presence of aberrant gait biomechanics after the first year post-anterior cruciate ligament reconstruction. Overground walking may not elucidate differences in those further removed from surgery due to the unexact nature of the task. Deleterious gait biomechanics following ACLR are partly attributable to quadriceps dysfunction. Downhill walking may exacerbate aberrant gait biomechanics, as this task places greater demands on the quadriceps compared to level walking.

PURPOSE: To compare gait biomechanics between individuals with ACLR and healthy controls during level and downhill walking conditions.

METHODS: 24 individuals more than 1 year removed from primary ACLR (83% female, age= 21 ± 3 yr, time since ACLR 44 ± 26 mo, BMI= 23 ± 3 kg/m²) and 24 healthy controls (79% female, age= 21 ± 1 yr, BMI= 24 ± 3 kg/m²) completed both level and downhill (10° grade) gait biomechanics assessments on an instrumented split-belt treadmill at their preferred walking speed. Peak variables were evaluated over the first 50% of stance including the vertical ground reaction force (vGRF), internal knee abduction moment, internal knee extension moment, knee flexion angle, and knee abduction angle. Moments were normalized to %body weight*height (%BW*Ht) and vGRF was normalized to %body weight. Dependent variables were compared across groups and conditions via two-way repeated measures ANCOVA controlling for gait speed.

RESULTS: There were no significant condition*group interaction effects nor group main effects for any outcomes. However, there were significant condition main effects for peak internal knee extension moment ($p = 0.020$, level to downhill mean increase of 0.042 %BW*Ht) and peak knee flexion angle ($p = 0.018$, level to downhill mean increase of 13.2°).

CONCLUSIONS: Downhill walking necessitates a larger internal extension moment and knee flexion angle compared to level gait. Our results suggest that changes in gait biomechanics between level and downhill conditions do not differ between individuals with ACLR > 1 year post reconstruction and controls. These results suggest that aberrant gait biomechanics may be mitigated over time in those with ACLR.

991 Board #117 May 27 1:30 PM - 3:00 PM
Fewer Steps Per Day Associates With Greater Cartilage Breakdown Biomarkers Post Anterior Cruciate Ligament Reconstruction

Hope C. Davis-Wilson, Christopher D. Johnston, Alyssa Evans-Pickett, A.C. Hackney, J. Troy Blackburn, Louise Thoma, Lara Longobardi, Jason Franz, Brian Pietrosimone, FACSM. *UNC Chapel Hill, Chapel Hill, NC.* (Sponsor: Brian Pietrosimone, FACSM)
 Email: davishc@live.unc.edu
 (No relevant relationships reported)

PURPOSE: Individuals with anterior cruciate ligament reconstruction (ACLR) engage in fewer steps per day (steps/day) compared to uninjured controls. While regular physical activity can improve outcomes of idiopathic knee osteoarthritis such as disability, it is unknown if physical activity influences post-traumatic knee osteoarthritis outcomes following ACLR. Cartilage oligomeric matrix protein (COMP) is a biomarker outcome associated with cartilage breakdown, and it is responsive to mechanical loading during walking. Therefore, the purpose was to determine the association between steps/day and change in COMP (ΔCOMP) following walking in individuals with an ACLR. **METHODS:** Steps/day was assessed over 7 days using ActiGraph accelerometers worn on the right hip in 31 participants (age=22±4years, body mass index=23.9±2.9kg/m², 52±37 months post-ACLR, 55% females) with primary unilateral ACLR ≥ 6 months at the time of testing. Subjects walked at a preferred speed for 3000 steps (~30 minutes) on a treadmill to introduce cartilage loading. Blood samples were collected immediately pre- and post-walking, and serum COMP concentrations were analyzed with ELISA kits. ΔCOMP was calculated with post-walking concentrations expressed as a percentage of pre-walking levels. Greater

ΔCOMP was interpreted as greater cartilage breakdown during the walking protocol. A univariate linear regression was conducted to determine the association of steps/day with ΔCOMP.

RESULTS: Fewer steps/day (mean±SD: 9,626±2,452) associated with greater ΔCOMP (+11.5±16.4%; $R^2=0.152$, $\beta=-0.003$, $p=0.030$).

CONCLUSIONS: Individuals after ACLR who habitually engage in fewer steps/day demonstrated greater ΔCOMP during a walking protocol. We postulate fewer steps/day in individuals with a history of ACLR may result in deleterious changes in cartilage homeostasis due to inadequate mechanical stimulation of joint tissues. Future studies should determine if increasing steps/day improves knee cartilage outcomes following ACLR.

Does Lower Limb Dominance Change After An Anterior Cruciate Ligament Reconstruction?

Kathryn Lucas, Geetanjali Gera, Mary Lloyd Ireland, FACSM, Brian Noehren, FACSM. *University of Kentucky, Lexington, KY.*
 (No relevant relationships reported)

Changes in limb dominance, the limb to kick a ball or recover a fall, after an anterior cruciate ligament reconstruction (ACLR) could occur if the limb has not fully recovered. Due to the impact of an ACLR on the quadriceps, a poor quadriceps limb symmetry index (Q-LSI) could influence changed limb dominance. The difference in the leg used during a quick regain of balance (step-limb) from the subjects' self-reported limb dominance, could identify poor motor planning required to use the limb.

PURPOSE: Evaluate if patients reporting tearing their dominant, defined as the leg to kick a ball, (DOM group) or non-dominant (N-DOM group) limb is the same as the step-limb used during a reactive balance test. For the DOM group, Q-LSI was compared between subjects who switched dominance and those that did not.

METHODS: 36 ACLR (15M, 18±5 years) reported their dominant leg 6-months after ACLR. A reactive balance test was performed where subjects were passively leaned forward 10 degrees. In 5 out of 10 trials they were released and had to step to regain their balance. The most frequently used (3 out of the 5 trials) step-limb was recorded. Q-LSI were calculated through the maximum voluntary isometric contractions at 90 degrees of knee flexion. A Fisher's exact evaluated if the step-limb was similar to the reported dominant limb, comparing the DOM and N-DOM groups. For the DOM group, a Student's t-test compared the differences in Q-LSI between switchers and non-switchers.

RESULTS: 75% (27 DOM: 9 N-DOM) of the subjects tore their DOM limb. When a loss of balance occurred, 48% of the DOM group (13:14) switched dominance. This was significantly greater than the N-DOM group (11%, 1:8, $p=0.02$). The DOM group who did not switch limbs had higher Q-LSI (switchers: 57% Q-LSI, non-switchers: 78% Q-LSI, $p=0.04$).

CONCLUSIONS: Almost half of the subjects who tore their dominant limb stepped with their uninjured/non-dominant limb 6-months after an ACLR and had a lower Q-LSI than those who stepped with their dominant limb. These results suggest that with lower Q-LSI, subjects' preplanning of initial movements is altered. Switching limb dominance to the non-dominant/uninjured limb may affect performance during tasks that require quick movements. Future studies should evaluate the effects of changes in limb dominance on subsequent injuries after ACLR.

Altered Corticospinal Tract Structure And Excitability In Patients With Anterior Cruciate Ligament Reconstruction

Adam S. Lepley¹, Monica T. Ly², Dustin R. Grooms³, Jeffery M. Kinsella-Shaw², Lindsey K. Lepley¹. ¹University of Michigan, Ann Arbor, MI. ²University of Connecticut, Storrs, CT. ³Ohio University, Athens, OH.
 Email: alepley@umich.edu
 (No relevant relationships reported)

Underlying neural factors contribute to poor outcomes following anterior cruciate ligament reconstruction (ACLR). Neurophysiological adaptations have been identified in motor cortex activation and corticospinal tract excitability, however limited evidence exists on neurostructural changes that may influence motor recovery in ACLR patients.

PURPOSE: To 1) quantify hemispheric differences in structural properties of the corticospinal tract in patients with a history of ACLR, and 2) assess the relationship between excitability and corticospinal tract structure. **METHODS:** Ten ACLR participants (age: 22.6 ± 1.9 yrs; height: 166.3 ± 7.5 cm; mass: 65.4 ± 12.6 kg, months from surgery: 70.0 ± 23.6) volunteered for this cross-sectional study. Corticospinal tract structure (volume; fractional anisotropy [FA]; axial diffusivity [AD]; radial diffusivity [RD]; mean diffusivity [MD]) was assessed using diffusion tensor imaging, and excitability was assessed using transcranial magnetic stimulation (motor evoked potentials [MEP]) for each hemisphere. Hemispheric differences were evaluated using paired samples t-tests. Pearson product moment correlational analyses were conducted on structural and excitability outcomes. Alpha level was set at $p \leq 0.05$. **RESULTS:**

The hemisphere of the ACLR injured limb demonstrated lower volume (567.1 ± 75.3 voxels; $p = 0.005$), lower FA (0.49 ± 0.01 ; $p = 0.02$), higher MD ($7.58 \times 10^{-4} \pm 0.35 \times 10^{-4}$; $p = 0.01$), and smaller MEPs (0.013 ± 0.007 ; $p = 0.04$) compared to the hemisphere of the non-injured limb (659.7 ± 64.3 voxels; 0.53 ± 0.02 ; $7.23 \times 10^{-4} \pm 0.10 \times 10^{-4}$; 0.028 ± 0.010), indicating disrupted white matter structure and a reduction in excitability of the corticospinal tract. Correlation analyses revealed a strong, positive correlation between corticospinal tract volume and MEP of the ACLR injured limb ($r = -0.890$; $p = 0.001$). **CONCLUSIONS:** ACLR patients demonstrated asymmetry in structural properties of the corticospinal tract that may influence the recovery of motor function following surgical reconstruction. More research is warranted to establish the influence of neurostructural measures on patient outcomes and response to treatment in ACLR populations.

Gait Biomechanics Linked To Post-traumatic Osteoarthritis Following Anterior Cruciate Ligament Reconstruction Are Improved With Vibration

TROY BLACKBURN¹, Brian Pietrosimone, FACS¹, Darin Padua¹, Derek Dewig¹, Jonathan Goodwin², Chris Johnston¹.
¹University of North Carolina at Chapel Hill, CHAPEL HILL, NC. ²Elon University, Elon, NC. (Sponsor: Brian Pietrosimone, FACS¹)
 Email: troyb@email.unc.edu
 (No relevant relationships reported)

PURPOSE: Anterior cruciate ligament reconstruction (ACLR) incurs a high risk of post-traumatic knee osteoarthritis (PTOA). Aberrant gait biomechanics contribute to PTOA and are attributable in part to quadriceps dysfunction. Vibration improves quadriceps function following ACLR, but its effects on gait biomechanics are unknown. The purpose of this study was to evaluate the effects of whole body vibration (WBV) and local muscle vibration (LMV) on gait biomechanics in individuals with ACLR. **METHODS:** 75 volunteers with primary unilateral ACLR (72% females; age 21 ± 3 yr; time since ACLR 27 ± 16 mo) were randomized to WBV, LMV, or Control interventions. WBV and LMV were applied 6×1 minute (30Hz, 2g). Walking biomechanics were assessed prior to and following the interventions. Outcomes included the peak vertical ground reaction force (vGRF) and its loading rate, peak internal knee extension and valgus moments, and peak knee flexion and varus angles during the first 50% of stance. vGRF magnitude and rate were normalized to body weight (BW) and moments were normalized as % body weight*height (%BW*Ht). ACLR limb change scores (post-pre) for each outcome were compared across groups via one-way ANCOVA controlling for gait speed, time since ACLR, and baseline values. **RESULTS:** Change scores did not differ across groups for peak knee flexion ($p = 0.374$) or varus ($p = 0.801$) angles, vGRF ($p = 0.656$), or internal valgus moment ($p = 0.866$). However, changes in vGRF loading rate differed across groups ($p = 0.024$), with a significant decrease in the LMV group (-3.6 BW/s) that was greater than the changes in the WBV (-0.3 BW/s; $p = 0.035$) and Control (0.5 BW/s; $p = 0.010$) groups. Additionally, the change in peak internal extension moment differed across groups ($p = 0.016$), with a significant increase in the WBV group (0.27 %BW*Ht) that was greater than the change in the Control group (-0.17 %BW*Ht; $p = 0.005$) but not the LMV group (0.01 %BW*Ht; $p = 0.101$). **CONCLUSIONS:** Lower knee extension moments and greater loading rates during gait have been linked to declines in joint health following ACLR. WBV acutely increased the peak knee extension moment and LMV decreased loading rates. These data suggest that vibration has the potential to mitigate aberrant gait biomechanics, and may represent an effective approach for mitigating PTOA risk following ACLR.

Can Increased Gait Speed Improve Knee Loading Mechanics Following Anterior Cruciate Ligament Reconstruction?

Sara Almansouri, William Barclay, Anushree Dighe, Carole Gong, Meagan Chow, Susan Sigward. University of Southern California, Los Angeles, CA.
 Email: s.almansouri@usc.edu
 (No relevant relationships reported)

Knee extensor moments (KEM) deficits during gait persist long term following anterior cruciate ligament reconstruction (ACLR) and are attributed to progression of osteoarthritis. KEM are reduced in surgical limb through modulation of heel rocker mechanics (HRM): reduced knee flexion excursion (KFE), shank anterior angular velocity (SAV) and posterior ground reaction force (pGRF). Improved KEM are more therapeutically desirable if accomplished by improving underlying HRM. Increased gait speed increases knee loading in healthy individuals but it is not known if those with long term deficits post-ACLR respond to gait speed with improved KEM or if these improvements are accomplished by improving underlying HRM

PURPOSE: To determine if individuals with long term KEM deficits post-ACLR respond to increase treadmill gait speed with increase KEM and HRM and if improved KEM is related to improved HRM

METHODS: Individuals > 1 year post-ACLR with KEM deficits >10% are recruited; data collection on-going. Participants (N=4, 61.4±29.8 months post-ACLR) walked on a treadmill at self-selected (SS) and 50% faster than SS (FAST) speeds (3 minutes/ speed). 3D kinematics (Qualisys) and kinetics (Bertec) were collected in last 30 seconds (6 steps/limb). KEM (inverse dynamics), SAV, pGRF and KFE during loading response (surgical limb) were compared between speeds; strength of difference indicated by effect size (ES). Pearson correlations used to determine association between percent increase (SS to FAST speed) in peak KEM and increase in HRM (peak SAV, peak pGRF and KFE)

RESULTS: KEM ($97.1 \pm 74.8\%$, $ES = 1.1$), SAV ($44.9 \pm 4.4\%$, $ES = 1.5$), pGRF ($62.9 \pm 3.5\%$, $ES = 1.6$) and KFE (4 ± 1.9 degrees, $ES = 1.3$) increased with speed. Increased KEM correlated with increases in KFE ($r = .92$, $p = .08$), and SAV ($r = .99$, $p = .01$) but not pGRF ($r = -.18$, $p = .82$)

CONCLUSIONS: This preliminary analyses suggest that increased gait speed improves KEM and all features of HRM. A 97% increase in KEM was strongly related to improvements in KFE and SAV. Sample size calculations suggests these results will hold up in our full study sample (expected for May presentation). If results hold, it will suggest that increasing treadmill gait speed may be an effective stimulus for retraining kinematic features of HRM and KEM in those who have persistent KEM deficits during gait following ACLR

Bilateral Changes In Running Biomechanics Observed From Pre-injury To 6-months Post Anterior Cruciate Ligament Reconstruction

Keith A. Knurr, Mikel R. Stiffler-Joachim, Sara E. Harper, Darryl G. Thelen, Bryan C. Heiderscheid. University of Wisconsin- Madison, Madison, WI.
 Email: knurr@ortho.wisc.edu
 (No relevant relationships reported)

Reduced knee function during running has been observed in anterior cruciate ligament reconstructed (ACLR) knees, persisting up to 5 years after surgery. Current evidence is limited to cross-sectional design and often utilizes the contralateral limb for comparison with questionable appropriateness. Pre-injury running biomechanics, although difficult to obtain, can be used to assess post-surgical changes in both the involved and uninvolved limbs. Through pre-season injury screening, we obtained running mechanics on collegiate athletes. This study utilizes this pre-injury data for evaluation of bilateral changes in those athletes who sustained an ACL injury and then underwent ACLR. **PURPOSE:** To assess changes in knee joint mechanics during running from pre-injury to 6-months post-ACLR in Division 1 collegiate athletes. **METHODS:** Whole body kinematics and ground reaction forces (GRF) were collected during treadmill running for 9 athletes (5 females) prior to a primary ACL injury (PRE) and 6.1±0.3 months post-ACLR (6M). Athletes ran at a maximally comfortable speed at 6M (3.8 ± 0.5 m/s) and speed-matched PRE data was reviewed. Knee joint mechanics and GRF variables were compared between PRE and 6M within the involved (INV) and uninvolved (UNI) limb using Wilcoxon Signed-Rank Tests. Results are presented as within-limb percent change (kinetics, GRF) or median difference (kinematics) between PRE and 6M.

RESULTS: Knee joint metrics decreased from PRE to 6M in the INV limb: knee flexion excursion during stance (5.4° , $p < 0.01$), knee extensor impulse (59.1% , $p < 0.01$), rate of knee extensor moment (37.0% , $p < 0.01$). No change in knee joint mechanics were observed in the UNI limb ($< 5\%$, $p > 0.1$). Furthermore, INV limb demonstrated reduced vertical GRF impulse (2.8% , $p < 0.01$) and braking impulse (13.6% , $p = 0.01$), while both metrics increased in the UNI limb (vertical, 5.7% , $p = 0.01$; braking, 23.8% , $p = 0.01$).

CONCLUSIONS: This is the first study to assess changes in running biomechanics following ACLR relative to the pre-injury state. Consistent with cross-sectional studies, INV knee kinematics and kinetics did not return to pre-injury state by 6 months post-ACLR. Additionally, the UNI limb appears to be a valid comparator for the INV limb for knee joint specific running mechanics at 6M, but not for GRF variables. NIH award TL1TR002375

Gait Variability Of Younger Children Is More Altered By Footwear Type Compared To Older Children

Bryon C. Applequist. University of Hawaii at Hilo, Hilo, HI.
 (Sponsor: John Mercer, FACS¹)
 Email: bapple@hawaii.edu
 (No relevant relationships reported)

The role footwear plays on the development of children's gait and gait variability is not often considered. Many factors contribute to the development of children's gait, including growth, coordination, and motor control, but little attention is paid to the

added constraint of footwear and its role in guiding the development of children's gait. **Purpose:** To determine the affect different footwear types have on children's gait variability at different stages in development. **Methods:** 28 healthy children were divided into four groups by ages 2-3, 4-5, 6-7, and 8-10 years old respectively. Gait variability (coefficient of variation (CV)) measures of stride length (SL) and stride time (ST) parameters were collected for three minutes of treadmill walking in barefoot (BF), moccasin (MO), athletic (AT), and rigid shoes (RS) conditions. A mixed factorial ANOVA (4 age x 4 shoe) was performed to determine significant differences. Tukey post-hoc tests were conducted where applicable. **Results:** There was a significant age x shoe interaction for ST CV ($p=.003$). Specifically, MO decreased from youngest to oldest while BF, AT, and RS increased from 2-3 to 4-5 before decreasing to 6-7 and 8-10. There was a significant age x shoe interaction for SL CV ($p=.007$). There was linear decrease for the MO condition from youngest group to oldest group for SL CV while SL CV increased from 2-3 to 4-5 old before decreasing for the 6-7 and decreasing again for the 8-10 for the BF, AT, and RS conditions. **Conclusion:** Younger children were more sensitive to the varying types of footwear conditions than older children. Concerning footwear, MO most closely resembles BF gait compared to AT and RS. It is important to note the increased sensitivity to footwear differences for younger children. The results of this study raised the concern of what types of footwear should be most appropriate for a developing child, recommending moccasin type shoes and not typical athletic or rigid shoes.

CV Spatiotemporal

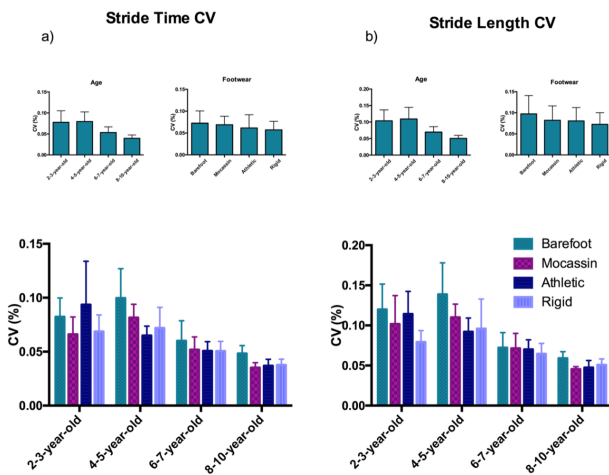

Figure: Bar charts showing the mean and standard deviation for CV Stride time and CV stride length spatiotemporal time series. Data are reported for main effect of age group and footwear condition as well as pairwise comparisons.

AG: -2.9%) angle showing the more leveled foot angle control. There was a greater reduction of foot elevation at mid-swing in CG than AG ($p=0.007$; CG: -11.1%; AG: 8.6%). Lower lateral step variability ($p=0.021$; CG: 5.2%; AG: 34.5%) and greater reduction of lumbar motion in transverse plane ($p=0.030$; CG: -27.7%; AG: -9.4%) were also exhibited in CG. **CONCLUSION:** The study highlights that to attain a comparable secondary task performance with adults, children group adopted more cautious gait patterns when walking and texting. The observed changes, therefore, may suggest that a greater compromise in motor-domain seems necessary in younger age smartphone users under dual-tasking conditions.

Sex And Height Differences Associated With High Impact Physical Activities In Children
 Carlos Santillan, Illinois State University, Bloomington, IL.
 Email: Cksantil@gmail.com
 (No relevant relationships reported)

INTRODUCTION: During childhood mechanical loading is important for developing a resilient skeleton. High impact activity interventions cause improvements in bone mineral density in youth and can promote long term bone health. When designing interventions, it is important to know if sex and height play a role in loading magnitudes experienced during various jumping activities. **PURPOSE:** Examine if sex and height impact the magnitude of peak ground reaction forces (pGRF) during different jump tasks. **METHODS:** Four males (Age: 9±1 years; Height: 1.36 ± 11 m; Mass: 31 ± 5 kg) and four females (Age: 11±1 years; Height: 1.46±0.05 m; Mass: 36±6 kg) performed five trials for each jump condition. Each subject performed a broad jump (BJ), countermovement jump (CMJ), jumping jack (JJ), leap jump (LJ), and a drop jump (DJ). Data were collected on a force plate (1000 Hz), and pGRF in units of body weight (BW) was determined during the landing phase. A mixed ANOVA was employed to assess sex differences across conditions. Correlation analysis assessed the relationship between height and pGRF for each condition. **RESULTS:** No differences in pGRF were observed between males (m) and females (f) across conditions [BJ (m: 2.14± 0.09, f: 2.33± 0.18 BW), CMJ (m: 2.42±0.2, f: 2.44±0.25 BW), JJ (m: 2.55±0.16, f: 2.53±0.25 BW), LJ (m: 1.98±0.02, f: 2.02±0.15 BW), and DJ (m: 2.88±0.31, f: 3.25±0.48 BW)]. There was a moderate correlation between height and pGRF for DJ ($r = 0.59$). **CONCLUSION:** Larger pGRF exhibited with taller subjects during the DJ condition can be explained by considering a higher center of mass contains more gravitational potential energy converted to kinetic energy during the DJ, and thus requires a larger pGRF to slow the participant's center of mass during landing. Height differences should be considered when designing interventions involving drop jumps to elicit bone adaptations in youth.

Comparison Of Gait Characteristics Between Children And Adults During Walking And Texting
 Eun Hye Kwon, Jongil Lim, Henry Martinez, Ian Martinez.
 Texas A&M University San Antonio, San Antonio, TX.
 (No relevant relationships reported)

Average age for a child getting their first smartphone is getting younger. While well-established negative impacts of using smartphone on walking characteristics were generally found for the adult population, its age-related differences are not clear. **PURPOSE:** To examine age-related differences in gait characteristics during walking and texting. **METHODS:** A total of 24 participants were recruited in this study: 12 children (CG; age = 11.7±1.0 years; 1.15 ± 0.11 m; 50.5 ± 13.8 kg) and 12 adult participants (AG; age = 24.8±2.5 years; 1.61 ± 6.3 m; 65.4 ± 18.6 kg). Two conditions were employed (No-texting and Texting). In each condition, subject performed two 60 sec walking trials at their preferred speed along a rectangular walkway (8 x 12 m). Participants were asked to walk while matching a preferred foot strike to the beat of an auditory metronome corresponding to a preferred step frequency measured in baseline. Gait parameters including spatial and temporal step characteristics were measured from wireless inertial sensor system. Dual-task cost (DTC) was calculated as the percentage change between single-task (No-Texting) and dual-task (Texting) conditions. Two-way repeated measures ANOVA's were performed for all dependent variables, with texting condition as a within-subjects variable and group as a between-subjects variable. **RESULTS:** No significant group differences in DTC were observed for texting speed and accuracy. DTC for the gait speed was not significantly different between groups (CG: -14.1%; AG: -11.3%). CG exhibited greater DTCs of foot strike ($p=0.008$; CG: -12.9%; AG: -7.9%) as well as toe-off ($p=0.023$; CG: -6.0%;

Loading Profiles Associated With High Impact Physical Activities In Children
 Zach L. Fassett, Adam E. Jagodinsky, Carlos Santillan, David Q. Thomas, FACSM, Skip M. Williams, Illinois State University, Normal, IL.
 (No relevant relationships reported)

INTRODUCTION: Physical activities that involve impact loading are important for improving bone strength and bone mineral density in children. However, there is little research quantifying the impact loads associated with various high impact activities. **PURPOSE:** Examine the magnitude of peak ground reaction forces (pGRF) of a variety of jumping tasks. **METHODS:** Eight adolescents, within the ages of 8-12 years (age: 9.63±1.49 years; height: 1.42±0.08 m; mass 33.69±4.81 kg), performed five trials for each jump condition. Each subject performed a broad jump (BJ), countermovement jump (CMJ), jumping jack (JJ), leap jump (LJ), and a drop jump (DJ). All jumps were performed on a force plate (1000Hz). pGRF was determined during the landing phase of each jump condition, and expressed in units of body weight (BW). A repeated measures ANOVA was employed to assess differences in pGRF across conditions. **RESULTS:** DJ exhibited significantly greater pGRF (3.09±0.46 BW) in comparison to the BJ (2.25± 0.2 BW; $P=.003$), and LJ (2.01±0.1 BW; $P=.002$). LJ exhibited significantly less pGRF compared to the CMJ (2.45±0.22 BW; $P=.001$), JJ (2.56±0.21 BW; $P<.001$), and DJ ($P=.002$). **CONCLUSION:** Vertical jumping tasks (CMJ, JJ, DJ) elicited greater vertical impact loads compared to horizontal tasks (BJ and LJ) due to the nature of landing. Previous studies indicated loads between 3-9 BW are sufficient for stimulating increases in bone mineral density in pre and early pubertal

children. All conditions except DJ exhibited loading below three BW, suggesting these activities may not sufficiently stimulate bone remodeling to influence bone mineral density.

Strength And Power As Indicators Of Differences In Fiber Type Contributions In Children And Adolescents
 Zachary M. Gillen, Marni E. Shoemaker, Nicholas A. Bohannon, Nicholas A. Bohannon, Joel T. Cramer, FACSM. *University of Nebraska-Lincoln, Lincoln, NE.*
 (No relevant relationships reported)

PURPOSE: Examine individual patterns of peak torque (PT) and mean power (MP) across a range of angular velocities in children and adolescents and how these patterns relate to measurements of growth. **METHODS:** Seventeen children (age = 11 ± 0.4 years) and 22 adolescents (age = 14 ± 0.6 years) performed maximal voluntary isometric contractions, isokinetic leg extensions at 60, 120, 180, 240, and $300^\circ \cdot s^{-1}$, and 50 consecutive maximal isokinetic leg extensions at $180^\circ \cdot s^{-1}$. Patterns of responses for PT and MP across angular velocity were fit with quadratic equations for each subject with r^2 values ranging from 0.803-0.934 for PT and 0.908-0.996 for MP, respectively. Derivatives of each quadratic formula quantified velocity-related changes in PT and MP. Each quadratic formula predicted the peak velocity at which torque could be generated (V_{PT}) or the velocity at which the greatest MP would occur (V_{MP}). The percent of fast-twitch fibers (FT%) was estimated from the fatigue index of the 50-repetition test. Measurements of growth included age, maturity offset, height, body mass, fat-free mass, and quadriceps femoris muscle cross-sectional area. **RESULTS:** All measurements of growth, PT, and MP were greater for adolescents than children ($p \leq 0.003$). As expected, PT decreased quadratically ($p < 0.001$), while MP increased quadratically to $180\text{--}240^\circ \cdot s^{-1}$ ($p < 0.001$) and plateaued ($p = 0.056$) or decreased ($p < 0.001$) to $300^\circ \cdot s^{-1}$. V_{PT} was 352 ± 18 Nm for children and 527 ± 34 Nm for adolescents ($p < 0.001$), while V_{MP} was 216 ± 11 W for children and 268 ± 11 W for adolescents ($p < 0.001$). FT% was $39 \pm 4\%$ for children and $46 \pm 4\%$ for adolescents ($p < 0.001$). Derivatives indicated that PT decreased while MP increased across velocity more rapidly in adolescents than children ($p \leq 0.016$). Derivatives of PT vs. velocity exhibited a high relationship with body mass for adolescents ($r = -0.727$), while derivatives of MP vs. velocity exhibited high relationships with body mass and fat-free mass in children ($r = 0.714\text{--}0.795$). V_{TO} and V_{MP} exhibited high relationships with age for adolescents ($r = 0.884$). **CONCLUSION:** Isometric and isokinetic muscle actions in children and adolescents indirectly demonstrate growth-related increases in fast-twitch fiber contributions to maximal, voluntary muscle strength and power across the velocity spectrum.

Relationship Between Core Stability And Running Mechanics In Adolescent Runners
 Allison Hoffee, Scott Monfort, James Becker. *Montana State University, Bozeman, MT.*
 Email: james.becker4@montana.edu
 (No relevant relationships reported)

Stability of the lumbopelvic "core" is essential for the control and movement of the lower extremity and for absorption and transfer of force. In adult runners, poor core stability is related to increased running injury risk and decreasing core stability results in negative effects on mechanical variables associated with running injuries. It is currently unknown if relationships between core stability and running mechanics exist in adolescent populations. **PURPOSE:** Evaluate the relationship between core stability and mechanical variables associated with running injuries in adolescent runners. **METHODS:** 20 adolescent runners (11 M/9 F; age: 12.38 ± 0.79 years; easy training run pace: 3.24 ± 0.17 m/s) participated in this study. Kinematics and kinetics were recorded using a motion capture system as participants ran on an instrumented treadmill. Core stability was assessed using a novel method which evaluates center of pressure movement over 30 seconds while participants sit still on an unstable surface. Core stability was calculated as total center of pressure excursion (CoPEX) during the test, and Pearson's product-moment correlations were used to determine relationship between CoPEX and running mechanics. **RESULTS:** Mean CoPEX was 1.39 ± 0.41 m, and mean values for running mechanical variables are shown in Table 1. CoPEX was not correlated with any of the mechanical variables. **CONCLUSIONS:** In contrast to what has been reported in adult runners, core stability was not related to running mechanics in this sample of adolescent runners. Without fully developed motor control, adolescent runners may have more overall variability in their running gait, leading to minimal relationships between running mechanics and core stability. Further research is needed to reveal whether reducing core stability influences injury risk factors, as has been shown in novice adult runners, or whether relationships between core stability and running mechanics change as adolescents mature.

Table 1. Mean, standard deviation (SD), p-value, and correlation coefficient (r) for eight injury risk-related mechanics; VALR: vertical average loading rate; BW: body weight

Variable	Mean	SD	p-value	r
Peak hip abductor moment (Nm/kg)	1.81	0.37	0.95	0.01
Hip abductor impulse (Nm/kg*s)	0.18	0.04	0.96	0.01
Peak knee extensor moment (Nm/kg)	1.82	0.50	0.65	-0.11
Knee extensor impulse (Nm/kg*s)	0.13	0.07	0.75	-0.07
Peak knee abductor moment (Nm/kg)	0.67	0.29	0.15	0.34
Knee abductor impulse (Nm/kg*s)	0.03	0.04	0.44	0.18
Peak impact force (BW)	1.85	0.42	0.74	0.08
VALR (BW/s)	72.12	16.80	0.85	0.05

Movement Screening For Adolescent Runners: Relationship Between Single Limb Step Down Performance And Running Mechanics
 James Becker, Allison Hoffee, Scott Monfort. *Montana State University, Bozeman, MT.*
 Email: james.becker4@montana.edu
 (No relevant relationships reported)

The single limb step down (SLSD) is a movement screen commonly used to assess neuromuscular control of the lower extremity. In adult runners, performance on the SLSD is predictive of running mechanics. However, it is unknown whether this is also the case for adolescent populations. If so, the SLSD could be a useful tool for injury risk screening in adolescent athletes. **PURPOSE:** Determine whether performance on the SLSD predicts running mechanics in adolescent runners. **METHODS:** 21 runners participated in this study (12 M/9 F; age: 12.38 ± 0.79 years; weekly mileage: 23.2 ± 6.4 miles; easy training run pace: 3.25 ± 0.17 m/s). Participants ran for five minutes on an instrumented treadmill after which 10 SLSD trials were performed bilaterally from a 15 cm box. Running and SLSD kinematics were recorded using motion capture. Peak frontal plane hip, knee, and ankle, and transverse plane hip and knee angles were calculated during both SLSD and running. The sum of the frontal plane angles was calculated to indicate total medial collapse (TMC). Five additional kinetic variables previous linked to running injuries were calculated for the running trials. Linear regressions were used to determine whether performance on the SLSD predicted kinematics or kinetics during running, with left and right limbs analyzed separately. **RESULTS:** Kinematics on the SLSD predicted kinematics during running (Figure 1). However, TMC during SLSD did not predict vertical loading rates ($R^2 = .008, p = .568$), peak hip adductor moments ($R^2 = .021, p = .363$) or impulses ($R^2 = .007, p = .602$), or peak knee abductor moments ($R^2 = .014, p = .446$) or impulses ($R^2 = .039, p = .209$) during running. **CONCLUSIONS:** The SLSD can predict kinematics during running in adolescent runners. However, performance on the SLSD does not provide information regarding kinetic factors associated with running injuries. Additional research is required to confirm the suitability of the SLSD for identifying adolescent runners at risk of injury.

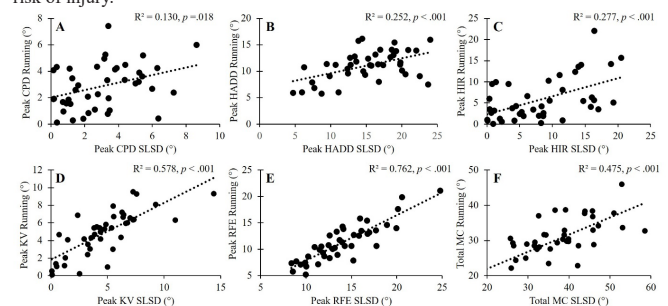

Figure 1. Plots of kinematics on the single limb step down (SLSD) versus kinematics during running for peak contralateral pelvic drop (CPD; A), peak hip adduction (HADD; B), peak hip internal rotation (HIR; C), peak knee valgus (KV; D), peak rearfoot eversion (RFE; E), and total medial collapse (MC; F).

Effects Of Rehabilitation Exercise On Muscle Group Working Characteristics Of Adolescent Patients With Scoliosis
 Yu Zhou¹, Qiang Feng². ¹National Institute of Education Science, Beijing, China. ²China Institute of Sport Science, Beijing, China.
 Email: saucyqj@163.com
 (No relevant relationships reported)

PURPOSE: At present, most studies using surface electromyography (sEMG) to diagnose muscle working characteristics of scoliosis patients were limited to static status. The purpose of the study was to explore the acute effects of corrective exercise

for adolescent scoliosis. METHODS: Adolescent scoliosis patients with Cobb angle between 10-40° were screened. Patients with other predisposing spinal and neurological abnormalities were excluded. 19 girls (age 14.18 ± 2.58) were recruited into experimental group, including 9 patients with thoracic right protrusion (TRP), 7 patients with lumbar left protrusion (LLP) and 3 patients with S-shaped curvature of spine (SSC). 20 healthy subjects (age 14.91 ± 1.23) were randomly selected. The experimental group was given rehabilitation exercises of 60 minutes for twice. sEMG was used to test the muscles at T2, T7, T10 and L4 level. Basic movements were tested in relax mode (RM) and spine correction mode (SCM). RESULTS: 1. For patients with TRP, when sitting, iEMG of muscle groups at T2 level (left -4.53±3.58, p<0.05; right -2.59±0.96, p<0.01), T7 (left -3.19±1.94, p<0.05; right -1.27±1.16, p<0.05) and right muscle group at T10 level (-3.78±2.19, p<0.01) were lower in SCM than in RM; when walking, iEMG of left muscle group at T7 level (-2.07±1.61, p<0.05) was lower in SCM than in RM. Compared to control group, for SCM of this sub-group, when sitting, activation of the left muscle group at T2 level was increased (2.32±1.58, p<0.05). 2. For patients with LLP, compared to control group, when sitting, activation level of right muscle group at L4 level was increased (0.33±0.69, p<0.05). 3. For patients with SSC, when sitting, the iEMG of right muscle group of T2 level was lower in SCM than that in RM (-1.39±0.45, p<0.05). In SCM of standing with balanced legs, compared to control group, this sub-group has higher activation level of the L4 right muscle group (2.71±1.20, p<0.05). CONCLUSION: 1. The asymmetry between convex and concave sides of paraspinal muscles in adolescents with scoliosis was not obvious. 2. The muscle activation of the thoracic spine-related muscle group was more important for the adjustment of adolescent scoliosis. 3. Posture corrective exercises for adolescent scoliosis had good acute rehabilitation effects and contributed to the maintenance of good postures in daily life.

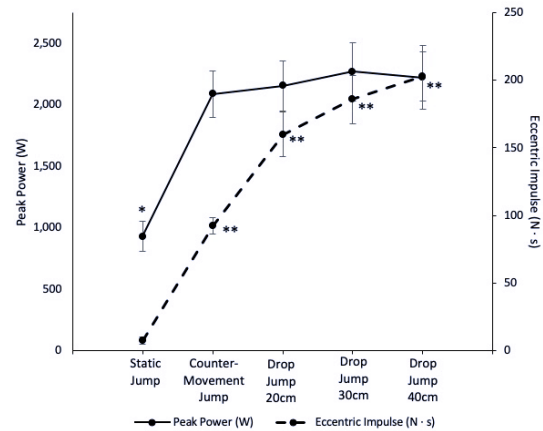

Figure 1. Increases in peak power (PP, left axis) with increases in eccentric pre-loading (ECC, right axis) across vertical jump techniques. * PP for SJ < CMJ, DJ20, DJ30, DJ40; ** ECC for SJ < CMJ < DJ20 < DJ30 < DJ40.

Effects Of Eccentric Pre-loading On Vertical Jump Performance In 9-17-year-old Female Athletes

Nicholas A. Bohannon, Zachary M. Gillen, Marni E. Shoemaker, Sydney M. Gibson, Joel T. Cramer, FACSM. *University of Nebraska-Lincoln, Lincoln, NE.* (Sponsor: Joel Cramer, FACSM)
(No relevant relationships reported)

PURPOSE: Examine peak force (PF), rate of force development (RFD), peak power (PP), eccentric impulse (ECC), concentric impulse (CON), and jump height (JH) during static (SJ), counter-movement (CMJ), and drop (DJ) jumps in young female athletes.

METHODS: Twenty females ranging from 9-17-years old performed SJs, CMJs, and DJs from drop heights of 20, 30, and 40 cm (DJ20, DJ30, and DJ40, respectively) in random order. Measurements included PF, RFD, PP, ECC, CON, and JH for each vertical jump condition. Measurements of growth included age, maturity offset, height, body mass, fat-free mass (FFM), and thigh muscle cross-sectional area (CSA).

RESULTS: As an indicator of eccentric pre-loading, ECC increased systematically from SJ to CMJ to DJ20 to DJ30 to DJ40 (p < 0.001-0.038) (Figure 1); however, CON was not different across vertical jump conditions (p = 1.0). PF and RFD increased from SJ to CMJ (p = 0.009) and from CMJ to DJ20 (p < 0.001), but did not change from DJ20 to DJ30 (p = 1.0) or DJ30 to DJ40 (p = 1.0). PP increased from SJ to CMJ (p < 0.001), but remained constant from CMJ to DJ40 (p = 0.486-1.0) (Figure 1). JH during the CMJ was greater than all other vertical jumps (p ≤ 0.001). The change in PP from SJ to CMJ was moderately to highly correlated with growth measures (r = 0.558-0.815, p ≤ 0.010), except thigh CSA (r = 0.416, p = 0.068).

CONCLUSIONS: These findings were consistent with previous evidence in young male athletes indicating that eccentric pre-loading beyond the CMJ does not result in greater vertical jump power in young female athletes. In contrast to previous evidence in young males, thigh CSA was less related to the increase in vertical jump power from SJ to CMJ than other measures of growth (age, maturity offset, height, body mass, and fat-free mass). In young females, compared to young males, factors other than muscle size contribute more to vertical jump power production. It is unclear how landing mechanics may have influenced the DJ performance measures.

Baseline Assessment High School Athlete: Normative Functional Movement Values

Kristen Renner, Stefanie Bourassa. *The Bone & Joint Institute of Hartford Hospital, Hartford, CT.*
Email: kristen.renner@hhchealth.org
(No relevant relationships reported)

A significant amount of research has aimed to understand ACL injuries, a common injury in high school athletes. It has yet to be determined how to best evaluate athletes' injury risk. To accomplish this, we need functional movement and injury data for a cohort of athletes across time. **Purpose:** To determine functional movement quality in high school athletes and explore the impact of age, gender, single-sport participation on movement quality and changes over time. **Methods:** 121 male (15.83±1.14 yo, 1.77±0.38m, 75.68±16.8kg) and 70 (15.95±1.19 yo, 1.63±0.08m, 59.04±8.78kg) female high school athletes were recruited to complete a Functional Movement Screen (FMS), a Landing Error Scoring (LESS) test, and a hop series including a single limb hop (SH), triple hop (TH), crossover hop (CH) and a 6m timed hop. For the hop series, a limb symmetry index was calculated by: (Right/Left)*100%. SPSS was then used to determine if differences exist between the youngest 25% of athletes tested and the oldest 25%, sexes, or athletes of a single sport and athletes who participated in multiple high school sports using a t-test (α=0.05). Additionally, 42 athletes were re-tested 9.53±3.5 months after the first visit. A 2x2 repeated measures ANOVA (Gender: Male (n=25), Female (n=17); Time: Visit 1, Visit 2) to identify differences in the population over time (α=0.05). **Results:** The males had higher symmetry on the single limb hop compared to the females. Additionally, the older students performed better on the LESS, SH, and CH. Between visits there was a significant increase in limb symmetry on the SH. **Conclusion:** Several differences exist between age groups, while only SH symmetry varied between genders and over time. This work provides a basic understanding of how high school athletes move and provides a data set to investigate injury risk.

 Email: tajiljs22@gmail.com
 (No relevant relationships reported)

Lunge technique variations can affect the biomechanics of lower extremity. However, only a few studies have examined the muscle forces during the forward lunges.
PURPOSE: The purpose of this study was to compare the force of individual muscles of the lower limb during the forward lunges with the change of step length and speed.
METHODS: Three healthy adults performed (1 male, 2 females 35 ± 8 years) forward lunges with different step lengths and speeds. The step lengths were set at 70% and 100% of the leg length (from the greater trochanter to the lateral malleolus); the speeds were set to slow, normal, and fast (30, 40 and 50 lunges/min, respectively). Kinematic and kinetic data were sampled using a three-dimensional motion analysis system and force plate, respectively. Individual muscles of the lower extremities including four muscles of the quadriceps (rectus femoris, vastus medialis, vastus intermedius, vastus lateralis) and four muscles of the hamstrings (semitendinosus, semimembranosus, biceps femoris long head, and biceps femoris short head) were analyzed. Total forces (active+passive force) were calculated using the musculoskeletal modeling technique (Seth et al., 2018). Two-way repeated measure ANOVAs were used to find the effects of the step and speed on the forces of hamstring and quadriceps muscles.
RESULTS: The total forces of the four hamstring muscles were similar between two-length conditions (3.16±2.90 vs. 3.34±3.53 N/kg; 70% vs. 100%; all muscle forces of each speed conditions were pooled, p-values > 0.05) and three-speed conditions (4.26±4.08 vs. 2.60±2.36 vs. 2.89±2.81 N/kg; Slow vs. Normal vs. Fast; all muscle forces of each length conditions were pooled, p-values > 0.05). The total forces of the four quadriceps muscles were similar between two-length conditions (2.23±0.81 vs. 2.29±1.15 N/kg; all muscle forces of each speed conditions were pooled, p-values > 0.05) and three-speed conditions (2.71±1.10 vs. 1.89±0.71 vs. 2.18±0.96 N/kg; all muscle forces of each length conditions were pooled, p-values > 0.05).

CONCLUSIONS: Our preliminary results suggest that the changes in the step length and the speed used in this study did not affect the kinetics of hamstring and quadriceps muscles. This might be due to the limited number of subjects. Further studies are needed.

Knee Medial Compartment Joint Loads In Stationary Cycling With Increased Q-factor

Tanner Thorsen, Erik Hummer, Joshua Weinhandl, Jeffery Reinbolt, Songning Zhang, FACSM. University of Tennessee, KNOXVILLE, TN. (Sponsor: Songning Zhang, FACSM)
 Email: tthorsen@vols.utk.edu
 (No relevant relationships reported)

As Q-Factor (QF: inter-pedal width) is increased, the knee abduction moment also increases. Though the knee abduction moment has been associated with knee medial compartment joint load, it is not a direct measure of joint contact forces. In the absence of *in vivo* measurement using an instrumented knee implant, musculoskeletal modeling simulations may provide a viable option for estimation of knee joint contact forces.

PURPOSE: To estimate the total knee joint compressive force (TCF) and knee medial compartment joint compressive force (MCF) in stationary cycling with increasing QF using musculoskeletal simulation.

METHODS: Five recreationally active males cycled on a stationary ergometer at a workrate of 80 Watts and a cadence of 80 rotations per minute at two QF: original QF (150mm), and wide QF (276mm). Wide QF was increased using pedal extenders. Three-dimensional kinematic data (240 Hz, Vicon) and pedal reaction forces using two custom instrumented bike pedals (1200 Hz, Kistler) were collected. A modified gait2392 model with a knee that includes hinge joints for the medial and lateral compartments was used to estimate muscle forces with static optimization and TCF and MCF with joint reaction analysis (3.3 OpenSim, SimTK, Stanford University). Paired samples t-test and Cohen's d were used to detect differences between conditions.

RESULTS: Peak TCF increased from original to wide QF (960.2 ± 258.2 N to 1117.3 ± 202.1 N; p = 0.299; d = 0.54) and MCF increased from original to wide QF (792.2 ± 98.4 N to 1029.2 ± 315.5 N; p = 0.116; d = 0.89).

CONCLUSION: Large standard deviations and small sample size may account for the lack of statistical significance, yet medium and large effect sizes may allude TCF and MCF increases with greater QF (Figure 1). It appears the majority of TCF is born by the medial compartment; TCF and MCF ranged from 1.46 and 1.14 BW for original and 1.75 to 1.42 BW for wide QF, respectively. These loads are much smaller than 2.0-2.5 BW found in walking and 4.0 BW in jogging.

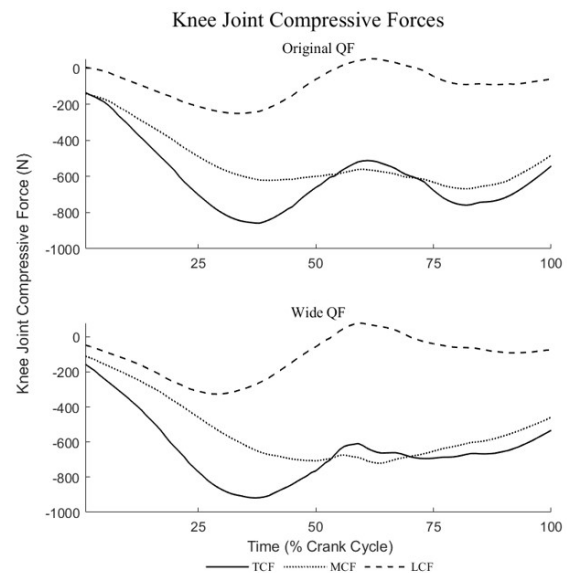

Figure 1: Ensemble curves of the total knee contact force (TCF), medial compartment compressive force (MCF), and lateral compartment compressive force (LCF) during stationary cycling.

The Influence Of The Asymmetry Of Myodynamia On Bilateral Lower Limbs On Kinetics And Kinematics Performance

Kai-Xiang WENG¹, Xiao HOU². ¹Beijing Sport University, Beijing, China. ²Tsinghua University, Beijing, China.
 Email: cowkxe@163.com

(No relevant relationships reported)

PURPOSE: The experiment aims to research the kinetics and kinematics differences between bilateral lower limbs of athletes who have the asymmetry of myodynamia on bilateral lower limbs and provide some basis for avoiding sports injury.

METHODS: The experiment test subjects' Peak Torque of their extensor kinematic chain of bilateral lower limbs. Define subjects whose difference value of peak torque is great than 10% as the experimental group, the rest is the control group. Each group has 10 subjects. Two groups will finish 3 kinematics tests items including running with full power, triple jump by left leg and triple jump by right leg. And also every subject will finish 4 kinetics test items including drop jump, vertical jump by two legs, vertical jump by left leg and vertical jump by right leg on the force platform.

RESULTS: In the intra-group testing, the peak force and impulse in the takeoff phase of vertical jump by two legs (the dominant side peak force is 1000.814±194.59N, the non-dominant side peak force is 852.346±198.23N; the dominant side impulse is 315.887±70.87N*s, the non-dominant side impulse is 255.821±72.00 N*s), the impulse in the takeoff phase of vertical jump by single leg (the dominant side impulse is 611.121±82.10 N*s, the non-dominant side impulse is 430.946±106.76 N*s) and the peak force in the takeoff phase of drop jump (the dominant side peak force is 916.301±272.47N, the non-dominant side peak force is 772.171±159.04N), these four indexes of dominant-side is much higher than the opposite side in the experimental group (p<0.05). But there is no significant difference in control group. There was neither significant difference in the two groups of dominant side nor in the two groups of non-dominant side.

CONCLUSIONS: There are no significant influence on the sports performance of running, vertical jumping and drop-jumping caused by asymmetry of myodynamia of bilateral lower limbs when the Peak Torque of their extensor kinematic chain of bilateral lower limbs is lower than 27% , but it will have a great significant influence on sports performance and sports ability of some relative movements like long jump with single leg and vertical jump with single leg.

M-mode Ultrasound Detects Changes In Lumbopelvic-hip Muscle Activity Using Body Mass Normalization Technique

Courtney Caputo, Sarah Akbarpour, L. Colby Mangum.
 University of Central Florida, Orlando, FL.

(No relevant relationships reported)

M-mode or motion mode allows for non-invasive assessment of contractile tissue movement from echogenicity changes. This method has been used in muscles surrounding the lumbopelvic-hip complex, including the gluteals, however this measurement has not been explored to our knowledge in the rectus abdominis, external oblique, or erector spinae. A normalization technique has not been utilized for M-mode to ensure proper comparison within and between groups as normalization strategies have been applied with other musculoskeletal ultrasound techniques, such as B-mode imaging.

PURPOSE: To determine activity ratio and timing of rectus abdominis (RA), external oblique (EO), erector spinae (ES), gluteus maximus (Gmax), and gluteus medius (Gmed) with a body mass normalization technique. **METHODS:** Ten healthy, physically active individuals with no history of low back or lower extremity injury (21.1±0.7yrs, 67.1±14.8kg, 168.1±6.9cm, 5F) participated in this study. B-mode ultrasound images were collected at rest and during contraction: supine, hook-lying for RA and EO; prone for ES; and side-lying for Gmax and Gmed. Thickness from B- and M-mode images were normalized to body mass (kg) and timing of M-mode was measured in seconds (s). Contracted muscle thickness was divided by rested muscle thickness to calculate activity ratios from B-mode images. Paired *t*-tests were used to compare activity ratios and contraction timing (cm-s/kg) between muscles. **RESULTS:** There were no significant differences (p>.05) between activity ratios, although the EO had the largest activity (1.66±0.72). The RA followed with the second highest activity ratio (1.48±0.38), then ES (1.34±0.43), Gmed (1.30±0.51), and finally Gmax (1.06±0.27). ES exhibited the greatest output from the M-mode normalization technique (0.019± 0.004cm-s/kg) and EO had the least at 0.0053±0.002cm-s/kg (p<.001). **CONCLUSIONS:** The anterior musculature assessed, EO and RA, generated the largest activity ratios, while ES and EO had the greatest disparity detected during motion. The balance of activity between anterior and posterior muscles of the lumbopelvic-hip complex should be noted especially with M-mode activity with this body mass normalization application as the variance in size of muscle plays a major role in how ultrasound data may be interpreted.

Patellofemoral Joint Loading Performing The Forward And Side Lunge With Step Height Variations

Rafael F. Escamilla, FACSM¹, Naiquan Zheng², Toran D. MacLeod¹, Rodney Imamura¹, Shangcheng Wang², Kevin E. Wilk³, Glenn S. Fleisig⁴. ¹Sacramento State University, Sacramento, CA. ²University of North Carolina, Charlotte, Charlotte, NC. ³Champion Sports Medicine, Birmingham, AL. ⁴American Sports Medicine Institute, Birmingham, AL.
 Email: rescamil@csus.edu

(No relevant relationships reported)

PURPOSE: Forward and side lunge exercises are frequently employed during patellofemoral joint syndrome rehabilitation. The purpose was to compare patellofemoral joint force and stress while performing the forward and side-lunge at ground level and up to a 10 cm platform. **METHODS:** Sixteen participants performed a forward and side lunge at ground level and up to a 10 cm platform. Electromyography, ground-reaction-force, and kinematic variables were collected and input into a biomechanical optimization model, and patellofemoral joint force and stress were calculated as a function of knee angle during the lunge descent and ascent and assessed with a repeated-measures 2-way analysis of variance (p<0.05). **RESULTS:** Collapsed across step-height, at 10° (p=0.003) knee angle during lunge descent and 10° and 30° (p<0.001) knee-angles during lunge ascent patellofemoral joint force and stress were greater in forward lunge than side lunge. At 40°(p=0.005), 50°(p=0.002), 60°(p<0.001), 70°(p=0.006), 80°(p=0.005), 90°(p=0.002), and 100°(p<0.001) knee angles during lunge descent and 50°(p=0.002), 60°(p<0.001), 70°(p<0.001), 80°(p<0.001), and 90°(p<0.001) knee angles during lunge ascent patellofemoral joint force and stress were greater in side lunge than forward lunge. Collapsed across lunge type, at 60° (p=0.009) knee angle during lunge descent and 40°(p=0.008), 50°(p=0.009), and 60°(p=0.007) knee angles during lunge ascent patellofemoral joint force and stress were greater lunging at ground level than up to 10 cm platform. No interactions occurred between lunge type and step height. **CONCLUSIONS:** Patellofemoral joint loading changed according to lunge type, step height, and knee angle. When the goal is to initially minimize and then gradually progress patellofemoral joint loading, the following may be a prudent lunging progression: 1) forward lunge at lower knee angles(0°-30°) at ground level or up to 10 cm platform; 2) forward lunge at middle knee angles(0°-60°) up to 10 cm platform and progressed to ground-level; 3) side lunge at middle knee angle(0°-60°) up to 10 cm platform and progressed to ground level; 4) forward lunge at higher knee angles(0°-100°) up to 10 cm platform and progressed to ground level; and 5) side lunge at higher-knee angle(0°-100°) up to 10 cm platform and progressed to ground level.

Interpreting Knee Valgus: Orthogonal Distance Vs Cardan/Euler Angles

Steven M. Hirsch¹, Devon Frayne², Stephen Brown², David M. Frost¹. ¹University of Toronto, Toronto, ON, Canada. ²University of Guelph, Guelph, ON, Canada.

Email: steven.hirsch@mail.utoronto.ca

(No relevant relationships reported)

Cardan/Euler angles (EAs) are commonly used to quantify knee valgus. Although EAs precisely describe the orientation of segments, their geometrical interpretation may not relate well to the underlying joint *kinetics* and can be difficult for practitioners to interpret. Having a metric that is both better related to the knee joint kinetics (e.g. knee abduction moment (KAM) and tibial external rotation moment (TRM)) and easier to interpret would be advantageous for researchers and practitioners. **PURPOSE:** Assess the relationship between (1) EAs and a novel kinematic descriptor of knee valgus - the orthogonal distance of the knee joint center from the hip-foot plane (OD), and (2) EAs and OD with KAM and TRM. **METHODS:** Two datasets were used; in the first, 26 varsity athletes performed 10 bodyweight squats and 10 jump squats. In the second, 13 participants performed 4-5 drop vertical jumps. EAs were used to decompose orientation matrices between the shank and thigh. OD was computed by first creating a plane using the midpoint between the 1st and 5th metatarsals, the ankle joint center, and the hip joint center. Then, the scalar projection of the knee joint center and a vector normal to this plane was computed. Newton-Euler equations of motion were used to compute net joint moments at the knee. Repeated-measures correlation (*r*) and percent agreement (%AG) scores were used to compare continuous and binary (i.e. valgus vs no valgus) metrics at initial contact (Purpose 1), peak knee flexion (Purpose 1 & 2), and the instant when KAM was highest (Purpose 1 & 2). **RESULTS:** EA and OD demonstrated poor correlations (*r*= -0.28 – 0.43) and low agreement when categorizing valgus vs not valgus (%AG= 17.69 – 56.45%). The OD showed stronger links to KAM and TRM in comparison to EAs (Table 1). **CONCLUSION:** Although both kinematic measures were poorly correlated with KAM and TRM, OD was better able to categorize knee valgus kinetics. OD may also be easier to visually observe.

Table 1.

	KAM		TRM	
	r	%AG	r	%AG
OD	-0.39 - -0.13	67.74 - 95.16%	0.21 - 0.51	48.39 - 96.77%
EA	-0.71 - -0.28	24.19 - 38.71%	-0.48 - 0.10	33.87 - 70.78%

Effects Of An 8-week Nordic Hamstring Vs. Isokinetic Eccentric Training Intervention On Biceps Femoris Muscle-tendon Interactions

Antonio Jesús Morales-Artacho¹, Jurdan Mendiguchia², Gaël Guilhem¹. ¹French Institute of Sport, Paris, France. ²ZENTRUM Rehab and Performance Center, Barañain, Spain.

Email: antonio.morales@insep.fr

(No relevant relationships reported)

Resistance eccentric training triggers adaptations in both active and passive elements of the muscle tendon unit (MTU). Previous research highlight the buffering role that tendinous tissues may play to mitigate muscle strain and to optimize operating fascicle lengths. However, the effects of eccentric training on the muscle-tendon interactions of the *biceps femoris* remain unexplored. **PURPOSE:** To evaluate the effects of eccentric training on torque and muscle-tendon interactions of the *biceps femoris* muscle during lengthening contractions. **METHODS:** Eighteen participants completed an 8-wk standardized eccentric training intervention comprising 15 sessions of Nordic Hamstring (NH) or isokinetic leg curl (IK; n=10) exercise. Pre and post training, torque and fascicle, tendinous tissue and MTU length of the *biceps femoris* muscle were measured during maximal 70° lengthening knee extensions at 60°.s⁻¹. One sample t-test statistical parametric mapping (SPM) analyses were performed to evaluate fascicle and tendon behaviour during the contractions. Training effects were evaluated with two-way repeated measures ANOVA and paired t-test SPM. **RESULTS:** Both groups increased torque from 38% to 100% of the contraction duration, with greater improvements in IK from 78.5 to 100% (p < 0.001). The contribution of tendinous tissue to MTU length changes slightly increased only in IK at the last 2% of the contraction (p = 0.04). Despite opposite trend changes in NH, no training effects on fascicle or tendon behavior occurred. The tendinous tissues contribution to MTU lengthening was greater than fascicles up to 75% of the contraction. The fascicles contribution progressively augmented at the end of the contraction (p < 0.05). **CONCLUSION:** We provide novel findings on the muscle-tendon interactions of the *biceps femoris* muscle during lengthening contractions. A 15-session eccentric training program comprising NH or IK exercise does not seem to affect muscle-tendon interactions.

Relationships Between Body Mass Normalized Abdominal Wall Thickness And Self-reported Activity And Global Health

L. Colby Mangum, Courtney Caputo, Sarah Akbarpour.
 University of Central Florida, Orlando, FL.

Email: L.Colby.Mangum@ucf.edu

(No relevant relationships reported)

The anterolateral abdominal wall, rectus abdominis (RA), external oblique (EO), and internal oblique (IO), contributes to lumbopelvic-hip strength; and its role in injured populations such as low back pain has been well explored. However, it is important to establish the association between a body mass normalized measure of muscle size with overall physical activity in a healthy population due to their utility as a frequently used control group and for the potential of this measurement technique in aging, resistance training, and abdominal fat assessment.

PURPOSE: To determine relationships between muscle thickness (at rest and during contraction) of RA, EO, IO and patient-reported outcome measures on physical activity and health. **METHODS:** Eight active participants with no history of low back or lower extremity injury (23.1±5.4yrs, 171.1±11.3cm, 70.6±15.1kg, 4F) completed a single imaging session of RA, EO, and IO. Before imaging, participants completed the PROMIS Global Health (GH), PROMIS Physical Function (PF), and International Physical Activity Questionnaire Short Form (IPAQ). Ultrasound images were collected at rest while supine, hook-lying and during contraction with participants instructed to perform an abdominal crunch for RA, and crunches toward either knee for EO and IO. Thickness measures were normalized to body mass (kg). Pearson's r correlation coefficients were used to determine relationships. **RESULTS:** Six of the 8 participants scored high on the IPAQ (≥3000 METmin/week) and the rest were moderate (≥600 METmin/week). The average hrs/day participants spent sitting was 4.6±2.3hrs. The PROMIS GH (37.5±4.7) and PROMIS PF (98.9±2.4) both confirmed overall health and activity levels. Right side EO at rest (r=.74, p=.04) and during contraction (r=.84, p=.01) were strongly related to hours spent sitting per day. **CONCLUSIONS:** Normalized EO muscle thickness was found to increase, at rest and during contraction, as healthy, active individuals sat longer. Although this was the only significant correlation, this controversial finding may be explained due to the relative 17.4% decrease in EO activity on the right side, compared to the left. The connection between the abdominal wall and self-reported physical activity is important to distinguish, especially with a body mass normalization technique.

Kinematic Analysis Of Single-leg Hopping In Adults With And Without Autism Spectrum Disorder

Adriana Conrad-Forrest¹, Teri Todd¹, Melissa Mache², Danielle Jarvis¹. ¹California State University, Northridge, Northridge, CA. ²California State University, Chico, Chico, CA.

(No relevant relationships reported)

Purpose: Adults with Autism Spectrum Disorder (ASD) may be predisposed to deficient biomechanics or neuromuscular control. This study compared the biomechanics of adults with and without ASD completing a single-leg hopping task. We hypothesized that adults with ASD would demonstrate deficient biomechanics (i.e., decreased pelvic control and greater dynamic limb valgus) compared to adults without ASD.

Methods: 10 participants with ASD (8 male; mean age 23.3, SD ± 3.8) and 10 without ASD (8 male; mean age 21.5, SD ± 2.5) were included in this analysis. 3D motion capture data were collected while participants performed five consecutive single-leg hops. Two of the middle hops were analyzed and kinematic values were averaged across hops. Dynamic limb valgus and frontal plane pelvis range of motion were compared between groups using independent samples t-tests.

Results: No statistically significant differences were observed between the individuals with and without ASD (Table).

Conclusion: Our hypothesis was not supported. Individuals with ASD did not demonstrate deficient biomechanics during the single-leg hopping task when compared to individuals without ASD. The high-level of function of the adults with ASD in the present study may be related to their proficient hop performance. It is also possible other biomechanical variables not presently measured may highlight differences in performance between populations. The present results suggest adults with ASD have similar biomechanics as adults without ASD, though further study is needed.

Table: Comparison of Kinematic Variables Between Groups

	ASD (n=10)*	Non-ASD (n=10)*	Between-Group Differences	p-value
Pelvis ROM	-8.3±2.81	-6.7±2.35	-1.6	0.194
Hip flexion	45.7±8.69	45.9±11.03	0.2	0.965
Hip adduction	8.1±3.99	4.4±4.81	-3.7	0.077
Hip internal rotation	6.6±6.16	9.3±5.6	2.7	0.321
Knee abduction	7.1±4.81	3.6±3.94	3.5	0.100
Knee flexion	50.1±8.77	49.9±5.78	0.2	0.888
Ankle dorsiflexion	24.4±2.98	22.01±6.52	2.4	0.4

 Email: dscarborough@mgh.harvard.edu
Reported Relationships: D.M. Scarborough: Salary; FIGUR8, Inc. Ownership/interest/stock; future stock options.

INTRODUCTION: The Kinematic Sequence (KS) refers to the order of peak angular velocities of connected body segments during a specific movement. There are many possible KS patterns. The proximal-to-distal sequence (PDS) KS ordered: pelvis->trunk-> arm-> forearm-> hand is reported as the most efficient pattern for overhead throwing. Simulation studies report that the PDS KS results in reduced torques across the joints of the overhead throwing limb, potentially reducing risk of injury. Another KS is the PDS Variant which has a similar PDS pattern of pelvis-> trunk-> arm->, but with simultaneous forearm & hand peak velocities. A third KS pattern, Delayed CORE, demonstrates delayed peak velocity of the trunk: pelvis-> hand -> trunk-> simultaneous arm & forearm. While the PDS KS concept is instructed in fastpitch softball pitching, KS studies have not been published. The study purpose was to investigate the KS in a group of fastpitch softball pitchers.
METHODS: 3D biomechanical analyses using high-speed motion capture cameras (240Hz) were performed on 140 fastball pitches from 21 softball pitchers (16 high school, 5 collegiate, mean age 16.15 ± 2.31 y). For each fastball pitch, Visual 3D v6 biomechanical analysis software calculated the peak angular velocity of the pelvis, trunk, arm, forearm and hand after the time of stride which allowed KS identification. Shoulder compression forces and stride length was also calculated for each of 3 primary groups of fastball pitches PDS n=12, PDS Variant n= 28 and the Delayed CORE n= 27. ANOVA and T-test comparisons were performed.
RESULTS: There were no significant differences in stride length between the 3 KS patterns, p = 0.14. The Delayed CORE KS pattern demonstrated statistically significantly greater shoulder compressive force than the other groups, mean= 8.23 ± 1.04 (F(2,64)= 23.45, p< 0.01). There were no differences in shoulder compression forces between the PDS (6.89BW ± 0.5) and the PDS Variant (6.74BW ± 0.73) group, p= 0.524.
CONCLUSION: This foundational study is the first to apply a KS classification system to the fastball softball pitch. Use of the PDS or PDS Variant KS promoted less shoulder compression force than the Delayed CORE group. The KS classification system could potentially guide underhand pitching instruction for injury prevention.

A Comparison Of Pitch Velocity And Elbow Valgus Torque Between Collegiate Baseball Pitchers Trained With And Without Weighted-ball Exercises
 Arnel Aguinaldo, Estevan Gomez. *Point Loma Nazarene University, San Diego, CA.*
 Email: arnelaguinaldo@pointloma.edu
(No relevant relationships reported)

Several training strategies have been suggested and evaluated for their effects on baseball pitching performance and injury risk. There is some data in the current literature which indicates that plyometric based weighted-ball training is effective at altering the kinematics and kinetics of the throwing motion. However, it is unclear whether weighted-ball trained pitchers throw faster with lower joint kinetics than those trained otherwise. **PURPOSE:** To compare throwing velocity and maximum elbow valgus torque (MEV) between collegiate male baseball pitchers trained with weighted-ball exercises and those without. It was hypothesized that weighted-ball trained pitchers exhibit higher throwing velocity and MEV than pitchers trained without weighted-ball exercises. **METHODS:** Twenty-one collegiate baseball pitchers participated in this study, 13 of whom trained using weighted baseballs and 9 of whom trained without weighted baseballs as part of their in-season training regimen. After providing written informed consent, each participant threw 15 fastballs while ball speed and MEV were measured using a radar gun and a wearable inertial measuring unit (IMU), respectively. **RESULTS:** There was no significant difference in ball speed between weighted-ball trained pitchers (36 ± 1 m/s) and non-weighted-ball trained pitchers (35 ± 3 m/s, p = .108). Conversely, weighted-ball pitchers threw with greater MEV (110 ± 28 N-m) than non-weighted-ball trained pitchers (52 ± 6 N-m, p < 0.001). **CONCLUSION:** These findings suggest that pitchers who train using weighted-ball exercises throw at ball speeds comparable to those who do not but may do so at a higher risk of a pitching-related elbow injury.

The Relationship Of Stride Length And Joint Stresses Among Adolescent Female Fastpitch Softball Pitchers
 Rachel Keller, Shannon Linderman, Luke S. Oh, Eric Berkson, Donna Scarborough. *Massachusetts General Hospital, Boston, MA.*
 Email: rkeller2@mgh.harvard.edu
(No relevant relationships reported)

PURPOSE: During the softball windmill pitch delivery, power is generated from the lower extremities and transferred up through the kinetic chain out to the throwing hand. At time of stride, the lead lower extremity incurs significant momentum breaking forces that could contribute to injury risk. Joint angle positions at the time of stride may vary based on stride length and extreme ranges of stride length may correlate with biomechanics that are associated with vulnerability to injury. This study investigates the relationship between stride length and 1) joint angles of the lead lower extremity at time of stride and 2) peak joint torques of the lead hip and throwing shoulder during the softball windmill pitch.
METHODS: 17 pitchers (mean age= 15.4 ± 1.4 y) underwent 3D biomechanical analysis of 80 fastballs using a 20 motion capture camera system (Vicon Motion Systems Ltd UK) at 240 hz. A 15-segment whole-body model for each pitcher was created. Ankle, knee, hip, and pelvis angles of the lead lower extremity and peak hip and shoulder torques at time of stride were calculated within a biomechanical analysis software (Visual 3D v6, C-Motion). Analyses included 2-tailed Pearson correlations. **RESULTS:** Stride length correlated positively with peak shoulder external rotation torque (r= 0.245, p= 0.029), lead ankle eversion/inversion, and hip flexion/extension angle at time of stride. Stride length negatively correlated with lead knee valgus/varus, hip abduction/adduction, hip rotation, and pelvis flexion/extension angle at the time of stride (Table 1). No other correlations were observed.
CONCLUSION: The most prevalent reported injuries among softball pitchers occur at the shoulder, hip, and low back. Study findings suggest that pitch instruction on lead leg joint position at time of stride as well as stride length may be important for injury prevention during fast pitch softball pitching.

Table 1: Correlation of Joint Angles to Stride Length

Joint	Angle	Average (°) ± SD	Correlation Coefficient	P value
Ankle	Eversion (+)/ inversion (-)	-22.71 ± 10.29	.265	0.018*
Knee	Valgus (+)/ Varus (-)	10.08 ± 5.00	-.320	0.004*

Effects Of A 6 Week Balance Training Program On Throwing Velocity And Joint Kinetics In Collegiate Baseball Pitchers

Gretchen E. Hoffmann, Susan Ganz, Arnel L. Aguinaldo. *Point Loma Nazarene University, San Diego, CA.*
Email: gehoffmann21@gmail.com
(No relevant relationships reported)

It is known that high elbow valgus torque in the pitching motion can contribute to the occurrence of elbow injury. Lately, studies have shown pitchers with UCL tears had significantly lower balance measures than healthy players when tested after injury occurred. There is a paucity of research on the effect of balance-specific training on the joint loading of the elbow and player performance in baseball pitching.

PURPOSE To investigate the effect of a balance training intervention on the biomechanical factors that can contribute to a pitcher's increased risk of elbow injury. **METHODS** Thirteen collegiate baseball pitchers were randomly assigned to a training group: control or intervention. The control group did only the team training and the intervention group did the team training and a specific balance training program. The intervention was performed 3 times a week for 6 weeks. Measurements of balance (Y-Balance), limits of stability (center of pressure excursion), ball speed, and joint kinematics and kinetics, specifically maximum elbow valgus torque (MEV), through motion capture were collected before and after the 6-week training program. **RESULTS** None of the outcome measures showed a significant difference between training type (Y-Balance $p=.405$; COP excursion $p=.537$, ball speed $p=.150$; MEV $p=.945$). Three outcome measures, COP excursion ($p=.007$), ball speed ($p=.003$), and MEV ($p<.001$) showed significant decreases over time regardless of training type. A Pearson Correlation was run for the entire study population ($n=13$) between ball speed and MEV for initial ($p=.409$) and final ($p=.300$) testing and showed no significant correlation between the variables. **CONCLUSION** The balance training program had no observable effect on a pitchers' pitching performance or elbow kinetics. There was no significant difference between groups in pre or post measures, therefore, any change in balance measures can be attributed to normal in-season training strength development.

	Pre-Intervention	Post-Intervention
<i>Y-Balance</i>		
Control	123.1 ± 9.7 cm	124.5 ± 11.9 cm
Intervention	119.0 ± 7.7 cm	122.0 ± 9.6 cm
<i>COP Excursion</i>		
Control	160.5 ± 33.9 cm	129.4 ± 4.3 cm
Intervention	152.4 ± 24.7 cm	131.1 ± 13.0 cm
<i>Ball Speed</i>		
Control	81.2 ± 3.2 mph	77.9 ± 3.8 mph
Intervention	81.1 ± 2.6 mph	73.5 ± 3.4 mph
<i>Maximum Elbow Valgus</i>		
Control	103.6 ± 28.6 Nm	64.5 ± 8.7 Nm
Intervention	117.0 ± 27.2 Nm	77.0 ± 13.7 Nm

Validation Of A Wearable Sensor In The Estimation Of Elbow Valgus Torque During Baseball Pitching

Eric Burger, Arnel Aguinaldo. *Point Loma Nazarene University, San Diego, CA.*
(No relevant relationships reported)

Because of its relationship to pitching-related elbow injuries, the valgus torque at the elbow during baseball pitching has been a measure of interest that has clinical implications for the assessment and treatment of ulnar collateral ligament (UCL) injuries in pitchers. However, there currently is no feasible method to quantify elbow valgus torque in game-like settings. **PURPOSE:** To estimate the concurrent validity of a wearable sensor in measuring valgus torque at the throwing elbow during the pitching motion. **METHODS:** After providing informed consents, thirty-four adolescent pitchers threw 10 fastballs from a regulated mound while the joint kinematics and kinetics were simultaneously being measured with a 3D motion capture system and an inertial measurement unit (IMU) sensor, which was used to specifically estimate elbow valgus torque during baseball pitching. The Pearson correlation and Bland-Altman charts were used to estimate the concurrent validity and degree of accuracy of the IMU using the 3D motion capture system as the criterion method. **RESULTS:** The concurrent validity of the IMU in measuring elbow valgus torque was moderate ($r = 0.686$, $p < 0.01$) with a mean error of -3.48 N·m (Fig. 1). **CONCLUSION:** The wearable sensor was found to have moderate concurrent validity in estimating elbow valgus torque, the magnitude of which was underestimated by the sensor.

Relationship Between Kinematics, Strength, And Throwing Velocity Of Adolescent Softball Players During Overhand Throwing

Kyle Donaldson, Allison Oxner, Chelsea Martin, Kaylee Pobocik, Srikant Vallabhajosula. *Elon University, Elon, NC.*
(Sponsor: Dr. Stephen Bailey, FACSM)
Email: kdonaldson4@elon.edu
(No relevant relationships reported)

The kinematics of overhand throws by adolescent softball players is currently under-reported. Identifying the relationship between kinematics, strength and velocity can help guide further research and promote better understanding of the sport. Current research has investigated the differences between softball and baseball but has not looked at how kinematics and strength correlate with throwing velocity in softball. **Purpose:** To identify the relationship between kinematics, strength, and velocity of an overhand throw in adolescent softball players. **Methods:** 25 adolescent softball players performed 3 maximum effort overhand throws. The throws were filmed using a 2-D video analysis system consisting of 3 cameras set up in the frontal and sagittal planes. The velocity of the throws were recorded using a speed gun. Key positions were identified in six throwing phases and angles were measured using software on a tablet. Bilateral hip and shoulder strength of each player were measured using standardized methods via handheld dynamometer. Correlation coefficients were determined. **Results:** A moderate and significant correlation was found between the velocity of overhand throw and the stride knee flexion angle during the arm cocking phase ($r = .55$, $p = .004$), the stance knee flexion angle during stride phase ($r = .49$, $p = .015$), and the elbow flexion angle during arm acceleration phase ($r = -.45$, $p = .024$). A moderate and significant correlation was found between trunk flexion angle during follow through phase and hip internal rotation ($r = -.45$, $p = .04$) as well as hip external rotation ($r = -.53$, $p = .013$) strength. **Conclusion:** Increases in velocity were influenced by lower extremity variables including increases in stride knee flexion angle during the arm cocking phase and increased stance knee flexion during stride phase. Upper extremity

variables that related to higher velocity included decreased elbow flexion at the end of acceleration phase. Strength parameters including hip internal and external rotation strength were found to be related to higher velocities. These findings highlight the potential influence of lower extremity kinematic variables and strength on performance as measured by velocity. These results can benefit players or coaches who are teaching or learning how to do the overhand throw.

1023 Board #149 May 27 1:30 PM - 3:00 PM

Effects Of Weighted Baseball Throwing On Youth Glenohumeral Joint Reaction Force

Hiroshi Sagawa¹, Michael R. Torry¹, Adam E. Jagodinsky¹, Sean Higinbotham², Michelle Sabick³. ¹Illinois State University, Bloomington, IL. ²University of Denver, Denver, CO. ³Saint Louis University, St Louis, MO.
(No relevant relationships reported)

INTRODUCTION: Weighted baseball throwing programs are often used to increase pitch velocity. However, increased injury risk has been reported and questions regarding possible mechanism of injury exist. Kinematics and kinetics have been investigated with inverse dynamics approach, but the effects of individual muscle forces have rarely been taken into account by these models and in consideration of pitch mechanics. Analysis of shoulder joint reaction force with a musculoskeletal model including individual muscle forces may provide new insight on injury mechanism.

PURPOSE: To compare the effects of varied weighted baseballs on glenohumeral (GH) joint reaction forces during youth pitching.

METHODS: 7 baseball pitchers (Age 15.7 ± 2.4) participated in the study. Participants performed 5 pitches for strikes with 5oz, 7oz, and 9oz baseballs. Full body, 3D segment position data were collected using a motion capture system (200 Hz) and ball velocities were measured via radar gun. Highest velocities of 3 pitches were selected and 3D marker trajectories input into a 19 DOF musculoskeletal model utilizing a standard inverse dynamics and static optimization routine to produce individual muscle forces to yield GH joint reaction forces. Mean distraction force, anterior shear force, and superior shear force on GH joint were calculated and compared with RMANOVA (alpha = .05) during the acceleration phase of the pitch with Bonferroni post-hocs.

RESULTS: Differences were noted between the ball weights on ball velocity (5oz 66.9 ± 8.8mph, 7oz 61.6 ± 7.8 mph, 9 oz 56.9 ± 6.1 mph, p<0.001). Also, throwing heavier baseballs exhibited increased distraction forces (5oz 1987±472.5N, 7oz 2386±544.1N, 9oz 2414±601.1N, p = 0.007); while anterior shear force and superior shear force did not present distinct differences.

CONCLUSIONS: Distraction force pulls humeral head out of the glenoid fossa, and weighted baseball throwing program may cause more stresses on biceps brachii, rotator cuff, and surrounding structures by the increased distraction force.

The Kinematic Sequence Of The Baseball Bat Swing And Associated Upper Extremity Torques

Eric M. Berkson, Shannon E. Linderman, Hannah S. Stein, Connor M. Yong, Donna Moxley Scarborough. *Massachusetts General Hospital, Boston, MA.*
(No relevant relationships reported)

PURPOSE: The Kinematic Sequence (KS) is the timing of peak angular velocities generated across connected body segments during a movement pattern. The most efficient KS reported in sport is when the timing occurs in a proximal-to-distal (PDS) pattern. This 'ideal' KS follows the order of pelvis, trunk, arm, forearm, and hand. Based on simulated models of the golf swing, the PDS KS results in greater ball distance and decreased joint stresses. Despite similarities to the golf swing, there is limited research on the KS during batting. Study aims: 1) Identify KSs during the baseball swing and 2) compare the leading upper extremity torques across the 3 primary KSs.

METHODS: 23 baseball players (professional=2, collegiate=11, high school=10) underwent 3D biomechanical swing analysis, totaling 47 trials. A 15-segment model was constructed using a 20 Vicon™ camera motion capture system (240 hz). Body segment and bat velocities as well as peak shoulder and elbow torques were calculated using Visual 3D™ biomechanical software. Time of peak angular velocity of the pelvis, trunk, arm, forearm, and hand was recorded. The torques were compared across the two most performed KS patterns as well as the KS representing the closest to a PDS pattern. The KS patterns were labeled by the first body segment that disrupted the PDS pattern: proximal (PUE) and distal (DUE) upper extremity. Analyses included an ANCOVA using bat velocity as a covariant.

RESULTS: 11 unique KS patterns were identified. The most commonly performed KSs were DUE (n=23) then PUE (n=13). No batter displayed the exact PDS KS. Therefore, 5 trials that most closely represent the PDS, those with forearm and hand velocities peaking simultaneously, were grouped as PDS. Peak elbow extension torque

differed significantly between the 3 KS groups ($F(2,37)=4.95$, $\eta^2=0.21$, $p=0.012$) with lower values for PDS (PDS: 17.94 ± 12.83 Nm, PUE: 51.09 ± 25.19 Nm, DUE: 43.01 ± 22.26 Nm, $p=0.012$).

CONCLUSIONS: This foundational study is the first to apply a KS classification system to the baseball swing. Lower elbow extension torques for the PDS group are consistent with the idea that a PDS KS may result in decreased joint stress. KS analyses could potentially guide clinicians and hitting instruction to minimize biomechanical risk factors during batting.

The Measurement Of Thrust In Competitive Swimming: The Association Between Different Thrust Variables

Tiago M. Barbosa¹, Jia Wen Yam², Govindasamy Balasekaran, FACSM², Daniel A. Marinho³. ¹Polytechnic Institute of Bragança, Bragança, Portugal; ²Research Centre in Sports, Health and Human Development, Vila Real, Portugal; ³Nanyang Technological University, Singapore, Singapore. ²Nanyang Technological University, Singapore, Singapore. ³Research Centre in Sports, Health and Human Development, Vila Real, Portugal; ⁴University of Beira Interior, Covilhã, Portugal.
(No relevant relationships reported)

Swimming acceleration and velocity are the net balance between Drag Force and Thrust. It is a standard procedure to do the decomposition of the Thrust-Time curve, assessing the swimmer's thrust. However, there is not a convention or standard procedure on the variables to be selected. Researchers report on regular basis either the Peak Thrust, Mean Thrust or Thrust-Time Integral. It is yet unclear to which extend these variables can be used, reported and interpreted interchangeably. **PURPOSE:** To analyze the association between different thrust variables performing arm-pulls in competitive swimming. **METHODS:** 671 front-crawl arm-pull cycles of 14 competitive swimmers were analyzed. Thrust was collected by an in-house built system composed by differential pressure sensors and underwater camera (Aquanex, Swimming Technologies, USA). A customised software (LabVIEW®, v.2017) was used to acquire ($f=50$ Hz) and streaming time-series and video signal. Data was transferred to interface by a 14-bit resolution acquisition card (NI-6001, National Instruments, Austin, USA). Then, it was imported into a signal processing software (AcqKnowledge v.3.9.1, Biopac Systems, USA). It was extracted the Peak Thrust, Mean Thrust and Thrust-Time Integral of each arm-pull. Coefficients of Determination were computed between the three thrust variables. **RESULTS:** All Coefficients of Determination were significant ($P<0.001$). Peak Thrust vs. Mean Thrust was $R^2=0.49$, Peak Thrust vs. Force-time Integral $R^2=0.51$, and Force-time Integral vs. Peak Thrust $R^2=0.61$. Interception on Y-axis at the origin of the pairwise variables noted in the same SI unit (i.e. Newton) were very close to zero (-1.6948<c<4.5029) and standard error of estimate acceptable (6.54<S<12.14). **CONCLUSIONS:** There is a strong association between different thrust variables, even though the proportion of the variance is about 50-60%. Supported by: NIE AcRF Grant (RI 6/17 TB); Portuguese Foundation for Science and Technology (UID/DTP/04045/2019); European Fund for regional development (FEDER)-COMPETE 2020 (POCI-01-0145-FEDER-006969).

Power Parameters Appear Less Important To Water Polo Success Than Motor Control

Cameron A. Williams, William P. Lydon, Cynthia Villalobos, Christopher B. Perry, Alexia E. Amo, J. Mark VanNess, Courtney D. Jensen. *University of the Pacific, Stockton, CA.*
(No relevant relationships reported)

Conditioning programs for water polo players typically focus on muscular power to enhance the wrestling and shooting components of play. While improvements in strength training are easily quantifiable, the relationship between upper limb power and in-game performance has yet to be established. **PURPOSE:** To test the effect of upper limb force parameters on offensive performance in women's water polo players. **METHODS:** We conducted biomechanical testing on 12 D1 women's water polo players using Proteus (Proteus Motion, USA). After completing a familiarization and warm-up protocol, subjects performed a single set of 10 repetitions at 3lb of magnetic resistance in 3 different exercises: shoulder adduction, internal rotation of the shoulder while in horizontal abduction, and a throw motion. Proteus calculated peak power (PP), peak force development rate (PFDR), and consistency (accuracy of movement

replication in 3D space during successive repetitions). The corresponding season statistics (2018-2019) were tabulated for assists, goals scored, and shooting percentage. Descriptive statistics characterized the sample; linear regressions tested the effect of PP, PFDR, and consistency on in-game performance. **RESULTS:** During the test season, players scored 23.1 ± 19.9 goals, had a shooting percentage of $41.6 \pm 12.1\%$, and accomplished 10.5 ± 10.9 assists. In the throw motion, Proteus calculated a PP of 59.2 ± 15.5 watts, PFDR of 104.3 ± 33.0 watts/sec, and consistency of $81.0 \pm 8.7\%$. PFDR exhibited negative relationships with goals scored ($p=0.021$) and shooting percentage ($p=0.049$), and a non-significant negative relationship with assists ($p=0.111$). Similar relationships were found with throw PP as well as PP and PFDR in shoulder adduction and internal rotation; all corresponded to worse performance in every performance metric. Consistency in all motions had a positive, non-significant relationship with all performance metrics; statistical trends were reached with horizontal shoulder adduction in which consistency predicted 7.1% more goals ($p=0.062$) and 8.8% more assists ($p=0.050$). **CONCLUSIONS:** These data provide preliminary evidence that skill-based fine motor coordination may be more valuable than power development in offensive performance in women's water polo.

Core Temperature While Swimming In A Wetsuit During 1000-m Race Pace Swim

Alina P. Swafford, Melissa Aura, Boram Lim, John Mercer, FACSM. *University of Nevada, Las Vegas, Las Vegas, NV.* (Sponsor: John A. Mercer, FACSM)
(No relevant relationships reported)

Majority of fatalities that occur in the sport of triathlon happen during the swim portion of the race (Harris et al., 2010, JAMA). The potential risk of death while swimming has raised safety concerns. The governing body, USA Triathlon (USAT), has implemented guidelines related to water temperatures and the use of wetsuits. The varying water temperatures allow for a wide selection of wetsuits. Using a wetsuit while swimming in warm water may increase body heat storage which could increase core temperature. Currently, there are only limited data on the influence of triathlon wetsuits on core temperature when swimming in warm water while swimming a short distance at a somewhat hard swim pace (Aura et al., 2019, MSSE). **PURPOSE:** The purpose of this study was to examine core temperature while swimming a long distance (1000 m) at a fast pace in warm water (25.5°C) while wearing a wetsuit. **METHODS:** Two experienced triathletes (mean \pm standard deviation (SD), age 38.5 ± 23.3 years, height 1.83 ± 0.03 m, weight 80.1 ± 1.1 kg) participated in the study. At least 8 hours prior to attending the test session, participants swallowed an ingestible core temperature pill (BodyCap). Before beginning data collection, core temperature (T_c) data were transferred to a computer and sample rate was set to 0.1 Hz (1 sample every 10 s). Testing consisted of a self-directed warm up of 250-m followed by a 1000-m swim in an indoor pool (set to 25-m length) for each condition: no wetsuit (NW) and full sleeve wetsuit (FS). Participants swam at a self-selected pace at a "race pace" intensity (Borg Rating of Perceived Exertion = 16). Participants were required to rest until core temperature was within 0.5°C of baseline before starting the next condition. Core temperature data were transferred to a computer after each swim. Average T_c of each swim was computed for analysis. **RESULTS:** The average core temperatures of NW and FS were $37.75 \pm 0.11^\circ\text{C}$ and $37.74 \pm 0.46^\circ\text{C}$, respectively. The total swim time for the NW and FS conditions were $14:04 \pm 1:43$ and $13:05 \pm 1:06$ minutes. Mean stroke rate calculated for NW and FS were 30.12 ± 0.17 and 30.68 ± 0.45 strokes per minutes. Average swim speeds for NW and FS were 1.19 ± 0.15 and 1.28 ± 0.11 meters per second. **CONCLUSIONS:** Based upon the analysis of the results, the use of a wetsuit while swimming in warm water does not influence core temperature.

Is There An Optimal Vertical Ground Reaction Force Profile For Maximizing Jump Height In A Countermovement Jump?

Josef A. Cohen¹, Malachy P. McHugh, FACSM¹, Marc Hickok², Declan AJ Connolly². ¹Nicholas Institute of Sports Medicine and Athletic Trauma, New York, NY. ²University of Vermont, Burlington, VT. (Sponsor: Malachy McHugh, FACSM)
 Email: mchugh@nismat.org
(No relevant relationships reported)

PURPOSE: The vertical ground reaction force (VGRF) during a countermovement jump (CMJ) is classically described with a single peak force occurring at the low position of the countermovement. However, in practice, jumpers display a variety of CMJ VGRF profiles, including single and double peaks, and jumps where the peak force occurs at, or after, low position. The purpose of this study was to identify the optimal CMJ VGRF profile for maximizing jump height.

METHODS: The top 100 CMJs (based on jump height) from a database of over 2000 jumps, from 211 division one college athletes were analyzed. The 100 athletes (21 \pm 3 yr, 96 men) were from several different sports teams (hockey n=33, lacrosse n=25, soccer n=14, basketball n=14, other n=14). All jumps were performed with the hands

on the hips. Jumps were categorized as having a single or a double peak in VGRF and whether the peak GRF occurred at, after, or before low position. Jump heights were categorized as above average (1SD=mean), average (within 1SD of mean), or below average (1SD<mean). The association between jump metrics and VGRF profiles was examined using chi square analyses and independent t-tests.

RESULTS: Of the 100 CMJs 22 had a single peak VGRF, of which 14 occurred at low position and 8 occurred after low position. Of the 78 CMJs with a double peak, the 1st peak was higher in 47 jumps (30 at low position, 13 after low position, 4 before low position), the peaks were equal in 20 jumps (10 at low position, 10 after low position), and the 2nd peak was higher in 11 (all after low position). Peak GRF occurred at the low point of the countermovement for 82% (14 of 17) of the above average jumps versus 52% (33 of 64) of the average jumps and only 37% (7 of 19) of the below average jumps ($P=0.007$). For the 78 jumps with two distinct VGRF peaks the 1st peak was greater than the 2nd for 77% (10 of 13) of above average jumps, 61% (30 of 49) of average jumps and only 44% (7 of 16) of below average jumps ($P=0.033$).

CONCLUSIONS: The optimal VGRF profile appeared to be peak force occurring at low position regardless of whether there was a single or double peak. The worst VGRF profile appeared to be jumps with two peaks where the 2nd peak was greater than the 1st peak, or the 1st and 2nd peaks were equal, but the 1st peak occurred after low position. In conclusion, achieving peak VGRF at the low position of a CMJ appears to be optimal.

1029 Board #155 May 27 1:30 PM - 3:00 PM
Effect Of Countermovement Depth On The Neuromechanics Of A Vertical Jump

Malachy P. McHugh, FACSM, Josef A. Cohen, Karl F. Orishimo, Ian J. Kremenic. *Nicholas Institute of Sports Medicine and Athletic Trauma, New York, NY.*
 Email: mchugh@nismat.org
(No relevant relationships reported)

PURPOSE: The purpose of this study was to examine kinematic, kinetic and muscle activation metrics during countermovement jumps (CMJs) with varying countermovement depths. The hypothesis was that a shallow countermovement depth would compromise jump height by disrupting neuromechanical control.

METHODS: Ten healthy men (age 26 ± 8 yr, height 1.81 ± 0.08 m, mass 83.5 ± 9.0 kg) performed maximal CMJs at self-selected countermovement depth (self-selected CMJ), at reduced countermovement depth (shallow CMJ) and at increased countermovement depth (deep CMJ). Three jumps were performed in each condition on force plates with ankle, knee and hip motion recorded and electromyograms (EMG) recorded from the gluteus maximus (GM), vastus lateralis (VL) and medial gastrocnemius (MG) muscles. During CMJs knee flexion angle was recorded with an electrogoniometer. Jumpers were instructed to flex 15% less (shallow CMJ) and 15% more (deep CMJ) than the self-selected CMJs. Kinematic, kinetic and EMG metrics were compared between the different CMJ depths using repeated measures ANOVA.

RESULTS: Compared with self-selected CMJs, shallow CMJs had 26% less countermovement depth (9.5 cm less, $P<0.001$) and the deep CMJs had 28% greater countermovement depth (10.2 cm more, $P<0.001$). Jump height was 8% less for the shallow vs. self-selected CMJs (0.344 m vs. 0.373 m, diff 2.9 ± 2.5 cm, $P=0.007$) but not different between self-selected and deep CMJs (0.373 m vs. 0.378 m, diff 0.05 ± 0.19 cm, $P=0.254$). Shallow CMJs differed from self-selected CMJs at the initiation of the countermovement (unweighting phase). For self-selected CMJs force dropped to 43% of body weight during unweighting but only to 58% for shallow CMJs ($P=0.015$). During unweighting VL EMG averaged 5.5% of MVC during self-selected CMJs versus 8.1% for shallow CMJs ($P=0.014$). Percent decline in jump height with shallow versus self-selected CMJs was correlated with the difference in VL EMG during unweighting between shallow and self-selected CMJs ($r=0.651$, $P=0.041$). **CONCLUSIONS:** Failure to deactivate the quadriceps during the unweighting phase of shallow CMJs compromised unweighting and resulted in a reduced jump height. These findings highlight the importance of unweighting at the initiation of the countermovement in dictating subsequent jump performance.

Task Intensity Alters How Anterior Knee Pain Influences Frontal-plane Hip Biomechanics During Landing And Jumping

W. Matt Denning¹, Jihong Park², Kaitland Garner³, Zach Horton³, J. Ty Hopkins, FACSM³, Matthew K. Seeley³. ¹Brigham Young University Idaho, Rexburg, ID. ²Kyung Hee University, Yongin, Korea, Republic of. ³Brigham Young University, Provo, UT. (Sponsor: J. Ty Hopkins, FACSM)
 Email: denningw@byui.edu
(No relevant relationships reported)

Anterior knee pain (AKP) often affects individuals participating in activities involving high-intensity landing and jumping. Task intensity may alter the influence of AKP on lower-extremity landing and jumping biomechanics. **PURPOSE:** Determine whether

task intensity affects the influences of AKP on frontal-plane hip biomechanics during landing and jumping. **METHODS:** 13 healthy adults (6 females, 7 males; 70 ± 15 kg; 1.7 ± 0.1 m; 22 ± 2 years) performed three land and jump trials under three conditions: pre-pain, pain (1-ml hypertonic saline (5% NaCl) injection into the right infrapatellar fat pad), and post-pain. Subjects jumped over an obstacle, landed on a force plate, then jumped over a second obstacle. Obstacle heights of 80 and 50% of maximal vertical jump height defined high and low task intensities. Frontal plane hip angles and internal moments were calculated for the right leg. A functional analysis ($\alpha=.01$) was used to evaluate differences between conditions for each intensity, across the duration of foot contact with the force platform (ground contact). **RESULTS:** For the high intensity task, AKP resulted in increased hip adduction angle, as much as 2° between 1-20% and 75-95% of ground contact, and increased hip abduction moment, up to 6 Nm between 10-30% of ground contact (Figures 1E-F). For the low intensity task, AKP resulted in decreased hip adduction angle, as much as 1.3° between 25-75% of ground contact, and decreased in hip abduction moment, as much as 15 Nm between 25-60% of ground contact (Figure 1G-H). Changes due to AKP persisted after pain abatement (Figures 1I-L). **CONCLUSIONS:** Experimental AKP effects frontal plane hip biomechanics and these effects differ between task intensity. Especially during the high-intensity task, the AKP resulted in increased hip adduction angle and internal abduction moment. More data are needed to determine how/if the present changes influence the risk of chronic knee injury/disease.

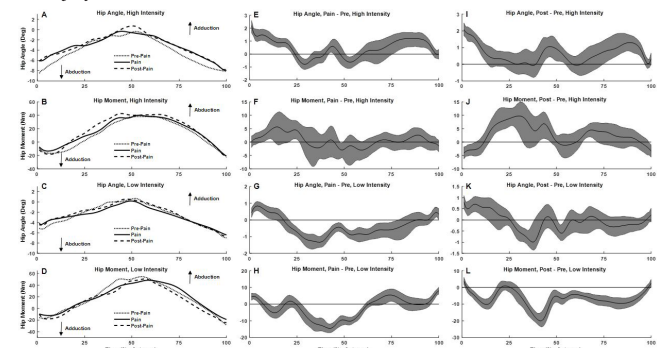

Figure 1. Grand ensembles for each condition and each intensity (A-D). Results of condition comparisons, pain minus pre-pain (E-G) and post-pain minus pre-pain (H-K). For plots E-K, mean differences and corresponding 95% confidence intervals are plotted as a function of time. When shaded area does not cross the zero line, condition differences exist ($p<.05$).

Breast Support Alters Knee Joint Biomechanics During A Landing Task.

Hailey B. Fong, Alexis K. Nelson, Jay Hinton, Alexander M. Carnall, Melissa A. Puppa, Douglas W. Powell, FACSM. *University of Memphis, Memphis, TN.* (Sponsor: Douglas W. Powell, FACSM)
 Email: hbfong@memphis.edu
 (No relevant relationships reported)

Females have a greater rate of traumatic knee injuries than male athletes. Trunk position has been shown to affect knee joint biomechanics during a landing task. Given the position of breast tissue, insufficiently supported breasts may also alter knee joint biomechanics. However, no previous research has investigated the effect of breast tissue or support on knee joint biomechanics during landing. **PURPOSE:** to determine the effect of breast support on knee and hip joint kinetics during a landing task. **METHODS:** Fifteen female athletes performed five step-off landings from a height of 40 cm in each of three bra support conditions: control (CON), low support (LOW) and high support (HIGH). 3D kinematics and ground reaction forces (GRFs) were simultaneously recorded using a 9-camera motion capture system (240 Hz.) and pair of force platforms (1200 Hz.) was used to calculate knee and hip joint angles and moments. Custom software (was used to determine peak joint angles and moments. Repeated measures ANOVAs with Tukey's post-hoc analyses were used to compare mean knee and hip joint kinetics. **RESULTS:** No differences in peak knee abduction moments were observed, though peak knee external rotation moments were smaller in the LOW compared to CON ($p = 0.007$) and HIGH conditions ($p = 0.013$). No differences were observed between CON and HIGH ($p = 0.423$). No differences were observed in peak hip abduction moment or peak hip external rotation moment. **CONCLUSIONS:** These findings indicate that knee joint biomechanics during a landing task are affected by breast support. The current study did not address the role of trunk orientation or differences in breast size amongst participants. Future research should address the role of breast motion on trunk kinematics and kinetics. Table 1. Mean knee and hip joint moments in the CON, LOW and HIGH support conditions.

Variable (Moments)	CON	LOW	HIGH	p-value
Knee Abduction	0.44 (0.35)	0.44 (0.30)	0.42 (0.21)	0.422
Knee External Rotation	-0.32 (0.21)	-0.24 (0.25)	-0.32 (0.22)	0.029
Hip Abduction	-0.62 (0.22)	-0.66 (0.26)	-0.57 (0.27)	0.216
Hip External Rotation	-0.57 (0.18)	-0.60 (0.16)	-0.58 (0.19)	0.353

The Effects Of Whole-body Vibration And Fatigue On Vertical Jump Performance

Sean Bonilla, Sergio Espericueta, Chanel Catunao, Nicole C. Dabbs. *California State University, San Bernardino, San Bernardino, CA.*
 Email: 005843249@coyote.csusb.edu
 (No relevant relationships reported)

Whole Body Vibration (WBV) is the exposure of oscillating vibration to the body, which may result in an increase of the rate of motor unit activation. Fatigue of knee extensor muscles has been shown to hinder vertical jump (VJ) performance. **PURPOSE:** The purpose of this study is to investigate the effects of WBV and fatigue on vertical jump (VJ) performance.

METHODS: Sixteen active males and females (age, 23.19 ± 2.56 ; weight, 79.05 ± 16.97 ; height, 174.36 ± 12.11) volunteered for five-day study. On day 1 familiarization, after completing an IRB approved informed consent and health screening questionnaire participants were prepped on testing protocols. Following a dynamic warm up, testing sessions 2-5 will include one of four conditions: No WBV and No Fatigue (C1), WBV and Fatigue (C2), WBV and No Fatigue (C3), and No WBV and Fatigue (C4). WBV was performed using a frequency of 50Hz and a low amplitude while performing quarter squats for a total of 4min with a 30s rest or work ratio. Lower-body fatigue induced using Bosco fatigue test, performing 60s of jump squats. VJ was performed using an AMTI force plate and peak force, velocity, and power were calculated and a Vertec was used to measure vertical jump height (VJH). VJ data was collected pre and post conditions each day. Percent change scores (% Δ) were calculated between pre and post conditions and used for analysis. SPSS was used to perform a Repeated Measures ANOVA.

RESULTS: There was significant differences between C1 and C2 ($p = 0.005$; $C1 = -1.21 \pm 5.91$; $C2 = -7.83 \pm 6.17$ % Δ), C1 and C4 ($p = 0.002$; $C1 = -1.21 \pm 5.91$; $C4 = -8.94 \pm 6.90$ % Δ), C2 and C3 ($p < .001$; $C2 = -7.83 \pm 6.17$; $C3 = 0.97 \pm 4.63$ % Δ), C3 and C4 ($p < 0.001$; $C3 = 0.97 \pm 4.63$; $C4 = -8.94 \pm 6.90$ % Δ) in VJH. There were significant differences between C1 and C4 ($p = 0.011$) and between C3 and C4 ($p = 0.017$) in peak force. There were significant differences between C1 and C2 ($p = 0.01$), C1 and C4 ($p = 0.02$), C2 and C3 ($p < 0.001$), and C3 and C4 ($p = 0.001$) in peak velocity. There were significant differences between was between C1 and C2 ($p = 0.03$), C1 and C4 ($p = 0.03$), C2 and C3 ($p = 0.004$), and C3 and C4 ($p = 0.008$) in peak power. There were no significant ($p > 0.05$) differences between other variables.

CONCLUSIONS: WBV did not show to change the detrimental effects of lower-body fatigue, however this study did show lower-body fatigue decreases vertical jump performance.

1033 Board #159 May 27 1:30 PM - 3:00 PM
Effects Of w' Depletion On The Torque Velocity Relationship In Cycling

Randolph E. Hutchison¹, Karlee S. Edwards¹, Gibson Klaphor¹, Lee Shearer¹, Gregory M. Mocko², Ardalan Vahidi². ¹*Furman University, Greenville, SC.* ²*Clemson University, Clemson, SC.* (Sponsor: Anthony CATERISANO, FACSM)
 Email: Randolph.Hutchison@furman.edu
 (No relevant relationships reported)

The torque-velocity (T-v) curve has been used to study the effects of energy expenditure on contractile muscles at various workloads related to VO_{2max} . **PURPOSE:** The purpose of this study was to further quantify changes to the T-v curve, but based on anaerobic energy (W') expenditure at powers above Critical Power (CP6). **METHODS:** A group of 10 subjects (37.8 ± 11.6 yrs, 72.8 ± 16.2 kg, $1.75 \pm .11$ m) performed a Time to Exhaustion Test (TTE) interspersed with 6-second sprints to generate their T-v curve at 3 stages of W' expenditure: after initial warmup (FRESH), fatigued (after 2 minutes at CP6, 2MIN), and at TTE. **RESULTS:** ANOVA results indicated a statistically significant decrease in normalized Maximal Power (P_{max}) from FRESH to 2MIN (16.89%, $p < .0005$), 2MIN to TTE (24.71%, $p = .004$), and from FRESH to TTE (41.6% $p = .04$). Statistically significant decreases in normalized Maximal Velocity (v_{max}) were seen from FRESH to 2MIN (14.1%, $p < .0005$), from 2MIN to TTE (11.8%, $p = .001$), and FRESH to TTE (25.9%, $p < .0005$). No significant changes occurred in Maximal Torque (T_{max}). Linear regression

models were run using W' expended to explain variations in P_{\max} , v_o , and T_o . There were significant negative correlations for T_o ($P = 0.020$) and significant strong negative correlations for P_{\max} ($P < 0.005$), and v_o ($P < 0.005$).

CONCLUSIONS: This suggests that W' expenditure can be used to predict the performance parameters Torque (T_o), Shortening velocity (v_o), and Maximal Power (P_{\max}) during continuous cycling above Critical Power.

1034 Board #160 May 27 1:30 PM - 3:00 PM
Effects Of Bicycle Crank Length On Hip And Knee Joint Kinematics And Compressive Forces

Christiane R. O'Hara, Michael Liang, Melodie Leroudier, Chaitanya Adiga, Robert D. Clark. *California Polytechnic State University, San Luis Obispo, CA.* (Sponsor: Todd Hagobian, FACSM)
 Email: crohara@calpoly.edu
 (No relevant relationships reported)

PURPOSE: Crank length (CL) on a bicycle may affect knee and hip joint compressive forces and range of motion (ROM). The relationship between knee/hip joint forces, moments, and ROM can have an influence on hip and knee joint health (i.e. osteoarthritis, patellofemoral disorder, ligament damage, etc.). The purpose of this study was to examine the effects of four different CL (155, 165, 175, and 185 mm) on ROM and resultant compressive forces on the hip and knee. **METHODS:** 12 non-cyclists (4M, 8F, aged 18-55) participated in a single blind randomized cross-over experiment with four CL. An Enhanced Helen Hayes marker protocol was used to place 32 retroreflective markers on anatomical landmarks to track kinematic data using a 12-camera 3D motion analysis system with Cortex software (Motion Analysis Corp., CA, USA). Kinetic data were collected using a stationary bike (SRM IndoorTrainer, Germany) retrofitted with custom pedals containing 6-axis load cells (AMTI, MA, USA). A 3 minute warm-up for each CL was performed at 1.5 W/kg and 70 rpm. 4x1 minute trials were conducted at 2 W/kg. The first two trials were at a constant cadence of 70 rpm and the second two trials were at a constant pedal speed (PS) of 1.47 m/s. There were 10 seconds of rest between trials and 5 minutes of recovery between each condition. Kinematic data was processed using Cortex software and filtered (4th order Butterworth, cutoff 6 Hz). Kinetic data was filtered using MATLAB (MathWorks, MA, USA). All data was averaged from 30 seconds of each trial. **RESULTS:** During submax cycling, the 155 mm CL had a significantly smaller hip ROM (42 deg vs. 49 deg; $p < 0.05$) and a significantly smaller knee ROM compared to the 185 mm CL (72 deg vs. 80 deg, $p < 0.05$). No significant differences were found at a cadence of 70 rpm: 155 mm CL peak hip compressive force (1.3 N/kg) vs. 185 mm CL (0.9 N/kg); 155 mm CL peak knee compressive force (2.8 N/kg) vs. 185 mm CL (2.6 N/kg). No significant differences were found at a PS of 1.47 m/s: 155 mm CL peak hip compressive force (0.6 N/kg) vs. 185 mm CL (0.7 N/kg); 155 mm CL peak knee compressive force (2.3 N/kg) vs. 185 mm CL (2.5 N/kg). **CONCLUSION:** Hip and knee ROM was significantly greater with a longer CL. There are no significant differences in hip or knee peak compressive forces. Implementation of a shorter CL at a PS of 1.47 m/s may minimize peak hip and knee joint compressive forces.

Effects Of Workrate And Seat Position On Knee Biomechanics In Recumbent Cycling

Tianyi Lu. *George Mason University, Manassas, VA.* (Sponsor: Songning Zhang, FACSM)
 Email: tlu7@gmu.edu
 (No relevant relationships reported)

Tianyi Lu, Tanner Thorsen, Jared Porter, Joshua Weinhandl, Songning Zhang, FACSM University of Tennessee, Knoxville, TN
 George Mason University, Fairfax, VA

Cycling is one of the most popular rehabilitation tools for knee osteoarthritis (OA) patients. In recent years, recumbent bicycle has become a popular trend over upright bikes in exercise and rehabilitation. Previous literature has largely focused on upright cycling with few examining knee biomechanics in recumbent biking in the sagittal plane. Little is known on the effects of workrate and seat position on knee biomechanics in recumbent bike. **PURPOSE:** To examine the effects of different workrates and seat positions on knee biomechanics during stationary recumbent cycling. **METHODS:** Fifteen healthy participants (55.5±3.7 years, 1.75±0.09 m, 84.3±15.7 kg) cycled on a recumbent ergometer in six test conditions of three seat positions at two workrates. Seat positions were "far" (20-30° of peak knee flexion angle), "medium" (30-40°) and "close" (40-50°), and the workrates were set at 60 and 100 Watts (W). A 3D motion analysis system (240 Hz, Vicon) and a pair of custom-made instrumented pedals were used to collect kinematic and kinetic data in each condition. A 3x2 (seat position x workrate) repeated measures ANOVA was used to determine if differences existed between conditions ($p < 0.05$). **RESULTS:** Peak knee extension moment, peak knee abduction moment (KAbM), peak knee extension angle and peak knee extension ROM were significantly higher at 100 W compared to 60W (all $p \leq 0.008$). There was a significant main effect of seat position for peak

knee flexion moment. Pairwise comparisons showed that peak knee flexion moment was significantly higher in the far seat position (-18.9±6.3 Nm) compared to medium (-13.1±6.5 Nm) and close seat position (7.28±7.33 Nm). In addition, the peak flexion moment was significantly higher in the medium seat position (-13.1±6.5 Nm) than close position (-7.28±7.33 Nm). **CONCLUSION:** Increased workrates significantly increased peak KAbM and knee extension moment. Different seat positions did not change either peak KAbM or knee extension moment. For patients with knee OA, a low workrate may be considered in recumbent cycling exercises, while the seat position could be chosen based on personal preferences.

1036 Board #162 May 27 1:30 PM - 3:00 PM
Preoperative And Postoperative Cycling Biomechanics Following Cam Femoroacetabular Impingement Corrective Surgery: A Pilot Study

Jenna E. Link, David J. Bennion, K. B. Foreman, James C. Martin, FACSM. *University of Utah, Salt Lake City, UT.* (Sponsor: James C. Martin, FACSM)
 (No relevant relationships reported)

PURPOSE: Cycling is commonly prescribed following femoroacetabular impingement (FAI) corrective surgery. This surgery alters gait mechanics in the postoperative period, but alterations in cycling mechanics have not been reported. In this case study, we sought to determine if cam FAI corrective surgery altered cycling biomechanics postoperatively in a highly active female subject. **METHODS:** Bilateral cycling biomechanics were collected preoperatively when the subject was asymptomatic and again 11-weeks postoperatively. During each visit, pedal forces and limb kinematics were collected and used to determine joint-specific work. The subject was instructed to target a power output of 240 W during isokinetic cycling at 80 RPM. Limb symmetry index (LSI) was calculated to compare power production at the pedal. Normalized joint-specific work was compared both inter- and intralimb, as well as pre- vs. postoperatively. **RESULTS:** LSI decreased from 96% to 84% postoperatively. Summed joint extension work increased in the surgical limb from 90% to 97% postoperatively. This increase was the result of a 67% decrease in hip extension work (30% to 10%, Figure 1) and a compensatory 28% increase in knee extension (50% to 64%, Figure 1) and 70% increase in ankle extension (10% to 17%, Figure 1) work within the surgical limb. In the nonsurgical limb, there was a 333% increase in knee flexion work postoperatively (3% to 13%, Figure 1). **CONCLUSION:** Cycling mechanics following FAI corrective surgery exhibited significant changes suggesting the development of compensatory patterns. The results of this pilot study combined with the prevalence of cycling in FAI surgery rehabilitation warrant further studies on the development and persistence of compensatory patterns and to possibly identify early intervention strategies.

Figure 1. Pre- to postoperative changes in joint-specific work for the surgical and nonsurgical limbs.

Biomechanics Metrics Associated With Golfing Prowess

Karl F. Orishimo, Catherine O'Mahoney, Ian J. Kremenec, Stephen J. Nicholas, Malachy P. McHugh, FACSM. *Nicholas Institute of Sports Medicine and Athletic Trauma, New York, NY.* (Sponsor: Malachy P. McHugh, FACSM)
Email: karl@nismat.org
(No relevant relationships reported)

PURPOSE: The biomechanics of the golf swing have been studied extensively but specific metrics related to golfing proficiency have not been identified. The purpose of this study was to compare golf swing biomechanics between proficient and average golfers and thereby identify specific metrics associated with golfing proficiency.

METHODS: Twenty-two male golfers were categorized as proficient (golf index <6, n=10) or average (golf index 10-24, n=12). Three-dimensional kinematics and ground reaction forces (GRF) were recorded as subjects hit standard golf balls into a net using a driver. Angular velocities of the pelvis, trunk, lead arm and golf club, as well as X-factor, were calculated from the kinematic data. GRF under the lead and back legs are expressed as a % of bodyweight. The effect of golf proficiency on golf swing biomechanics was assessed using independent samples t-tests.

RESULTS: Proficient golfers were younger (26±6 yr vs. 48±16 yr, P=0.001) but did not differ in height (P=0.114) or weight (P=0.330). Peak pelvis and trunk velocities were higher (P=0.004) in proficient golfers (525.1±91.6 deg/s and 621.8±89.4 deg/s, respectively) versus average golfers (414.3±67.7 deg/s and 521.3±75.5 deg/s, respectively) but peak club velocity was not different (2509.8±226.1 deg/s vs. 2446.6±420.3 deg/s; P=0.675). Proficient golfers had greater X-factor at the top of the backswing (56.0±6.0 degrees vs. 44.1±11.4 degrees, P=0.008), greater peak X-factor (61.4±5.7 degrees vs. 49.3±11.8 degrees, P=0.008) and greater X-factor at ball impact (34.2±5.8 degrees vs. 22.5±6.5 degrees, P=0.001). Proficient golfers had a higher peak GRF on the lead leg compared with average golfers (142±17 %BW vs. 122±18 %BW, P=0.018), while paradoxically having a lower lead leg GRF at ball impact (56±18 %BW vs. 89±17 %BW, P<0.001).

CONCLUSIONS: The higher X-factor in proficient golfers is indicative of a more effective use of elastic energy in the trunk that is sustained through ball impact. The GRF data indicate that proficient golfers more effectively loaded the lead leg during the initiation of the downswing and more effectively unloaded the lead leg prior to ball impact. In conclusion, golf swing proficiency appears to be a function of a more effective transfer of power from the ground and a more effective use of elastic energy in the trunk.

1038 Board #164 May 27 1:30 PM - 3:00 PM

Biomechanical Comparison Of The Half To Full Golf Swing - Clinical Implications

Audrey L. Millar, FACSM, Kelly Boss, Chloe Gilgannon, Chr. Wendt. *Winston-Salem State University, Winston-Salem, NC.*
Email: millaral@wssu.edu
(No relevant relationships reported)

PURPOSE: Golf is popular, with many middle-aged participants. A concern for healthcare workers is how to advise those wishing to return to golf after a lower extremity (LE) injury or surgery. A common recommendation is to use a half swing, however, it is not known whether this reduces the motion or muscular torque for the LE. The purpose of this study was to examine the peak torques and positions of the hip during a half swing versus a full golf. **METHODS:** 11 healthy amateur male golfers with handicaps ≤ 21 participated in this study. All participants completed 20 golf swings (10 full swings, 10 half swings). A 10-camera motion analysis system, with force plates, were used to record swing data. Data was reduced using a 3-D modeling program and standard inverse dynamics were used to determine internal net joint torques. Peak torques (Nm; normalized by %BWHT) and movement positions (degrees) were analyzed in SPSS (Version 24) Differences and correlations considered significant if at the .05 level of probability. A repeated measures ANCOVA (club-head velocity in mph, as the covariate) was used to compare half to full swing for each movement. **RESULTS:** Subjects had an average age of 44±16 years and an average handicap of 13±6. Club-head speed ranged from 69 to 113mph, with an average of 91±12mph. The highest torques in both full (12.02±1.97 Nm/%BWHT) and half swings (12.04±2.07 Nm/%BWHT) occurred in trail hip extension. This was followed by lead hip flexion and hip abduction, and trail hip abduction in both swing styles. (6.58±2.46, 6.04±2.07 and 5.75±1.11 Nm/%BWHT, respectively). The highest peak positions were in the trail leg for flexion and abduction. There was a significant correlation between each half and full swing position ranging from r=.85 to r=.98. Repeated measures ANCOVAs found no significant differences between half and full golf swings.

CONCLUSIONS: Contrary to a pilot study, our data show that using a half swing did not reduce the amount of internal torque around the hip, as compared to a full swing. All torques were similar to a published study in which it was noted that the torques

were much higher than reported hip torques for walking and activities of daily living. These findings suggest that clinicians should use caution in recommending a half vs a full swing for those returning to golf following an injury or surgery.

1039 Board #165 May 27 1:30 PM - 3:00 PM

Correlation Of Lumbopelvic-hip Complex Stability To Pain In NCAA Division III Golfers

Jessica Washington, Morgan Willoughby. *Berry College, Mount Berry, GA.*
Email: jwashington@berry.edu
(No relevant relationships reported)

Lumbopelvic-hip complex (LPHC) stability is known to be a major contributor in injury prevention of ballistic movement. However, the literature primarily focuses on the kinematics of the hips and trunk relative to swinging sports, specifically in professional golfers. Data is sparse regarding isometric strength (ISO) and muscular endurance (ME) of the LPHC relative to pain in male and female collegiate golfers.

PURPOSE: Therefore, the purpose of this study was to determine the relationship of LPHC isometric strength and muscular endurance to upper extremity, lower extremity, and back pain in NCAA Division III golfers. **METHODS:** Thirty-two NCAA Division III golfers (19.8 ± 1.3 yrs.; 70.0 ± 11.1 kg.; 173.4 ± 11.1 cm) volunteered to participate. Thirteen were female, and nineteen were male. A health history questionnaire was used to establish current pain or stiffness within each athlete. Bilateral internal and external rotation ISO, as well as adduction and abduction ISO, was measured using a handheld dynamometer. Two trials were conducted for each variable, and the mean was used for statistical analysis. Additionally, ME of the anterior and posterior trunk was measured using the trunk flexor endurance and trunk extensor endurance tests of the standardized McGill's Torso Muscular Endurance Test Battery. A Pearson product-moment correlation was run to determine relationships between ISO and ME to current pain. **RESULTS:** A statistically significant, negative correlation was found between lead hip internal rotation ISO, relative to the golf stance, and current pain (r = -.369, n = 32, p = .038). Of the 14 reported cases of pain, 11 instances were localized to the back and hips. No other statistically significant correlations were established between current pain and ME or ISO of bilateral external rotation, abduction, adduction, and internal rotation of the back hip. **CONCLUSION:** Deficient internal rotation isometric strength of the lead hip could be considered a risk factor for hip and back pain in collegiate golfers.

Balance And Kinematic Swing Sequence In Older Female Golfers

Michael C. Rabel, Katherine James, Kyle Goodwin, Drew Jordre, Samantha Phillips, Hayley Fake, Meaghan Wagner. *University of Maryland Eastern Shore, Princess Anne, MD.*
(No relevant relationships reported)

Female golfers account for approximately 25% of the entire golfing population in the United States and 16% of female golfers are over the age of 60. While balance and golf swing kinematic sequence are frequently cited as important performance determinants, literature involving the older female golfer is limited.

PURPOSE: To examine the balance profile (during specific dynamic tasks) and kinematic golf-swing pattern displayed in older female golfers. **METHODS:** Thirteen female golfers using a right-handed swing strategy (mean age ± SD, 67.5 ± 5.5) completed the Modified Clinical Test of Sensory Integration of Balance and the Rhythmic Weight Shift (RWS) protocols in order to collect balance data. A golf-swing kinematic assessment was also performed. Three recorded drives were used to analyze the swing and establish a dominant sequence. Balance outcome data were examined with reference to established age-matched normal values. Golf-swing kinematic sequence patterns were compared between those participants within (N=7; mean age ± SD, 66.1 ± 5.2) and outside of (N=6; mean age ± SD, 69 ± 5.9) normal Forward-Backward Directional Control (FBDC).

RESULTS: All participants displayed normal directional velocity values for the RWS assessment but only half demonstrated normal FBDC. The kinematic sequence analysis revealed that 53.8% of all participants optimally initiated the downswing by leading with the pelvis. Golfers with normal FBDC (mean % time on axis ± SD, 79.1 ± 5.5), were more likely (71.4%) to initiate a normal kinematic swing sequence compared to 33.3% of those with abnormal FBDC (mean % time on axis ± SD, 64 ± 7).

CONCLUSIONS: The results of this study suggest that this population of golfers may need to consider exercise or training programs designed to improve forward/backward dynamic balance control as a means to assist in optimizing the kinematic sequence and overall golf-swing performance.

1041 Board #167 May 27 1:30 PM - 3:00 PM

Crosse Use Effects On Running And Drop Jump Mechanics In Male And Female Lacrosse PlayersHeather K. Vincent, FACSM, Michelle L. Bruner, Cong Chen, Sharareh Sharififar, Kevin R. Vincent, FACSM. *University of Florida, Gainesville, FL.*

Email: vincehk@ortho.ufl.edu

(No relevant relationships reported)

PURPOSE: A unique feature of lacrosse is the use of a crosse to move the ball during complex running and jumping movements. It is unclear whether there is a differential biomechanical effect of holding the crosse during key sport-specific motions in female and male youth and high-school/collegiate players. The purpose of the study was to determine the motion differences of running and drop jumps when holding a short stick or a defensive pole in youth (11.8±1.4 yrs; 21% female) and high-school/collegiate players (18.4±1.9 yrs; 35% female).

METHODS: Players (N=70) performed drop jumps and running at near sprint speed. Drop jumps were completed under three conditions: bare hands, short stick and defensive long pole. Running was performed under three conditions: bare hands, and dominant side one-handed and two-handed holds while cradling. A 3D motion tracking system and floor embedded force plates captured motion about the ankle, knee, hip, pelvic and trunk during three trials of each condition for each motion. Sex and age group differences were tested using univariate analyses of variance.

RESULTS: For drop jumps, foot landings (heel, mid or toe) differed more often when holding a crosse versus bare hands for all players (31.4%-34.2% vs 27.1%). Irrespective of age, female players demonstrated more ankle 7°-9° dorsiflexion than males in all conditions (p<.05). Youth demonstrated 28% more knee adduction in all jump conditions than high-school/collegiate players (p<.05). Compared to males, females had 5.2°-6.5° less anterior trunk flexion at initial ground contact when holding a short or long stick and 9.8%-20% less anterior flexion after landing versus bare hands (p<.05). During running, females had 12.7% more hip adduction and 43% more trunk lateral lean than males with one or two-hand holds compared to bare hands irrespective of age (p<.05). A two-handed hold produced greater trunk transverse rotation than other conditions compared to males and across conditions (p=.001).

CONCLUSIONS: Holding a crosse differentially affects biomechanics in female and male players but not by age group. Preseason conditioning with movements while holding the crosse may provide help reduce excessive motion at affected joints. Funded by US Lacrosse.

Relationships Between Accelerometer-derived Training Loads And Rpe In Collegiate Women'S Volleyball PlayersNatalie Kupperman, Jay Hertel, FACSM. *University of Virginia, Charlottesville, VA.**(No relevant relationships reported)*

Purpose: The relationship between ratings of perceived exertion (RPE) and objective training load metrics in women's volleyball players is unknown. This study examined relationships between RPE and accelerometer-derived variables in practices and games in this population.

Methods: External training loads were measured with triaxial accelerometry during team practices and games along with subjective RPE collected on the Borg CR-10 scale. Data from 12 athletes over a 7-week in-season period (13 games, 19 practices) were collected from an NCAA Division I women's volleyball team. The accelerometer-derived variables were: total playerload (PL), total change of direction (COD), total jumps, total accelerations, total decelerations, and total repeated high-intensity events (RHIE). Relationships between RPE and the accelerometry variables in practices and games were analyzed using Pearson correlations (r) and least ordinal squares regression.

Results: Correlations with RPE during games and practices were: PL (0.79, 0.57), COD (0.57, 0.23), jumps (0.68, 0.46), accelerations (0.55, 0.30), decelerations (0.76, 0.61), and RHIE (0.52, 0.52). Regression models for games revealed that accelerometry measures explained 70% of variance in RPE (PL, jumps, decelerations, $p < 0.05$; COD, accelerations, RHIE, $p > 0.05$). For practices, accelerometry variables explained 44% of variance in RPE (PL, decelerations, RHIE, $p < 0.05$; COD, jumps, accelerations, $p > 0.05$). PL alone explained 62% and 33% of the variance in RPE for games and practices, respectively ($p < 0.001$).

Conclusions: Accelerometer-derived variables informed the understanding of athlete-reported RPE in collegiate women's volleyball players. The selected volume-based accelerometer-derived variables had a stronger relationship with RPE for games than practices. The calculation of PL includes aspects of the other accelerometry variables assessed which may explain why PL was the strongest single predictor of RPE.

Effects Of Hip Thrust And Resistance Training On Shuttle Run, Hand Grip Strength And Countermovement Jump In Colombian Elite Male Volleyball PlayersCristian Yanez, Cesar Lovera, Luis Cardozo, Jhonatan Peña, Felipe Martin, Frank Rincon, Angela Perdomo. *Area Andina Foundation University, Bogota, Colombia.*

Email: cyanez@areandina.edu.co

(No relevant relationships reported)

PURPOSE: This study aimed to determine whether a hip thrust and resistance training could improve performance on shuttle run, hand grip strength and countermovement jump in elite volleyball athletes.

METHODS: eleven elite male volleyball players (23,09 ± 2,87 years), body weight (84.91 ± 10.15 kg), average weight lean muscle (40,18 ± 3.07%), body fat (18.16 ± 5.45%) completed 2 training sessions per weeks, which included hip thrust exercise and upper resistance training. Over the 10 week season, the athletes performed 3-4 sets of 6-10 repetitions for resistance exercises during each training session. All sessions were supervised by one of the investigators as well as by the Colombian team coach. Shuttle run, hand grip strength and countermovement jump were assessed before and after the 10 week training program. A total of 12 variables was analyzed through CMJ: (peak flight time (PFT), peak contact time (PCT), Peak eccentric duration (PDE), peak concentric duration (PDC), Peak eccentric work (PWE), Peak Concentric work (PWC), Peak jump height (PMH), Peak maximum velocity (PMV), Peak maximum power (PMP), Peak maximum force (PMF), Peak rate of force development (PRFD) and Peak time to maximum force (PTFM) were simultaneously quantified with the Gyko inertial sensor system (Microgate, Bolzano, Italy).

RESULTS: Non parametric data were analysed by Wilcoxon and Spearman test. Significant correlations (r) were found next to the p value and the effect size (ES) of shuttle run, hand grip strength and those of countermovement jump respectively. Shuttle run (SR, $p=0,000$, $r=0,96$, $ES=0,23$), Right hand grip strength (HGS R, $p=0,000$, $r=0,90$, $ES=0,18$), Left hand grip strength (HGS L, $p=0,000$, $r=0,91$, $ES=0,22$). CMJ performance variables: Peak concentric duration (PDC, $p=0,000$, $r=0,68$, $ES=0,44$), Peak Jump Height (PMH, $p=2,0$, $r=0,88$, $ES=1,1$), Peak maximum velocity (PMV, $p=0,000$, $r=0,63$, $ES=0,61$).

CONCLUSIONS: The findings suggest that elite male volleyball players can improve speed, agility, hand grip strength and vertical jump performance during the pre competition season by implementing a well designed training program that includes both hip thrust and resistance training exercises.

1044 Board #170 May 27 1:30 PM - 3:00 PM

Examination Of Landing Error Scoring System Scores For Division 1 Basketball PlayersJessica Smith, Timothy G. Coffey. *Longwood University, Farmville, VA.**(No relevant relationships reported)*

The injuring of the anterior cruciate ligament (ACL) is one of the most prevalent sports related knee injuries to occur in athletics, specifically female athletes. **PURPOSE:**

To examine differences in LESS (Landing Error Scoring System) scores between frontcourt and backcourt, male and female NCAA Division 1 basketball players and to measure any changes in LESS scores between the beginning and end of the season.

METHODS: Participants were 24 Division 1 basketball athletes (10 females, 14 males). Participation for the initial LESS screen prior to the season was 24 participants, but only 15 completed the postseason LESS screen (12 males, 3 females). These losses in participants were due to team departures, injuries, and NCAA restrictions on team activities post season. They completed a LESS screen (three consecutive jumps per screen) while being filmed in the frontal and sagittal plane and these videos were analyzed using a visual analysis computer system (Darfish). The clinician examined the torso, feet, knees, and hips in the frontal and sagittal plane and assigned the athlete a score based on the landing performance. Athletes who scored above five points indicated an increased risk for an ACL injury. These screens were scored by a researcher using the LESS scoring sheet determined by Padua and then analyzed using an ANOVA 2x2 repeated measures test in SPSS to test for statistical significance. Statistical results were considered significant if they had a p-value ≤ .05.

RESULTS: There were no statistically significant difference in LESS scores between position ($p=0.650$) or gender ($p=0.904$), but there was a significant decrease in preseason LESS scores versus postseason LESS scores for men and women ($p \leq 0.001$). Preseason men LESS scores averaged 6.30 ± 1.31 and women averaged 6.38 ± 1.63 . Postseason LESS scores for men averaged 5.47 ± 1.09 and women averaged 6.44 ± 0.84 .

CONCLUSIONS: This sample of Division 1 basketball athletes' LESS scores did not seem to differ based on gender or position which could conclude that the athletes training regimens may be similar to each other and not determined by ACL risk, gender, or positions. The significant decrease in preseason LESS scores to postseason LESS scores could be attributed to the similar training regimens.

1045 Board #171 May 27 1:30 PM - 3:00 PM
Lower Extremity Joint Work During Braking Phase Of The Triple Hop For Distance
 Alexander M. Carnall, Daniel A. Greenwood, Douglas W. Powell, FACSM. *University of Memphis, Memphis, TN.*
 (Sponsor: Douglas W. Powell, FACSM)
 Email: mcarnall@memphis.edu
 (No relevant relationships reported)

The triple hop for distance (THD) involves three consecutive single leg hops for maximal horizontal displacement. This task imposes variable mechanical demands challenging balance, coordination and leg strength. While THD is common during late-stage rehabilitation, these demands may also qualify THD as appropriate for healthy athletes. While research shows that energy absorption strategies vary between landing styles, genders and heights, a limitation is the use of a single contact for analysis or training. As a result, changes in landing strategy over repeated landings are not well understood. **PURPOSE:** To determine changes in sagittal plane joint energetic landing strategy during each contact of THD. **METHODS:** Nine female college soccer players performed THD on the dominant limb. Ground reaction forces and lower extremity kinematics were measured using a force platform (1200Hz) and 9-camera motion capture system (240Hz). Three trials were collected of each contact in the THD sequence. Negative joint work was calculated as negative joint power integrated with respect to time. Total negative joint work (TJW) is the sum of eccentric work done on the hip, knee, and ankle, and the proportion of TJW done on each joint was defined as relative negative joint work (RJW). **RESULTS:** TJW increased from the first (-80.5 ± 26.3J) to the second (-95.5 ± 33.7J), and third (-145.2 ± 42.5J) landings. From the first to second contacts, RJW done on the ankle (33.5% vs 34.7%, $d = 0.10$), knee (53.9% vs 52.1%, $d = 0.20$), and hip (12.6% vs 13.1%, $d = 0.08$) was unchanged. From the second to third contacts, RJW done on the ankle was substantially decreased (34.7% vs 18.4%, $d = 1.67$), while RJW done on the hip was substantially increased (13.1% vs 25.4%, $d = 1.68$). RJW done on the knee was modestly greater (52.1% vs 56.3%, $d = 0.54$) in the second compared to third contacts in THD sequence. **CONCLUSION:** The serial nature of THD requires athletes to adapt to different demands in each ground contact. This includes progressively greater braking forces and landing strategy modulation during each contact. This represents a task which exposes athletes to variable demands of both ground reaction forces and joint work in a controlled manner. THD may therefore address multiple athletic performance qualities during performance enhancement and rehabilitation.

1046 Board #172 May 27 1:30 PM - 3:00 PM
Kinematic And Kinetic Differences During A Conventional Deadlift With And Without Shoes
 Elizabeth L. Avila¹, Kellie Walters¹, Alexis S. Camacho¹, Fany Alvarado¹, Joshua A. Cotter, FACSM¹, Hunter J. Bennett², Kevin A. Valenzuela¹. ¹*California State University Long Beach, Long Beach, CA.* ²*Old Dominion University, Norfolk, VA.* (Sponsor: Joshua A. Cotter, PhD, FACSM)
 Email: elizabeth.avila@student.csulb.edu
 (No relevant relationships reported)

Despite the popularity of deadlifting without shoes, little research has examined the kinematic and kinetic differences during a conventional deadlift when performing the exercise barefoot. Excess joint torque in the frontal plane can be indicative of injury. **PURPOSE:** To examine the differences in frontal plane mechanics of the lower extremity and force development during a conventional deadlift with and without shoes. **METHODS:** Thirty participants with a mean height and weight of 1.75±0.10 meters and 81.12±16.05 kg. Participants recruited had consistently performed the conventional deadlift for six or more months and strength training at least two days per week. During the participant's first visit, a one repetition maximum (1RM) using NSCA guidelines was determined. A second visit occurred at least 72 hours or more after the 1RM testing. Kinematic and kinetic data were collected using a 15-camera Qualisys Oqus system (240Hz) and two Bertec force plates (1200Hz). Participants performed five consecutive reps at 70% of their 1RM in random order (shoes and barefoot). Visual 3D was used to process raw marker and force data and to calculate frontal plane joint moments at the hip, knee, and ankle during the concentric phase. A one-way MANOVA ($p < 0.05$) was used to investigate the different footwear conditions. **RESULTS:** There was a statistically significant difference between shoes (-0.28 ± 0.11 Nm/kg) and no shoes (-0.38 ± 0.14 Nm/kg) for internal ankle eversion moments ($p = 0.018$). No significant differences were detected for knee and hip abduction moments. Peak vertical ground reaction force in the barefoot condition (1035.2±281.4 N) was not significantly different than the shoe condition (1044.9±286.5 N). **CONCLUSION:** The absence of shoes created an increase in frontal plane ankle moments, but there was no change in the vertical force characteristics. An increased internal eversion moment did not affect the joint moments further up the kinetic chain despite undergoing similar loading patterns.

1047 Board #173 May 27 1:30 PM - 3:00 PM
The Effects Of Whole-body Vibration And Fatigue On Isometric Mid-thigh Pull
 Sergio Espericueta, Sean Bonilla, Chanel Catunao, Nicole C. Dabbs. *California State University, San Bernardino, San Bernardino, CA.*
 Email: 006194782@coyote.csusb.edu
 (No relevant relationships reported)

Musculature exposed to continuous stress overtime will begin to decrease performance as a result of fatigue. However, past research has shown that Whole Body Vibration (WBV) can have a positive effect on performance by increasing motor unit recruitment.

PURPOSE: The purpose of this study is to analyze the effects of WBV and Fatigue on Isometric Mid-Thigh Pull (IMTP).

METHODS: Sixteen active males and females (age: 23.19 ± 2.56yr, weight: 79.05 ± 16.97kg, height: 174.36 ± 12.11cm) volunteered to participate in a 5-day study. Day 1 consisted of familiarization where participants completed an IRB approved informed consent, Health History Questionnaire, and a PARQ. Following anthropometrics measurements, participants were familiarized with all the testing protocols and interventions. Day 2-5 testing sessions consisted of a dynamic warm-up followed by pre-testing of IMTP's. Post-tests for IMTP were taken following the completion of one of 4 conditions, each performed on separate days. Conditions consisted of C1 (No WBV-No Fatigue), C2 (WBV-Fatigue), C3 (WBV-No Fatigue), and C4 (No WBV-Fatigue) in a randomized order. Peak Force for the IMTP was measured using an AMTI Portable Force Plate. WBV was administered while performing quarter squats at a frequency of 50Hz and low amplitude on for a total of 4min with a work to rest ratio of 30s/30s. The Bosco fatigue protocol was administered to induced lower-body fatigue by having participants perform 60s of jump squats. Percent change scores were calculated between pre- and post-tests for each condition and analyzed for statistical differences between conditions. SPSS was used to run a Repeated Measures ANOVA to compare condition differences of percent change scores (%Δ). An alpha level was set at $p < 0.05$ to determine significance.

RESULTS: There were no significant ($p = 0.84$) differences found between conditions (C1 1.25 ± 9.98 %Δ; C2= -0.79 ± 7.77 %Δ; C3= 1.53 ± 5.95 %Δ; C4= 1.32 ± 10.69 %Δ) for peak force.

CONCLUSIONS: Although no significant differences were found for peak force between pre- and post-tests for IMTP, further studies need to investigate alternative ways to evaluate the effects WBV on lower-body muscular performance.

NEUROMUSCULAR FATIGUE ASSESMENT IN HAMSTRING MUSCLES IN ELITE ULTIMATE FRISBEE PLAYERS
 Rodrigo Andrés Laverde Cortina¹, Rodrigo Esteban Argothy Bucheli², Jenner R. Cubides³, Daniel Dylan Cohen⁴, Mauricio Serrato Roa². ¹*National University of Colombia, Bogotá, Colombia.* ²*Ministry of Sport, Bogotá, Colombia.* ³*Military School of Cadets, Bogotá, Colombia.* ⁴*University of Santander (UDES), Bucaramanga, Colombia.*
 Email: ral13@hotmail.com
 (No relevant relationships reported)

Ultimate Frisbee (UF) is a new team-sport, with more than 1.5 million practitioners worldwide. It is characterized by changes of direction, accelerations / decelerations, jumps and landings. It has been found that the incidence and prevalence of lower body injuries is 68% of total injuries and 73% are hamstring injuries.

PURPOSE: To determine hamstring neuromuscular fatigue in UF players.

METHODS: A descriptive observational study with analytical component was performed in 18 elite male UF players (age: 26 ± 5 years, weight: 67.5 ± 7kg, height: 1.73 ± 0.05m, BMI: 22 +/- 2), who participated and won the Colombian Interclubes National Tournament 2019. The strength of the hamstrings was evaluated using force platforms with isometric hamstring test, each player performed a maximum isometric contraction in supine position, 90° hip flexion and knee of the analyzed leg. The athlete exerts maximum force with the heel on the force platform for 3 seconds. 3 attempts were made with each leg with 30 seconds rest between each attempt, at the start of the tournament and at the end of the tournament. The athletes played 8 90-minute matches during 4 days of competition. A statistical analysis was performed using the student T test and the Wilcoxon test.

RESULTS: Significant differences were found between the pre and post-tournament evaluation in the variables of peak vertical force of the right leg (314 ± 51.5 vs 256 ± 38.5 N $p = < 0.001$), compared with the peak vertical force of the left leg (272 ± 43.5 vs 246 ± 46.6 N $p = 0.4$) that had a non statistically significant change. It was also found that the force in the right leg had significant differences at 100 ms (113 ± 37.6 vs 95 ± 40.1 $p = 0.02$) 150 ms (165 ± 52.8 vs 133 ± 53.9 $p = 0.002$) and 200 ms (200 ± 57.3 vs 167 ± 57.5 $p = 0.0004$).

CONCLUSIONS: The decrease found in hamstring peak vertical force corresponds to the fatigue that athletes present and accumulate during the tournament and predispose to be a risk factor for hamstring and anterior cruciate ligament injury due to changes in direction and unipodal landings. They are frequent in this sport. Likewise, the predisposition of the right leg as the dominant leg increases the incidence of injuries in the knee joint compromising dynamic stability

Effect Of Moxibustion On Knee Joint Stiffness Characteristics In Recreational Athletes Pre And Post Fatigue

Dan Wang¹, Peng Yuan², Yilin Xu², Yufeng Zhang³, Zhiye Zhang³, Ziron Bai³, Zun Wang³, Eamonn Delahunty⁴. ¹Shanghai University of Sport, Shanghai, China. ²Jiangsu Research Institute of Sports Science, Nanjing, China. ³Nanjing University of Chinese Medicine, Nanjing, China. ⁴University College Dublin, Dublin, Ireland.
 Email: wangdan@sus.edu.cn
 (No relevant relationships reported)

Stiffness is the coupling of nervous system and joint mechanics, and thus the comprehensive representative of joint stability. It has been reported that moxibustion can improve weakness and alleviate fatigue symptoms.

PURPOSE: To investigate whether moxibustion could enhance knee joint stiffness characteristics in recreational athletes pre and post fatigue. **METHODS:** Twenty-four participants were partially randomized into intervention (9 males: 20.2 ± 1.5 yr; 6 females: 20.7 ± 1.2 yr) and control group (5 males: 19.4 ± 0.9 yr; 4 females: 20.5 ± 0.6 yr). Intervention group: Acupoints ST36 (bilateral) and CV4 for indirect moxibustion 30 min every other day for 4 consecutive weeks; control group: no moxibustion intervention. Peak torque (PT) of right knee extensors, relaxed and contracted muscle stiffness (MS) of vastus lateralis, knee extensors musculoarticular stiffness (MAS) were assessed by isokinetic dynamometer IsoMed 2000, Myometer and free oscillation technique respectively, at three time points: pre-intervention (time-point 1), post-intervention (time-point 2), and after a treadmill fatigue protocol (time-point 3). **RESULTS:** Two-way repeated measures ANOVA found a significant interaction between time and group in MAS ($p = 0.001$) and normalized PT ($p = 0.004$). Post-hoc tests with the Bonferroni-adjusted α were conducted and identified that MAS in intervention group (time-point 1: 521.8 ± 201.3 N/m, time-point 2: 637.7 ± 181.2 N/m) increased more from pre to post intervention when compared to the control group (time-point 1: 615.4 ± 196.6 N/m, time-point 2: 597.1 ± 190.4 N/m) ($p = 0.022$). There was a tendency that after fatigue MAS increased more in intervention group (time-point 2: 637.7 ± 181.2 N/m, time-point 3: 712.1 ± 156.9 N/m) than in control group (time-point 2: 597.1 ± 190.4 N/m, time-point 3: 629.8 ± 172.7 N/m) ($p = 0.202$); and the tendency that normalized PT (PT/body mass) increased in intervention group (time-point 2: 1.49 ± 0.20 Nm/kg, time-point 3: 1.53 ± 0.17 Nm/kg) whilst it decreased in control group (time-point 2: 1.41 ± 0.21 Nm/kg, time-point 3: 1.34 ± 0.21 Nm/kg) ($p = 0.033$). **CONCLUSION:** Moxibustion enhanced the knee MAS, may benefit the ability of fatigue resistance in young recreational athletes, and thus could be utilized in injury prevention.

Acute Effects Of Practical Blood Flow Restriction On Knee Proprioception During Low Intensity Aerobic Exercise

Yujiro Yamada¹, Ryan Kasprzak², Alec Mathew², Shelby Shotton³, Addyson Miller-Brown³, Trent Cayot⁴, John Thistlethwaite⁵. ¹University of Mississippi, University, MS. ²Ohio University, Athens, OH. ³Ohio Dominican University, Columbus, OH. ⁴University of Indianapolis, Indianapolis, IN. ⁵Wittenberg University, Springfield, OH.
 (No relevant relationships reported)

Practical blood flow restriction (pBFR) exercise techniques decreases blood flow to targeted muscles while increasing local metabolic accumulation, both of which could impair joint proprioception post-exercise. The impaired proprioception which typically occurs after high intensity aerobic exercise can provide faulty sensory feedback to the brain during movement, resulting in increased risk of injury. Currently, there have been no studies investigating whether pBFR low intensity aerobic exercise has an effect on joint proprioception. **PURPOSE:** To investigate how low intensity aerobic exercise with pBFR affects knee joint proprioception. **METHODS:** Fourteen participants (8 males and 6 females) completed 3 sessions. On the first session, participants walked at 5.6 km/h at a 0% grade for two minutes followed by a 2% increase in the incline each minute until 40% of their heart rate reserve was achieved. Participants were familiarized with a "7/10" (moderate tightness) on the perceived tightness scale using elastic knee wraps as well as the position sense and countermovement jumps.

On session 2 or 3, participants walked on a treadmill for 15 minutes with or without elastic wraps at 5.6 km/h at the grade determined on the first session. Absolute angular error (AAE) was measured before and immediately after each treadmill walking protocol. Muscle fatigue was determined by changes in average power and peak power measured during countermovement jumps. Change scores were computed for each condition and paired sample t-tests were used to determine differences between pBFR and Control. **RESULTS:** The change in AAE was not different (pBFR: -1.5 vs. Control degrees: 0.19, $p = 0.171$) between low intensity exercise with and without pBFR [mean difference of -1.73 (-4.3, 0.85) degrees]. The change in peak power was also similar (pBFR: -34.5 vs. Control: 150.1 W, $p = 0.739$) between exercise with and without pBFR [mean difference of -185 (-1358, 988) W]. Similarly, the change in average power (pBFR: 9.1 vs. Control: -3.4 W, $p = 0.544$) was also not different [mean difference of 12.6 (-31.1, 56.2) W]. **CONCLUSION:** The walking exercise with pBFR did not effect joint proprioception in young adults, suggesting that walking exercise with pBFR might be safely applied without increasing the risk of injury.

1051 Board #177 May 27 1:30 PM - 3:00 PM
Flight Stability Control Mechanism Of Ski Jumping In Lateral Wind Environment

Qi Hu¹, Yu Liu². ¹China Institute of Sport Science, Beijing, China. ²Shanghai University of Sport, Shanghai, China.
 Email: huqi@ciss.cn
 (No relevant relationships reported)

Wind is not only closely associated with the discussion of fairness in ski jumping, but also very important to flight safety. Flight stability is essential for performance and safety in ski jumping, and mainly involved several factors, such as environmental wind and flight posture. However, the flight stability control mechanism of ski jumping in lateral wind environment remains unclear.

PURPOSE: To determine the flight stability control mechanism of ski jumping in lateral wind environment.

METHODS: The aerodynamic characteristics of ski jumping during flight under different lateral wind and yaw angles are predicted by numerical simulation of computational fluid dynamics, and the effects of the above two elements on flight stability are compared and analyzed. The jumper and skis were regarded as a multi-body system, and partially averaged Navier-Stokes turbulence model was used to simulate aerodynamic characteristics of the system based on a general flight attitude and then the forces and torques were obtained. The lateral wind speed involved in the numerical prediction includes 1.5 m/s, 3 m/s, 4.5 m/s and 7.5 m/s, and the flight yaw angle involved includes 2.5°, 5° and 7.5°.

RESULTS: When lateral wind speed is small (less than 3m/s), yaw force, yaw torque and rolling torque are small and almost negligible, and when lateral wind speed is larger than 4.5m/s, yaw force, yaw torque and rolling torque are more obvious. When wind speed is 4.5m/s and 7.5m/s, yaw force, yaw torque and rolling torque are 9.5 N and 26.3 N, 2.3 Nm and 6.3 Nm, 2.8 Nm and 7.8 Nm, respectively. When yaw angles are 2.5°, 5° and 7.5°, yaw force, yaw torque and rolling torque are 6.8 N, 12.9 N and 21.9 N, 2.5 Nm, 5.0 Nm and 6.8 Nm, 2.7 Nm, 5.7 Nm and 8.3 Nm, respectively. When wind speed is 4.5 m/s and yaw angle is 2.5°, yaw force, yaw torque and rolling torque results of these two conditions are close to each other. Similarly, When wind speed is 7.5 m/s and yaw angle is 7.5°, yaw force, yaw torque and rolling torque results of these two conditions are close to each other.

CONCLUSION: The larger lateral wind can have a significant adverse effect on flight stability control of ski jumping, but it is possible to compensate or even eliminate this adverse effect by taking the appropriate flight yaw angle.

Effect Of Footwear On Leg Stiffness Of Female Athletes

Ioannis A. Bayios, Analina A. Emmanouil, Konstantinos S. Noutsos, Nikolaos G. Apostolidis, Elissavet N. Rousanoglou, Konstantinos D. Boudolos. *National and Kapodistrian University of Athens., Athens, Greece.*
 (No relevant relationships reported)

Leg stiffness is a fundamental property of the lower limb spring pattern, and is expressed by the ratio of the maximum vertical ground reaction force (GRF) to the vertical displacement of the body's center of mass. The foot-ground interface, i.e. the footwear (FW), is an important factor that contributes to the functional leg stiffness. **PURPOSE:** To examine the FW effect on leg stiffness of young female athletes in a variety of team sports. **METHODS:** Twenty - six female basketball, handball and volleyball players (24.9 ± 6.1 years, height 176.4 ± 7.6 cm, body mass 71.0 ± 6.9 kg) performed 30 s of two-legged hopping in place, barefoot (BF) and with their usual FW, at a preset hopping frequency (digital metronome at 2.2 Hz which approximates the natural hopping frequency). Two-legged hopping was performed on a force platform (Kistler 9260AA, 1000Hz, Bioware Software 2812 A1-3) which was used to record

the vertical GRF. The variables used for the statistical analysis of the FW effect were extracted from 10 consecutive hops, and were analyzed using two-way ANOVA ($p < 0.05$). **RESULTS:** leg stiffness was significantly increased in the FW condition, both in absolute (BF: 32.7 ± 8.5 kN/m, FW: 36.9 ± 8.3 kN/m, $p = 0.014$), as well as in relative to body mass values (BF: 0.478 ± 0.101 kN/m/kg, FW: 0.520 ± 0.110 kN/m/kg ($p = 0.017$)). Also, despite the instruction to follow the same hopping frequency as set by the digital metronome in both the BF and the FW, hopping duration was shortened (BF: 0.469 ± 0.022 s, FW: 0.430 ± 0.013 s, $p = 0.001$) and the propulsive vertical GRF was increased (BF: 32.4 ± 4.7 N/kg, FW: 33.7 ± 5.6 N/kg, $p = 0.048$) in the FW condition. **CONCLUSIONS:** FW appears to increase leg stiffness, which may favor the myotendinous force transfer and contribute to a more effective lower limb spring pattern.

Characteristics Of Eight Irish Dance Landings: Implications For Overuse Injury And Training

Natalie Van Wagoner, Sarah Klopp Christensen, Iain Hunter, Taryn E. Corey, Matthew S. McClung, A. Wayne Johnson. *Brigham Young University, Provo, UT.* (Sponsor: Pat Vehrs, FACSM)
Email: natalievw13@gmail.com
(No relevant relationships reported)

The aesthetics in Irish dance have evolved to create greater physical demands on dancer's bodies. Irish dancers must land from difficult movements without letting their knees bend or heels touch the ground, causing large forces to be absorbed by the body. The majority of injuries incurred by Irish dancers are due to overuse (79.6%). **PURPOSE:** The purpose of this study was to determine loads on the body in female Irish dancers, including peak force, rise rate of force, and impulse in selected Irish hard shoe and soft shoe dance movements. It was hypothesized that the 8 movements would produce different GRF characteristics. **METHODS:** Sixteen female Irish dancers were recruited from the three highest competitive levels. Each performed a warm-up, reviewed 8 common Irish dance movements, and then performed each movement three times upon a force plate. Of the 8 movements, 4 were performed in soft shoes and 4 were performed in hard shoes. Ground reaction forces (GRFs) were measured using a three-dimensional force plate recording at 1000 Hz. Peak force, rise rate, and vertical impulse were calculated. GRFs were normalized by each dancer's body weight. **RESULTS:** Peak forces, rise rates, and impulses were significantly different across movements ($F = 65.4$, $p < 0.01$; $F = 65.0$, $p < 0.01$; and $F = 67.4$, $p < 0.01$ respectively). The movement with the highest peak force was the stomp. The movement with the highest rise rate was the double-toe. The movement with the highest impulse was the leap. The skip had the lowest values for all GRFs measured. Individual peak forces ranged from 0.67-9.86 times body weight. Individual rise rates ranged from 10-147 body weights per second. Individual impulses ranged from -0.12 to 0.32 body weight seconds. Years of experience was not correlated with peak force, rise rate, or impulse ($p > 0.40$). **CONCLUSIONS:** There is a large range in GRF characteristics created by Irish dancers. Dance movements that have high average peak forces may be associated with higher risk of overuse injury. Irish dancers should use appropriate training methods to strengthen the tissues at greatest risk of overuse injury.

The Effect Of Treadmill Speed And Grade On Ice Hockey Skating Biomechanics

Colin W. Bond, Eric T. Piatt, Benjamin C. Noonan. *Sanford Health, Fargo, ND.*
Email: colin.bond@sanfordhealth.org
(No relevant relationships reported)

Skating treadmills are used by ice hockey players to develop stride efficiency, power, and endurance. **PURPOSE:** Evaluate the effect of treadmill speed and grade on biomechanics. It was hypothesized that greater speeds and grades would elicit larger ranges of motion (ROM) and decrease stride time. **METHODS:** Seven competitive male ice hockey players (22.0 ± 0.6 y, 86.5 ± 4.4 kg, 1.82 ± 0.06 m) skated at five speed and grade conditions including 4.47 m·s⁻¹ at 4% grade (10/4), 5.36 m·s⁻¹ at 0% grade (12/0), 5.36 m·s⁻¹ at 4% grade (12/4), 5.36 m·s⁻¹ at 8% grade (12/8), and 6.26 m·s⁻¹ at 4% grade (14/4). Left leg biomechanics were assessed using three-dimensional motion capture. Stride time was determined as the mean time between successive initial contacts of the left skate blade with the treadmill. Kinematics were normalized to percent of gait cycle. ROM was calculated as the difference between the maximum and minimum left hip and knee angles during the stance phase of the normalized kinematics. Separate repeated measures ANOVA and corrected, paired t-tests were used to assess the effect of condition. Significance was set to $p < .05$. **RESULTS:** A significant effect of condition on stride time ($p < .001$) was identified. Pairwise comparisons revealed that stride time was different for each condition (10/4 = $.87 \pm .07$ s, 12/0 = $1.18 \pm .13$ s, 12/4 = $.83 \pm .06$ s, 12/8 = $.68 \pm .05$ s, 14/4 = $.77 \pm .06$ s). A significant effect of condition on hip sagittal plane ROM ($p < .001$) was identified. 12/0

($57.4 \pm 4.4^\circ$) had smaller ROM than 12/4 ($65.4 \pm 6.6^\circ$), 12/8 ($70.8 \pm 7.0^\circ$), and 14/4 ($66.6 \pm 7.3^\circ$), 10/4 ($63.0 \pm 5.5^\circ$) had smaller ROM than 12/8, and 12/4 had smaller ROM than 12/8. A significant effect of condition on hip frontal plane ROM ($p = .007$) was also revealed, although no significant pairwise comparisons were identified (10/4 = $27.6 \pm 4.4^\circ$, 12/0 = $31.3 \pm 4.8^\circ$, 12/4 = $26.6 \pm 4.6^\circ$, 12/8 = $23.3 \pm 5.3^\circ$, 14/4 = $26.7 \pm 4.0^\circ$). No effect of condition on knee sagittal plane ROM was revealed ($p = .271$; 10/4 = $44.6 \pm 4.7^\circ$, 12/0 = $44.6 \pm 4.9^\circ$, 12/4 = $44.8 \pm 2.6^\circ$, 12/8 = $41.9 \pm 3.0^\circ$, 14/4 = $42.3 \pm 2.6^\circ$). **CONCLUSIONS:** In this small sample, increasing skating treadmill speed, grade, or both appears to decrease stride time, increase hip joint sagittal plane ROM, and have no effect on knee joint sagittal plane ROM. Results may aid in training program design and future ice hockey biomechanics research.

The Characterization Of The Transition Phase During A 180° Change Of Direction Task

Giancarlo Condello¹, Mauro Mandorino², Enrico Santoro², Chutimon Khemtong¹, Chi-Hsien Chen¹, Chiang Liu¹, Antonio Tessitore². ¹University of Taipei, Taipei, Taiwan. ²University of Rome Foro Italico, Rome, Italy. (Sponsor: Carl Foster, FACSM)
Email: giancarlo.condello@gmail.com
(No relevant relationships reported)

The evaluation of change of direction ability should not merely rely on the measurement of total sprinting time, but it should focus also on the understanding of specific movement patterns. **PURPOSE:** To evaluate the transition phase (TP) during a 180° change of direction (COD) task. **METHODS:** 14 recreational basketball athletes (age: 21.4 ± 2.6 years) were evaluated during a 10-m COD test. TP has been identified considering 3 consecutive steps (i.e., final decelerating foot contact [DFC], turning foot contact [TFC], first accelerating foot contact [AFC]), using two force platforms. Differences in total (TCT), braking (BCT), and propulsive (PCT) contact time, vertical braking (VBGRF) and propulsive (VPGRF) ground reaction force (relative to body mass), and vertical braking (VBI), propulsive (VPI), and total (VTI) impulse (relative to body mass) were evaluated in relation to leg preference, the 3 steps, and groups (slower vs. faster defined as those below and above the 50th percentile of total sprinting time). **RESULTS:** No differences emerged for leg preference. TP (1.199±0.11 s) contributed for an average of 42.6±3.4% to the total sprinting time (2.817±0.14 s), with DFC involving only a braking action, whilst TFC and AFC comprising both a braking and propulsive action. Differences ($p < 0.05$) among the 3 steps emerged for TCT (DFC: 0.380 ± 0.07 s; TFC: 0.525 ± 0.06 s; and AFC: 0.303 ± 0.04 s), VBGRF (DFC: 22.7 ± 7.5 N·kg⁻¹; TFC: 20.3 ± 2.8 N·kg⁻¹; and AFC: 8.1 ± 2.7 N·kg⁻¹), VBI (DFC: 2.1 ± 0.4 m·s⁻¹; TFC: 2.5 ± 0.5 m·s⁻¹; and AFC: 0.4 ± 0.2 m·s⁻¹), and VTI (DFC: 2.1 ± 0.4 m·s⁻¹; TFC: 5.6 ± 0.6 m·s⁻¹; and AFC: 2.6 ± 0.3 m·s⁻¹). Furthermore, differences ($p < 0.05$) between TCF and AFC were evident for VPGRF (TFC: 14 ± 1.2 N·kg⁻¹; and AFC: 15.6 ± 1.7 N·kg⁻¹) and VPI (TFC: 3.1 ± 0.6 m·s⁻¹; and AFC: 2.2 ± 0.4 m·s⁻¹). Differences between groups emerged in the TFC only, with faster individuals demonstrating shorter TCT (0.489 ± 0.1 s) and PCT (0.281 ± 0.1 s), and lower VPI (2.8 ± 0.5 m·s⁻¹) compared to slower individuals (TCT: 0.542 ± 0.1 s; PT: 0.339 ± 0.1 s; and VPI 3.4 ± 0.6 m·s⁻¹). **CONCLUSIONS:** Findings revealed specific movement patterns during the TP of a COD task and the central role played by the turning step in differentiating faster and slower recreational basketball athletes, with potential further implications for future testing and training procedures.

1056 Board #182 May 27 1:30 PM - 3:00 PM

Effects Of Different Pressure Compression Garments On Oxygen Uptake And Blood Lactate

Hanjun Li, Kaiyang Sun. *Beijing Sport University, Beijing, China.*
Email: LIHANJUN@BSU.EDU.CN
(No relevant relationships reported)

Compression garment (CG) has now been viewed as a potential tool for enhancing performance and recovery. CG may boost lactate removal and enhance oxygen supply. However, there are only a small amount of research supporting usefulness of CG. **PURPOSE:** To determine the effect of different pressure CG on oxygen uptake during running and lactate removal after exercise. **METHODS:** 12 recreational male long-distance runners (age 22.5 ± 1.9 y, height 1.78 ± 0.04 m, mass 70.7 ± 4.9 kg) participated in this study. Subjects performed 3 maximal incremental exercise test (the Bruce protocol) on a treadmill with 3 different garments. The subjects performed experimental trials with a high pressure CG (HCG, 17.5 mmHg at the middle of thigh), low pressure CG (LCG, 8.0 mmHg at the thigh), or without a CG (CON condition). The 3 tests were assigned in a random order under a cross-over design, and were conducted at the same time of the day, 3-5 day apart. Oxygen uptake were continuously determined using the METAMAX 3 system. Fingertip blood samples of 20 µl were taken at 1, 4, 7 and 10 min after exercise. The lactate concentration was determined by EKF Biosen C-Line Clinic system. An ANOVA with repeated measures followed by Bonferroni pairwise comparisons were used to analyze the differences in 3 conditions. All tests were two-tailed and a .05 probability level was considered

WEDNESDAY, MAY 27, 2020

significant. **RESULTS:** The Oxygen uptakes were significantly lower with CG at 6 min time point ($P < .05$, HCG 22.0 ± 1.5 , LCG 21.3 ± 2.0 vs CON 23.2 ± 2.7 ml/min*kg), and there were no significant differences on VO₂ between 3 conditions at any other time point. There were no significant differences on the maximum lactate and lactate elimination rates between 3 conditions at any time point. **CONCLUSIONS:** Different pressure CGs have no significant effect on the maximum oxygen uptake during running, but it is possible to reduce oxygen consumption during exercise at low intensity. CGs have no significant effect on the removal of blood lactate after running.

TABLE 1 Oxygen uptake (ml/min*kg) during maximal incremental exercise

TIME	HCG	LCG	CON
3min	15.45±1.03	14.87±1.09	15.04±0.74
6min	22.04±1.49*	21.34±1.96*	23.23±2.74

Parachuting Course Impact In The Lower Limbs Neuromuscular Performance In Militaries From Colombia

María Alejandra Díaz¹, Rodrigo Argothy², Jenner Rodrigo Cubides¹, Daniel Cohen³. ¹Military School, Bogotá, Colombia. ²Ministry of Sports, Bogotá, Colombia. ³University of Santander, Bucaramanga, Colombia.
 (No relevant relationships reported)

Most of the injuries in the military parachuting course (MPC) occur during the landing phase because of intrinsic or extrinsic variables. It is important to assess the lower limbs neuromuscular (NM) impact of the MPC to understand the muscular adaptations and the eccentric work, because via the reflex activated by the eccentric phase, it can strengthen the elastic characteristics of the muscle-tendon complex (MTC). Besides, the evaluation of the ground reaction forces (GRF) allow to evaluate muscles function in eccentric-concentric conditions, elastic and reflex components of the MTC through jumping tests that report NM changes due to a training. **PURPOSE:** Assess the lower limbs neuromuscular impact of the MPC in Colombian militaries. **METHODS:** A prospective study was performed in 43 male cadets from the military school who went to the MPC (4 weeks). Each cadet performed 5 drop jump (DJ) test before and after the course, and landed in uniaxial force platforms. For the statistical analysis a paired t-student was performed to determine the changes in the variables that described the DJ, due to the MPC. **RESULTS:** Positive changes were found in the reduction of contact time (0.43 ± 0.1 vs 0.38 ± 0.1 s, $p < 0.01$) and the increase of the eccentric mean force (1513.5 ± 281.4 vs. 1642.9 ± 289.1 N, $p < 0.01$). However, negative changes were observed in the reduction of the jump height (27.7 ± 3.9 vs. 24 ± 3.6 cm, $p < 0.01$), concentric impulse (165.7 ± 26 vs. 153.1 ± 23.7 Ns, $p < 0.01$) and vertical velocity at takeoff (2.34 ± 0.18 vs. 2.17 ± 0.16 m/s, $p < 0.01$) and an increase in the peak landing force (3836.4 ± 825.1 vs. 4461.5 ± 1032.2 N, $p < 0.01$). **CONCLUSION:** There is an improvement in the myotatic reflex related to the adaptations of the lower limb extensor in response to the eccentric force. However, the variables that defined the power and the GRF shown a negative effect over NM characteristics of LL performance, increasing their risk of injury because of high impacts that are not transfer properly to other soft tissues.

1058 Board #184 May 27 1:30 PM - 3:00 PM
Estimation Of Joint Torque During Countermovement Jump From Position Coordinates Using Deep Residual Recurrent Network

atsushi yuchi, takahiko sato, akinori nagano. *Ritsumeikan university, kusatsu-shi, Japan.*
 Email: sh0139sx@ed.ritsumei.ac.jp
 (No relevant relationships reported)

Mechanical outputs (MO) exhibited explosively in the lower limbs are important in many sports. Vertical countermovement jump (VCMJ) is often utilized to evaluate the ability to exhibit MO. To calculate MO, inverse dynamics is performed with body position data and ground reaction forces (GRFs) recorded by the motion-capture system and force-plates. However, it is difficult to obtain GRFs without laboratory setting because force-plates are usually quite expensive. Because of this device-dependent issue, it is hard to obtain MO in the common sporting scenes. **PURPOSE:** To create and develop an artificial neural network that is possible to estimate MO without force-plates, with body position data as inputs. **METHODS:** We designed a deep residual recurrent network (DRRN) to estimate the sagittal right knee torque as MO. Datasets were established for training and evaluating DRRN. Eighteen young males performed VCMJ under 3 conditions (make counter movement freely, deeply and shallowly) with arm swing. Body position data and GRFs were recorded by motion-capture system (250Hz) and force-plates (1250Hz). Three out of 18 subjects' data were randomly chosen as validation data (validation subject A, B, and C). The other 15 subjects' data were divided into two groups, i.e., 80% for training data and 20% for test data. As the objective variable, sagittal right knee torque was calculated using inverse dynamics. Explanatory variables were sagittal body position data. Parameters of DRRN were determined by an optimization calculation that aimed to reduce the difference between actual and estimated torque. To evaluate the predictive performance of DRRN, R² score (R²) and root mean square error (RMSE) were calculated. **RESULTS:** R² and RMSE of whole validation data were $87.7\% \pm 6.2$ and 0.23 ± 0.07 , respectively. These indicators suggest DRRN model has a consistency in the level of predictive ability. R² and RMSE of validation subject A, B and C were $82.8\% \pm 7.1$ and 0.26 ± 0.07 , $89.2\% \pm 3.6$ and 0.25 ± 0.06 , $91.2\% \pm 3.5$ and 0.18 ± 0.06 , respectively. These differences among subjects suggest that personal characteristics might not have been processed sufficiently. **CONCLUSIONS:** Deep RRN is effective in the estimation of joint torque with only body position data as inputs.

Three-dimensional, Isotonic Comparison Of Dominant And Non-dominant Upper Limb Force Production
 Gianna D. Maragliano, Nathaniel J. Holmgren, Kento J. Moriguchi, Courtney D. Jensen. *University of the Pacific, Stockton, CA.*
(No relevant relationships reported)

Athletes and coaches have traditionally relied on isokinetic devices to compare dominant and non-dominant strength ratios; the information provided is limited in its application. Recent technology permits strength and power comparisons in an isotonic, three-dimensional environment that is more compatible with the load profiles experienced during sport performance. **PURPOSE:** To determine the difference in power between dominant and non-dominant arms across various loads, motions, and planes. **METHODS:** 206 subjects performed 3,727 unilateral sets of 10 repetitions in upper-extremity movements on Proteus (Proteus Motion, USA). Loads were applied through magnetic resistance and ranged from 5-25 lbs; they were divided between dominant (n=1,975) and non-dominant (n=1,747) arms. The performance variables were explosiveness (peak force development rate), peak power, and braking (rate of deceleration). Descriptive statistics characterized mean performances. Linear regression models predicted the effect of arm dominance on performance parameters, holding the load and exercise constant. **RESULTS:** Across all sets, explosiveness was 852.61 ± 629.46 watts/sec, peak power was 206.40 ± 112.42 watts, and braking was 1059.90 ± 766.63 watts/sec. Dominant and non-dominant arms were different in explosiveness (p=0.005), peak power (p=0.041), and braking (p=0.035). With confounding variables held constant, linear regression found use of the non-dominant arm to predict a 10-watt decrease in peak power (R²=0.691; p<0.001), a 46-watt/sec decrease in mean explosiveness (R²=0.553; p=0.001), and a 65-watt/sec decrease in braking (R²=0.668; p<0.001). **CONCLUSIONS:** In an athletic population, the independent use of dominant and non-dominant limbs is often critical to success. It is important to know the non-dominant performance deficit in a setting applicable to sport performance. This information can contribute to optimal training protocols and return-to-play testing batteries.

Muscle Activity In Upper Extremity Is Modulated During Arm Cycling Exercises After Cervical Spinal Cord Injuries
 David M. Rouffet, Susan J. Harkema, Jessica M. D'Amico. *University of Louisville, Louisville, KY.* (Sponsor: Jason R. Jagers, FACSM)

Regaining upper extremity function following spinal cord injury (SCI) is one of the most important outcomes for quadriplegics with regards to enhancing quality of life. To facilitate locomotor recovery through increased activation of the lower limb muscles, ground reaction forces are commonly manipulated to optimal levels. Using similar mechanisms, manipulating power production during arm cycling exercises could facilitate activation of the upper limb muscles after SCI. **PURPOSE:** To determine if upper limb muscles activation is modulated during arm cycling exercises after SCI. **METHODS:** Five participants with chronic SCI at C4; classified as AIS A (1), B (2), C (1) and D (1) according to the American Spinal Injury Association Impairment Scale performed arm cycling exercises at four power levels (0, 5, 10, 15W) with their hands securely attached to the handles. Surface EMG signals were recorded during a series of 10 consecutive cycles from one muscle above the lesion: medial trapezius (C2-C4); and six muscles below the lesion: deltoid posterior (C5-C6), biceps brachialis (C5-C6), triceps brachialis (C6-C8), extensor digitorum (C6-C8), flexor carpi radialis (C6-C8) and extensor carpi radialis (C6-C8). **RESULTS:** Arm cycling exercises were successfully performed at cadences ranging from 30 to 50 rpm. EMG signals were detected in all muscles from all participants. Modulation of EMG signals within the cycle was seen in most exercise conditions and participants, while modulation was most identifiable when participants produced larger levels of power. Increasing power production from 0 to 15 W led to an increase in the peak EMG activity of the trapezius muscle, as well as in four muscles below the lesion: deltoid, biceps and triceps brachialis, and extensor carpi radialis (P < 0.05). **CONCLUSIONS:** Participants of all levels of impairment successfully performed the arm cycling exercises. Increasing power production up to 15W improved modulation of EMG signals during the cycle and increased activation of some muscles below the lesion, crossing the shoulder, elbow and wrist joints. Including arm cycling exercises

in rehabilitation programs should be considered to take advantage of spinal circuitry available below the level of injury and facilitate the recovery of upper extremity function after SCI.

An Investigation Of Bilateral Differences In Emg Responses During Submaximal Arm Ergometry
 Swapan Mookerjee, Kyle S. Beyer. *Bloomsburg University, Bloomsburg, PA.* (Sponsor: Daniel G. Drury, FACSM)
 Email: smookerj@bloomu.edu
(No relevant relationships reported)

PURPOSE: To determine bilateral differences in neuromuscular fatigue patterns in the Biceps Brachii (BB), Triceps (Tri), and Latissimus Dorsi (LD) muscle groups during arm cranking exercise. **METHODS:** A sample of 4 male and 4 female subjects (aged 22.2 ± 2.2 yrs) performed a submaximal arm cranking test for 10-minutes each @ 40% and 60% of the maximal workload attained previously, in randomized order. Oxygen consumption was determined continuously via indirect calorimetry. Mean EMG Root Mean Square (EMG_{RMS}) was calculated for 10 epochs from 15-second recordings at each minute. Slope coefficients were determined and a 2-way repeated measures ANOVA was used to analyze the differences between exercise intensity and side (left vs. right) for each of the three muscle groups. **RESULTS:** Submaximal VO₂ @ 60% (1.54 L·min⁻¹ ± 0.2) was significantly greater (p ≤ 0.01) than the VO₂ @ 40% (1.2 L·min⁻¹ ± 0.2) indicating an expected energy cost difference. However, there were non-significant differences in EMG_{RMS} for muscle (F=1.8, p ≥ 1.0) and intensity (F=0.49, p ≥ 0.4). **CONCLUSIONS:** During submaximal arm ergometry at two different workloads, possible limb dominant asymmetries were not evident, indicating similar time-dependent acute neuromuscular adaptations for the three muscle groups studied.
